

The background of the cover features a complex 3D molecular model with yellow, red, and white spheres connected by blue rods, set against a green grid. In the top right, a round-bottom flask is visible. In the bottom left, a blue beaker with volume markings (150 mL, 250 mL) and the 'WILEY' logo is shown. A magnifying glass is positioned in the top left, focusing on a part of the molecular structure. A small, faceted geometric object is in the bottom right.

BRIEF CONTENTS

About the authors *xiii*

1. The atom	1
2. The language of chemistry	28
3. Chemical reactions and stoichiometry	94
4. Atomic energy levels	134
5. Chemical bonding and molecular structure	196
6. Gases	256
7. Condensed phases: liquids and solids	302
8. Chemical thermodynamics	347
9. Chemical equilibrium	408
10. Solutions and solubility	456
11. Acids and bases	498
12. Oxidation and reduction	568
13. Transition metal chemistry	626
14. The <i>p</i> -block elements	692
15. Reaction kinetics	737
16. The chemistry of carbon	797
17. Chirality	873
18. Haloalkanes	913
19. Alcohols, amines and related compounds	950
20. Structure determination	1015
21. Aldehydes and ketones	1099
22. Carbohydrates	1150
23. Carboxylic acids and their derivatives	1184
24. Amino acids, peptides and proteins	1244
25. The chemistry of DNA	1284
26. Polymers	1314
27. Nuclear chemistry	1361

Practice exercise answers *1391*

Appendices *1438*

CONTENTS

About the authors xiii

CHAPTER 1

The atom 1

- 1.1 The essential concepts in brief 2
- 1.2 The atomic theory 3
- 1.3 The structure of the atom 7
 - Atomic mass 12
- 1.4 The periodic table of the elements 16
 - The modern periodic table 18
 - Naming the elements 19
- 1.5 Electrons in atoms 20
 - Summary 22
 - Key concepts and equations 23
 - Key terms 23
 - Review questions 24
 - Review problems 25
 - Additional exercises 26
 - Acknowledgements 27

CHAPTER 2

The language of chemistry 28

- 2.1 Measurement 28
 - SI units 28
 - Non-SI units 34
 - Dimensional analysis 35
 - Precision and accuracy 37
 - Uncertainties and significant figures 38
- 2.2 Representations of molecules and reactions 46
 - Chemical formulae 47
 - Structural formulae 49
 - Three-dimensional structures 54
 - Mechanistic arrows in chemical reactions 57
- 2.3 Nomenclature 59
 - Naming inorganic compounds 60
 - Naming organic compounds 63
 - Summary 77
 - Key concepts and equations 78
 - Key terms 79
 - Review questions 80
 - Review problems 82
 - Additional exercises 88
 - Maths for chemistry 90
 - Acknowledgements 93

CHAPTER 3

Chemical reactions and stoichiometry 94

- 3.1 Chemical equations 95
 - Specifying states of matter 96
- 3.2 Balancing chemical equations 97
- 3.3 The mole 99
- 3.4 Empirical formulae 102
 - Mole ratios from chemical formulae 102
 - Determination of chemical formulae 103
 - Determination of empirical formulae 105
- 3.5 Stoichiometry, limiting reagents and percentage yield 107
 - Mole ratios in chemical reactions 108
 - Limiting reagents 109
 - Percentage yield 111
- 3.6 Solution stoichiometry 113
 - The concentration of solutions 114
 - Applications of solution stoichiometry 119
 - Stoichiometry of solutions containing ions 120
 - Summary 125
 - Key concepts and equations 126
 - Key terms 126
 - Review questions 127
 - Review problems 128
 - Additional exercises 131
 - Acknowledgements 133

CHAPTER 4

Atomic energy levels 134

- 4.1 Characteristics of atoms 135
- 4.2 Characteristics of light 135
 - Wave-like properties of light 135
 - Particle properties of light 138
 - Absorption and emission spectra 142
 - Atomic spectra 143
 - Quantisation of energy 145
 - Energy level diagrams 146
- 4.3 Properties of electrons 149
 - The Heisenberg uncertainty principle 151
- 4.4 Quantisation and quantum numbers 151
 - Principal quantum number (n) 152
 - Azimuthal quantum number (l) 152
 - Magnetic quantum number (m_l) 153
 - Spin quantum number (m_s) 154
 - The Pauli exclusion principle 154
- 4.5 Atomic orbital electron distributions and energies 155
 - Atomic orbital electron distributions 155
 - Orbital energies 159

4.6	Structure of the periodic table	164
	The Aufbau principle and order of orbital filling	164
	Valence electrons	168
4.7	Electron configurations	168
	Electron–electron repulsion	171
	Orbitals with nearly equal energies	172
	Configurations of ions	173
	Magnetic properties of atoms	174
	Excited states	175
4.8	Periodicity of atomic properties	175
	Atomic radii	175
	Ionisation energy	177
	Electron affinity	180
	Sizes of ions	181
4.9	Ions and chemical periodicity	184
	Cation stability	184
	Anion stability	185
	Metals, nonmetals and metalloids	185
	s-block elements	186
	p-block elements	187
	Summary	188
	Key concepts and equations	189
	Key terms	190
	Review questions	191
	Review problems	192
	Additional exercises	194
	Acknowledgements	195

CHAPTER 5

Chemical bonding and molecular structure 196

5.1	Fundamentals of bonding	197
	The hydrogen molecule	198
	Bond length and bond energy	198
	Other diatomic molecules: F_2	199
	Unequal electron sharing	199
5.2	Ionic bonding	202
5.3	Lewis structures	204
	The conventions	204
	Building Lewis structures	205
	Resonance structures	207
5.4	Valence-shell-electron-pair repulsion (VSEPR) theory	209
	Two sets of electron pairs: linear geometry	210
	Three sets of electron pairs: trigonal planar geometry	210
	Four sets of electron pairs: tetrahedral geometry	211
	Five sets of electron pairs: trigonal bipyramidal geometry	213
	Six sets of electron pairs: octahedral geometry	215
5.5	Properties of covalent bonds	217
	Dipole moments	217
	Bond length	220

	Bond energy	222
	Summary of molecular shapes	224
5.6	Valence bond theory	225
	Orbital overlap	225
	Conventions of the orbital overlap model	225
	Hybridisation of atomic orbitals	226
	Multiple bonds	232
5.7	Molecular orbital theory: diatomic molecules	236
	Molecular orbitals of H_2 and He_2	237
	Molecular orbitals of O_2	239
	Homonuclear diatomic molecules	242
	Heteronuclear diatomic molecules	244
	Summary	248
	Key concepts and equations	250
	Key terms	251
	Review questions	251
	Review problems	253
	Additional exercises	254
	Acknowledgements	255

CHAPTER 6

Gases 256

6.1	The states of matter	257
6.2	Describing gases	257
	Pressure (p)	257
	The gas laws	259
	The ideal gas equation	260
6.3	Molecular view of gases	262
	Molecular speeds	263
	Speed and energy	264
	Average kinetic energy and temperature	265
	Rates of gas movement	266
	Ideal gases	268
6.4	Gas mixtures	270
	Dalton's law of partial pressures	271
	Describing gas mixtures	272
6.5	Applications of the ideal gas equation	274
	Determination of molar mass	274
	Determination of gas density	275
6.6	Gas stoichiometry	277
	Summary of mole conversions	279
6.7	Real gases	281
	The halogens	281
	Properties of real gases	282
	The van der Waals equation	283
	Melting and boiling points	285
6.8	Intermolecular forces	286
	Dispersion forces	287
	Dipolar forces	288
	Hydrogen bonds	290
	Binary hydrogen compounds	292
	Summary	296
	Key concepts and equations	297
	Key terms	297

Review questions	298
Review problems	299
Additional exercises	301
Acknowledgements	301

CHAPTER 7

Condensed phases: liquids and solids 302

7.1	Liquids	303
	Properties of liquids	303
	Vapour pressure	304
7.2	Solids	306
	Magnitudes of forces	306
	Molecular solids	307
	Network solids	308
	Metallic solids	309
	Ionic solids	310
7.3	Phase changes	311
	Supercritical fluids	314
	Phase diagrams	314
7.4	Order in solids	320
	Close-packed structures	320
	The crystal lattice and the unit cell	324
	Cubic structures	326
	Ionic solids	329
7.5	X-ray diffraction	332
7.6	Amorphous solids	334
7.7	Crystal imperfections	335
7.8	Modern ceramics	336
	Properties of ceramics	337
	Applications of advanced ceramics	338
	High-temperature superconductors	338
	Summary	341
	Key concepts and equations	342
	Key terms	342
	Review questions	343
	Review problems	344
	Additional exercises	345
	Acknowledgements	346

CHAPTER 8

Chemical thermodynamics 347

8.1	Introduction to chemical thermodynamics	348
8.2	Thermodynamic concepts	350
	Heat and temperature	350
	System, surroundings and universe	350
	Units	351
	State functions	352
	ΔG and spontaneity	353
8.3	The first law of thermodynamics	354
	Heat capacity and specific heat	356
	Determination of heat	358
8.4	Enthalpy	360
	Standard enthalpy of reaction	363

Hess's law	365
Standard enthalpy of formation	367
Standard enthalpy of combustion	371
Bond enthalpies	372

8.5	Entropy	378
	Entropy and probability	378
	Entropy and entropy change	379
	Factors that affect entropy	380
8.6	The second law of thermodynamics	383
8.7	The third law of thermodynamics	384
8.8	Gibbs energy and reaction spontaneity	387
	The sign of ΔG	387
	Standard Gibbs energy change	389
	Gibbs energy and work	391
	Gibbs energy and equilibrium	393
	Summary	397
	Key concepts and equations	398
	Key terms	399
	Review questions	399
	Review problems	400
	Additional exercises	404
	Acknowledgements	407

CHAPTER 9

Chemical equilibrium 408

9.1	Chemical equilibrium	409
9.2	The equilibrium constant, K , and the reaction quotient, Q	410
	Manipulating equilibrium constant expressions	415
	The magnitude of the equilibrium constant	416
	Equilibrium constant expressions for heterogeneous systems	418
9.3	Equilibrium and Gibbs energy	420
	Gibbs energy diagrams	420
	The relationship between $\Delta_r G^\circ$ and K	424
9.4	How systems at equilibrium respond to change	428
	Le Châtelier's principle	428
	Adding or removing a product or reactant	429
	Changing the pressure in gaseous reactions	431
	Changing the temperature of a reaction mixture	433
	Addition of a catalyst	434
9.5	Equilibrium calculations	436
	Calculating K_c from equilibrium concentrations: the concentration table	436
	Calculating equilibrium concentrations from initial concentrations	440
	Summary	447
	Key concepts and equations	448
	Key terms	449
	Review questions	449
	Review problems	451

Additional exercises	453
Maths for chemistry	455
Acknowledgements	455

CHAPTER 10

Solutions and solubility 456

10.1	Introduction to solutions and solubility	457
10.2	Gaseous solutions	457
10.3	Liquid solutions	458
	Gas-liquid solutions	458
	Liquid-liquid solutions	462
	Liquid-solid solutions	464
10.4	Quantification of solubility: the solubility product	469
	The relationship between K_{sp} and solubility	471
	The common ion effect	473
	Will a precipitate form?	476
10.5	Colligative properties of solutions	477
	Molarity	478
	Molality	478
	Mole fraction	479
	Raoult's law	479
	Solutions containing more than one volatile component	481
	Boiling point elevation and freezing point depression	482
	Osmosis and osmotic pressure	484
	Measurement of solute dissociation	488
	Summary	491
	Key concepts and equations	492
	Key terms	492
	Review questions	493
	Review problems	494
	Additional exercises	496
	Acknowledgements	497

CHAPTER 11

Acids and bases 498

11.1	The Brønsted-Lowry definition of acids and bases	499
	Conjugate acid-base pairs	502
11.2	Acid-base reactions in water	504
	The autoprotolysis of water	504
	The concept of pH	506
	The strength of acids and bases	510
11.3	Strong acids and bases	512
	pH calculations in solutions of strong acids and bases	513
	Suppression of the autoprotolysis of water	514
11.4	Weak acids and bases	515
	pH calculations in solutions of weak acids and bases	519
	pH calculations in solutions of salts of weak acids and bases	525
	Solutions that contain the salt of a weak acid and a weak base	528

Situations where simplifying assumptions do not work	528
---	-----

11.5	The molecular basis of acid strength	531
	Binary acids	531
	Oxoacids	533
11.6	Buffer solutions	536
	pH calculations in buffer solutions	536
11.7	Acid-base titrations	543
	Strong acid – strong base and strong base – strong acid titrations	544
	Weak acid – strong base and weak base – strong acid titrations	545
	Diprotic acids	549
	Speciation diagrams	549
	Acid-base indicators	551
11.8	Lewis acids and bases	553
	Recognising Lewis acids and bases	554
	Polarisability	556
	The hard-soft concept	556
	The hard-soft acid-base principle	558
	Summary	559
	Key concepts and equations	560
	Key terms	560
	Review questions	561
	Review problems	564
	Additional exercises	566
	Acknowledgements	567

CHAPTER 12

Oxidation and reduction 568

12.1	Oxidation and reduction	569
	Oxidation numbers	571
12.2	Balancing net ionic equations for redox reactions	573
	Redox reactions in acidic and basic solutions	574
12.3	Galvanic cells	579
	Example 1: metallic zinc in copper sulfate solution	579
	Example 2: copper in zinc sulfate solution	580
	Example 3: copper coil in a solution of silver ions	581
	Potential difference in galvanic cells	581
	Setting up a galvanic cell	581
	Processes in galvanic cells	583
12.4	Reduction potentials	587
	Cell and standard cell potentials	587
	Reduction and standard reduction potentials	588
	Determining standard reduction potentials	589
	Spontaneous and nonspontaneous reactions	593
	Oxidising and nonoxidising acids	595

- 12.5 Relationship between cell potential, concentration and Gibbs energy 597
 The Gibbs energy change, ΔG 597
 Equilibrium constant, K 598
 The Nernst equation 599
 Concentration cells 603
- 12.6 Corrosion 604
- 12.7 Electrolysis 606
 What is electrolysis? 606
 Comparison of electrolytic and galvanic cells 607
 Electrolysis in aqueous solutions 607
 Stoichiometry of electrochemical reactions 610
- 12.8 Batteries 611
 The lead storage battery 611
 Dry cell batteries 612
 Modern high-performance batteries 614
 Fuel cells 616
 Summary 617
 Key concepts and equations 618
 Key terms 619
 Review questions 620
 Review problems 622
 Additional exercises 624
 Acknowledgements 625

CHAPTER 13

Transition metal chemistry 626

- 13.1 Metals in the periodic table 627
- 13.2 Transition metals 629
- 13.3 Ligands 631
- 13.4 Transition metal complexes 637
 Structures of transition metal complexes 639
 Isomerism in transition metal complexes 642
 The nomenclature of transition metal complexes 646
 The chelate effect 649
 Inert and labile transition metal complexes 652
 Electrochemical aspects of transition metal complexes 653
 Bonding in transition metal complexes 654
 The colours of transition metal complexes 659
 The magnetic properties of transition metal complexes 664
- 13.5 Transition metal ions in biological systems 677
 Transport and storage metalloproteins 668
 Metalloenzymes 669
 Electron transfer proteins 670
- 13.6 Isolation and purification of transition metals 670
 Separation 671

- Conversion 672
 Reduction 673
 Refining 673
 Iron and steel 674
 Titanium 676
 Copper 676

- 13.7 Applications of transition metals 677
 Titanium 678
 Chromium 678
 Copper, silver and gold 680
 Zinc and mercury 681
 The platinum metals 682
 Summary 683
 Key concepts and equations 684
 Key terms 685
 Review questions 686
 Review problems 687
 Additional exercises 690
 Acknowledgements 691

CHAPTER 14

The *p*-block elements 692

- 14.1 The *p*-block elements 693
 Group 13 694
 Group 14 697
 Group 15 700
 Group 16 703
 Group 17 704
 Group 18 708
- 14.2 Reactivity of the *p*-block elements 711
 Bonding in the *p*-block elements 712
 Group 13 compounds 713
 Group 14 compounds 714
 Group 15 compounds 716
 Group 16 compounds 717
 Group 17 compounds 719
- 14.3 The biogeochemical cycles of nature 720
 The group 16 cycles 721
 The group 15 cycles 723
 Summary 732
 Key concepts and equations 733
 Key terms 733
 Review questions 733
 Review problems 734
 Additional exercises 735
 Acknowledgements 736

CHAPTER 15

Reaction kinetics 737

- 15.1 Reaction rates 738
- 15.2 Factors that affect reaction rates 742
 Chemical nature of the reactants 742
 Physical nature of the reactants 743
 Concentrations of the reactants 743
 Temperature of the system 744
 Presence of catalysts 744
- 15.3 Overview of rate laws 744

15.4	Types of rate laws: differential and integrated	746
	The differential rate law	747
	The integrated rate law	752
15.5	Theory of chemical kinetics	761
	Collision theory	761
15.6	Reaction mechanisms	769
	The rate-determining step	769
	The steady-state approximation	773
15.7	Catalysts	778
	Homogeneous catalysts	778
	Heterogeneous catalysts	779
	Enzyme kinetics	780
	Summary	784
	Key concepts and equations	785
	Key terms	785
	Review questions	786
	Review problems	788
	Additional exercises	793
	Maths for chemistry	795
	Acknowledgements	796

CHAPTER 16

The chemistry of carbon 797

16.1	Introduction to hydrocarbons	800
16.2	Alkanes	800
	Conformation of alkanes	802
	Cycloalkanes	804
	Naming alkanes and cycloalkanes	805
	Conformations of cycloalkanes	806
	Physical properties of alkanes	813
16.3	Alkenes and alkynes	816
	Shapes of alkenes and alkynes	817
	Nomenclature of alkenes and alkynes	821
	Physical properties of alkenes and alkynes	829
16.4	Reactions of alkanes	830
16.5	Reactions of alkenes	830
	Electrophilic addition reactions	831
16.6	Reactions of alkynes	843
16.7	Aromatic compounds	843
	The structure of benzene	844
	The concept of aromaticity	848
	Nomenclature	850
16.8	Reactions of aromatic compounds: electrophilic aromatic substitution	853
	Halogenation	854
	Nitration and sulfonation	855
	Alkylation	856
	Acylation	857
	Summary	859
	Key concepts and equations	860
	Key terms	861
	Review questions	863
	Review problems	867

Additional exercises	871
Acknowledgements	872

CHAPTER 17

Chirality 873

17.1	Stereoisomers	876
17.2	Enantiomerism	879
	Stereocentres	882
	Representing enantiomers of complicated organic molecules	884
17.3	Naming stereocentres: the <i>R,S</i> system	886
17.4	Molecules with more than one stereocentre	888
	Acyclic molecules with two stereocentres	889
	Cyclic molecules with two stereocentres	891
	Molecules with three or more stereocentres	894
17.5	Optical activity: detecting chirality in the laboratory	894
	Plane-polarised light	894
	Polarimeters	895
	Measuring the rotation of plane-polarised light	895
	Racemic mixtures	897
17.6	Chirality in the biological world	897
	How an enzyme distinguishes between enantiomers	897
17.7	Synthesising chiral drugs	899
	Resolution	899
	Asymmetric synthesis	900
	Summary	902
	Key concepts and equations	902
	Key terms	903
	Review questions	903
	Review problems	907
	Additional exercises	911
	Acknowledgements	912

CHAPTER 18

Haloalkanes 913

18.1	Haloalkanes	915
	Nomenclature	915
	Synthesis of haloalkanes	918
	Chlorination and bromination	918
	Principal reactions of haloalkanes	921
18.2	Nucleophilic substitution	924
	Mechanisms of nucleophilic substitution	926
	Experimental evidence for S_N1 and S_N2 mechanisms	928
18.3	β -elimination	933
	Mechanisms of β -elimination	935
18.4	Substitution versus elimination	937
	S_N1 versus $E1$ reactions	938
	S_N2 versus $E2$ reactions	938

Summary	941
Key concepts and equations	942

CHAPTER 19

Alcohols, amines and related compounds 950

19.1 Alcohols	951
Physical properties	955
Preparation of alcohols	956
19.2 Reactions of alcohols	958
Acidity of alcohols	958
Basicity of alcohols	959
Reaction with active metals	959
Conversion to haloalkanes	960
Acid-catalysed dehydration to alkenes	963
Oxidation of primary and secondary alcohols	965
Ester formation	968
19.3 Phenols	968
Acidity of phenols	970
Acid-base reactions of phenols	972
Oxidation of phenols	973
Ester and ether formation	974
19.4 Ethers	975
Physical properties	977
Reactions of ethers	979
19.5 Thiols	979
Physical properties	981
Reactions of thiols	981
19.6 Amines	982
Physical properties	987
Preparation of amines	987
19.7 Reactions of amines	989
Basicity of amines	989
Reaction with acids	993
Reaction of primary aromatic amines with nitrous acid	995
Amide formation	997
Summary	998
Key concepts and equations	999

CHAPTER 20

Structure determination 1015

20.1 Tools for determining structure	1016
The index of hydrogen deficiency	1016

20.2 Mass spectrometry	1018
Isotopes in mass spectrometry	1020
20.3 Infrared spectroscopy	1024
Electromagnetic radiation	1024
The vibrational infrared spectrum	1025
Molecular vibrations	1026
Correlation tables	1028
20.4 Interpreting infrared spectra	1031
General rules for interpretation of IR spectra	1031
Alkanes	1031
Alkenes	1032
Alkynes	1032
Alcohols	1033
Ethers	1033
Benzene and its derivatives	1034
Amines	1034
Aldehydes and ketones	1035
Carboxylic acids and their derivatives	1035
20.5 Nuclear magnetic resonance spectroscopy	1042
The origin of nuclear magnetic resonance	1042
Shielding	1043
An NMR spectrometer	1044
Equivalent hydrogen atoms	1046
Signal areas	1048
Chemical shift	1050
Signal splitting and the ($n + 1$) rule	1053
^{13}C -NMR spectroscopy	1056
20.6 Interpreting NMR spectra	1059
Alkanes	1059
Alkenes	1059
Alcohols	1060
Benzene and its derivatives	1061
Amines	1063
Aldehydes and ketones	1063
Carboxylic acids	1064
Esters	1064
Solving NMR problems	1065
20.7 Other tools for determining structure	1067
Summary	1071
Key concepts and equations	1072

ABOUT THE AUTHORS

Allan Blackman

Allan Blackman is a Professor of Chemistry at the Auckland University of Technology in Auckland, New Zealand. He obtained his BSc (Hons) and PhD degrees from the University of Otago, New Zealand. He has taught all levels of undergraduate chemistry, in the areas of inorganic and physical chemistry, for over 30 years. Allan's research interests lie mainly in the field of coordination chemistry, where he studies the synthesis, structure and reactivity of coordination complexes. He has spent research periods in the USA (Indiana University, the University of Minnesota), Australia (the University of Queensland) and France (Université Joseph Fourier, Grenoble). He has also given numerous undergraduate lectures at the National University of Defense Technology, Changsha, China, where he has been a Guest Professor. Allan regularly appears on TV and radio as a science commentator. In 2019, the 150th birthday of the Periodic Table, he, together with the noted science communicator Alison Ballance, recorded the 96-part podcast 'Elemental', a discussion of all the chemical elements. This is available at <https://www.rnz.co.nz/programmes/elemental>. Outside science, his interests include music and sport.

Steven Bottle

Steven Bottle is a graduate of the University of Queensland, where he completed Honours in Organic Chemistry. After working in various jobs in the pharmaceutical and mining industries, he undertook a PhD at Griffith University in collaboration with the CSIRO. On completion of his PhD he was awarded an Alexander von Humboldt Fellowship before taking up an academic position at QUT, where he has risen to the rank of full professor. He has served as a member of the Australian Research Council's College of Experts (2017–2019) and was elected President of the Royal Australian Chemical Institute (2020–2022). Steven is a teaching and research academic with an established reputation for excellence in both pure and applied research, matched with demonstrated teaching capabilities and professional expertise. He has a reputation for inventive and pioneering research, and has achieved international recognition for his expertise in the chemistry and applications of free radicals, especially in the context of antioxidant drugs and novel materials. Steven's particular interests include the use of stable nitroxide free radicals in synthesis, polymers and other materials as analytical tools and antioxidant drugs. Stable nitroxide free radicals play critical roles as additives (protecting coatings and plastics), as tools to make new materials and even as new antioxidant medicines. Steven has led much of the modern research on discovering new forms of nitroxide free radicals and applying them in a range of contexts, including as medicinally active compounds, detectors of free radical damage in materials and monitors of particulate pollution that impacts on human health.

Siegbert Schmid

Siegbert 'Siggi' Schmid is a Professor of Chemistry at the University of Sydney. He graduated with a PhD from the University of Tübingen, Germany. After a few years at the Australian National University, Canberra, he returned to Germany to complete a Habilitation at the University of Tübingen. Subsequently, he accepted a position at the School of Chemistry of the University of Sydney, combining both materials chemistry and chemistry education research. He leads the Chemistry Education & Communication Research (CECR) theme at the University of Sydney and is very active in chemistry education research and development. Siggi's education research aims to improve current teaching practices and learning outcomes for tertiary-level students as well as improve diversity and inclusion in chemistry teaching. His materials chemistry research interests lie in the synthesis and structural characterisation of aperiodic crystals and other materials with technological applications (e.g. electrode materials for rechargeable batteries). He is a Past Chair of the RACI Division of Chemical Education. His contributions to Chemistry Education have been recognised with many awards, including the Vice Chancellor's Award for Outstanding Teaching (The University of Sydney, 2012), an Office of Learning and Teaching Citation Award (2012) for Excellence in Teaching, and the Divisional Medal of the Royal Australian Chemical Institute's Division of Chemical Education (2016). In 2019, he was awarded the Fensham Medal of the Royal Australian Chemical Institute for outstanding contributions to chemical education.

Mauro Mocerino

Mauro Mocerino has enjoyed teaching chemistry at Curtin University for almost three decades. During this period he has sought to better understand how students learn chemistry and what can be done to improve their learning. This has developed into a significant component of his research efforts. He also has a strong interest in enhancing the learning in laboratory classes and led the development of a professional development program for those who teach in laboratories. Mauro's other research interests are in the design and synthesis of molecules for specific intermolecular interactions including drug–protein interactions, host–guest interactions, crystal growth modification and corrosion inhibition. He has received numerous awards for his contributions to learning and teaching, including the inaugural Premier's Prize for Excellence in Science Teaching: Tertiary (2003), an Office of Learning and Teaching Australian Award for Programs that Enhance Student Learning (2013) and the Royal Australian Chemical Institute's Fensham Medal (2018). Outside work, he enjoys playing basketball, trying new foods and (whenever possible) travelling.

Uta Wille

Uta Wille is a Professor in the School of Chemistry at the University of Melbourne. She studied chemistry at the University of Kiel in Germany, where she graduated with a PhD in physical chemistry and afterwards completed a Habilitation in organic chemistry. Uta moved to Australia in 2003 to take up an academic position in the School of Chemistry at Melbourne University. Her research interests lie in the area of physical organic chemistry, environmental free radicals and reaction mechanisms, and she is particularly interested in how environmental radical and non-radical oxidants damage biological and manufactured materials exposed to the atmosphere. More recently, her research interests branched out into the area of agricultural chemistry. Working within the Australian Research Council (ARC) Research Hub for Innovative Nitrogen Fertilisers and Inhibitors (Smart Fertilisers), Uta and her team are developing new urease and nitrification inhibitor compounds to increase nitrogen use efficiency in agriculture with the aim of reducing the negative environmental impact of nitrogen fertilisation. Uta teaches chemistry at both undergraduate and graduate levels and enjoys sharing her fascination and passion for chemistry with university students.

Lightboard contributors

Throughout the VitalSource digital text, there are numerous worked solutions by leading chemistry educators. These are presented as Lightboard videos and help bring to the fore some of the topics that students can struggle with the most. We thank the following contributors for volunteering time out of their busy teaching and researching schedules to spend days in the studio, bringing these concepts to life.

- Christopher Thompson
- Gwen Lawrie
- Sonia Horvat

The atom

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 1.1 define atoms, molecules, ions, elements and compounds
- 1.2 explain how the concept of atoms developed
- 1.3 describe the structure of the atom
- 1.4 explain the basis of the periodic table of the elements
- 1.5 detail the role of electrons in atoms.

What is the universe made of? This question has occupied human thinking for thousands of years. Some ancient civilisations thought that the universe comprised only four elements (earth, air, fire and water) and that everything was made up of a combination of these. Over the past 400 years, the advent of the science called chemistry has allowed us to show that this is not the case. We now know that matter — everything you can see, smell, touch or taste — is made up of atoms, the fundamental building blocks of the universe.

Atoms are incredibly small — far too small to be seen using conventional microscopes. While many experiments over many years have produced results consistent with the existence of atoms, only recently have we been able to ‘see’ individual atoms and the collections of atoms we call molecules. We now have the technology to observe individual molecules undergoing a chemical reaction, a process in which one chemical substance is converted into another. The images in figure 1.1 show a molecule called an alkyne, which contains three rings made up of carbon atoms, reacting when heated to over 90 °C to give a molecule containing seven rings. The images were obtained using an atomic force microscope (AFM), and the scale on the images ($3 \text{ \AA} = 0.000\,000\,000\,3 \text{ m}$) gives an idea of just how tiny atoms truly are.

FIGURE 1.1 AFM images of a three-ring alkyne reacting when heated to form a seven-ring molecule

Perhaps more remarkable still is the photograph in figure 1.2, which was taken with an ordinary digital SLR camera using a long exposure time. If we look closely, we can see a faint blue dot in the middle of the image. This is the light emitted by a single atom of the element strontium, Sr, which is suspended as close to stationary as possible in a strong electric field, with the entire apparatus being housed inside an ultra-high vacuum chamber. The atom is irradiated by a laser. This causes electrons within the atom to rearrange, thereby releasing energy that we see as visible light.

FIGURE 1.2

The blue dot is the light emitted by a strontium atom suspended in a strong electric field. The distance between the electrodes is about 2 mm.

Our current knowledge of the structure of the atom, and the way in which atoms pack together in three-dimensional space, owes much to experiments carried out by two Australasian-born scientists, Ernest Rutherford (1871–1937; Nobel Prize in chemistry, 1908) and William Lawrence Bragg (1890–1971; Nobel Prize in physics, 1915), both of whom would doubtless have been astonished by the images in figures 1.1 and 1.2. The New Zealand-born Rutherford was the first to show that the atom consists of a positively charged nucleus surrounded by tiny negatively charged electrons. William Lawrence Bragg (born in Australia), together with his British-born father William Henry Bragg, developed the technique of X-ray crystallography, in which X-rays are used to determine the three-dimensional structure of solid matter on the atomic scale. The contribution of the Braggs will be outlined further in the chapter that looks at condensed phases. This chapter is primarily concerned with the atom. It will examine the contribution of Rutherford and others to the determination of the structure of the atom, and will show how a particular structural feature of the atom forms the basis of the periodic table of the elements.

1.1 The essential concepts in brief

LEARNING OBJECTIVE 1.1 Define atoms, molecules, ions, elements and compounds.

Before we can begin our discussion of chemistry, you need to be familiar with various concepts. We will introduce these briefly here and discuss them in greater detail later in the text.

Chemistry is the study of **matter**, which is anything that has mass and occupies space. Chemists view matter as being composed of various chemical entities. **Atoms** are discrete chemical species comprising a central positively charged nucleus surrounded by one or more negatively charged **electrons**. Atoms are always electrically neutral, meaning that the number of electrons is equal to the number of protons in the nucleus. Individual atoms are rarely found free in nature. With some exceptions that we will meet in later chapters, atoms are usually bonded to other atoms. Thus, chemists regard the atom as the fundamental *building block* of all matter.

Molecules are collections of atoms that have definite structures and are held together by chemical bonds. The smallest molecules contain just two atoms, while the largest can consist of literally millions. Most gases and liquids consist of molecules, and most solids based on carbon (organic solids) are also molecular. Like atoms, molecules are electrically neutral and are, therefore, uncharged. Molecules are held together by **covalent bonds**, which involve the sharing of electrons between neighbouring atoms.

Ions are chemical species that have either a positive or negative electric charge. Those with a positive charge are called **cations**; those with a negative charge are called **anions** (respectively designated by a⁺ or ⁻). Ions can be formally derived from either atoms or molecules by the addition or removal of one or more electrons. For example, removing an electron (e⁻) from a sodium, Na, atom gives the Na⁺ cation.

Adding an electron to an oxygen molecule, which consists of two oxygen atoms bonded together and is designated O₂, gives the O₂⁻ (superoxide) anion.

Elements are collections of one type of atom only. At the time of writing, 118 elements are known. **Compounds** are substances containing two or more elements in a definite and unchanging proportion. Compounds may be composed of molecules, ions or covalently bonded networks of atoms. The **chemical formula** shows the relative number of each type of atom present in a chemical substance. For example, an oxygen molecule contains two oxygen atoms, and therefore has the chemical formula O₂, while a molecule of methane, which contains one carbon atom and four hydrogen atoms, has the chemical formula CH₄. Note that we do not have individual ‘molecules’ of an ionic compound such as sodium chloride. The chemical formula of sodium chloride, NaCl, simply represents the smallest repeating unit in an enormous three-dimensional array of Na⁺ ions and Cl⁻ ions. The same applies to certain covalently bonded structures. For example, quartz, which is composed of an ‘infinite’ three-dimensional network of covalently bound Si and O atoms, has the chemical formula SiO₂, which refers not to individual SiO₂ ‘molecules’ but to the smallest repeating unit in the network.

All of the chemical entities described above (atoms, molecules, ions, elements and compounds) may be involved as **reactants** in **chemical reactions**, processes in which they undergo transformations generally involving the making and/or breaking of chemical bonds, and which usually result in the formation of different chemical species called **products**.

1.2 The atomic theory

LEARNING OBJECTIVE 1.2 Explain how the concept of atoms developed.

Today, we take the existence of atoms for granted. We can explain many aspects of the structure of the atom and, in fact, current technology allows us to ‘see’ individual atoms, as we saw in the introduction to this chapter, and even manipulate them, as further described in the chemical connections feature on imaging atoms. However, scientific evidence for the existence of atoms is relatively recent, and chemistry did not progress very far until that evidence was found.

CHEMICAL CONNECTIONS

Imaging atoms

We cannot use optical microscopes to see atoms. This is because the smallest objects that can be resolved using visible light are those having dimensions of the order of the wavelength of such light, that is, 400–700 nm (nm is the abbreviation for nanometre, which is 1 × 10⁻⁹ m). The radii of atoms (~ 0.1–0.3 nm) are much smaller than this. In place of visible light, we can use a beam of electrons, which have shorter wavelengths, to obtain images; this is the principle behind the electron microscope. However, such apparatus is expensive and the samples require a significant degree

of preparation and careful handling. The energetic electrons can also damage the sample being imaged.

In the late twentieth century, two inventions — the scanning tunnelling microscope (STM) and the atomic force microscope (AFM) — revolutionised the imaging of objects having dimensions of the order of nanometres, and have allowed us to ‘see’ and, more remarkably, manipulate individual atoms. The STM and AFM operate using the same principle — moving the tip of an extremely fine stylus across a surface at a distance of atomic dimensions.

In the case of the STM, the surface must be electrically conducting, and this causes a current to flow between the surface and the tip. The magnitude of this current depends on the distance between the tip and the surface, so as the tip is moved across the surface, computer control of the current at a constant value will cause the tip to move up and down, thereby giving a map of the surface. Because of its tiny size, the tip can also be used to move individual atoms. This was first demonstrated in 1989 when Don Eigler, a scientist at IBM, manipulated 35 atoms of xenon on a nickel surface using an STM to spell the name of his employer (figure 1.3).

FIGURE 1.3 Individual Xe atoms (blue dots) on a nickel surface manipulated by an STM tip

An AFM (illustrated in figure 1.4) is used to study nonconducting samples. The stylus is moved across the surface of the sample under study. Forces between the tip of the probe and the surface cause the probe to flex as it follows the ups and downs of the bumps that are the individual molecules and atoms. A mirrored surface attached to the probe reflects a laser beam at angles proportional to the amount of deflection of the probe. A sensor picks up the

FIGURE 1.4 In an AFM, a sharp stylus attached to the end of a cantilever probe rides up and down over the surface features of the sample. A laser beam, reflected off a mirrored surface at the end of the probe, changes angle as the probe moves up and down. A photodetector reads these changes and sends the information to a computer, which translates the data into an image.

signal from the laser and translates it into data that can be analysed by a computer to give three-dimensional images of the sample's surface.

A typical AFM image is shown in figure 1.5. It involves manipulating single atoms to give what is probably the smallest known writing.

FIGURE 1.5 The world's smallest writing? The element symbol for silicon, Si, is spelled out with individual silicon atoms (dark) among tin atoms (light). The silicon atoms were manipulated with the tip of an AFM.

The concept of atoms began nearly 2500 years ago when the Greek philosopher Leucippus and his student Democritus expressed the belief that matter is ultimately composed of tiny indivisible particles; the word 'atom' is derived from the Greek word *atomos*, meaning 'not cut'. The philosophers' conclusions, however, were not supported by any scientific evidence; they were derived simply from philosophical reasoning. The concept of atoms remained a philosophical belief, having limited scientific usefulness,

until the discovery of two fundamental laws of chemistry in the late eighteenth century — the law of conservation of mass and the law of definite proportions. These may be stated as follows.

- The **law of conservation of mass**: No detectable gain or loss of mass occurs in chemical reactions. Mass is conserved.
- The **law of definite proportions**: In a given chemical compound, the elements are always combined in the same proportions by mass.

The French chemist Antoine Lavoisier (1743–1794) proposed the law of conservation of mass as a result of his experiments involving the individual reactions of the elements phosphorus, sulfur, tin and lead with oxygen. He used a large lens to focus the sun's rays on a sample of each element contained in a closed jar, and the heat caused a chemical reaction to take place. He weighed the closed jar and its contents before and after the chemical reaction and found no difference in mass, leading him to propose the law. The law of conservation of mass can be alternatively stated as 'mass is neither created nor destroyed in chemical reactions'. Lavoisier was beheaded following the French Revolution, the judge at his trial reputedly saying 'the Republic has no need of scientists' (in French, of course).

Another French chemist, Joseph Louis Proust (1754–1826), was responsible for the law of definite proportions, following experiments showing that copper carbonate prepared in the laboratory was identical in composition to copper carbonate that occurs in nature as the mineral malachite. He also showed that the two oxides of tin, SnO and SnO₂, and the two sulfides of iron, FeS and FeS₂, always contain fixed relative masses of their constituent elements. The law states that chemical elements always combine in a definite fixed proportion by mass to form chemical compounds. Thus, if we analyse *any* sample of water (a compound), we *always* find that the ratio of oxygen to hydrogen (the elements that make up water) is 8 to 1 by mass. Similarly, if we form water from oxygen and hydrogen, the mass of oxygen consumed will always be 8 times the mass of hydrogen that reacts. This is true even if there is a large excess of one of them. For instance, if 100 g of oxygen gas, O₂, is mixed with 1 g of hydrogen gas, H₂, and the reaction to form water is initiated, all the hydrogen would react but only 8 g of oxygen would be consumed; there would be 92 g of oxygen left over. No matter how we try, we cannot alter the chemical composition of the water formed in the reaction.

WORKED EXAMPLE 1.1

Applying the law of definite proportions

The element vanadium, V, can combine with oxygen, O, to form a compound called vanadium pentoxide. The primary use of this compound is as a catalyst in the production of sulfuric acid, the most produced chemical in the world. A sample of vanadium pentoxide contains 1.274 g of V for each 1.000 g of O. If a different sample of the compound contains 2.250 g of O, what mass of V does it contain?

Analysis

The law of definite proportions states that the proportions of V and O by mass must be the same in both samples. To solve the problem, we will set up the mass ratios for the two samples. In the ratio for the second sample, the mass of vanadium will be an unknown quantity. We will use the two ratios to determine the unknown quantity.

Solution

The first sample has a V to O mass ratio of:

$$\frac{1.274 \text{ g V}}{1.000 \text{ g O}}$$

We know the mass of O in the second sample, but not the mass of V. We do know, however, that the V to O mass ratio is the same as that in the first sample. We set up the ratio for the second sample using *x* for the unknown mass

of V. Therefore, from the law of definite proportions, we can write the following.

$$\frac{1.274 \text{ g V}}{1.000 \text{ g O}} = \frac{x \text{ g V}}{2.250 \text{ g O}}$$

We can solve for *x* by multiplying both sides of the equation by 2.250 g O, to give:

$$x \text{ g V} = \frac{1.274 \text{ g V} \times 2.250 \text{ g O}}{1.000 \text{ g O}} = 2.867 \text{ g V}$$

We use lots of equations in chemistry. The 'Maths for Chemistry' section at the end of the chapter on the language of chemistry provides help to develop skills in rearranging equations.

Is our answer reasonable?

To avoid errors, it is always wise to do a rough check of the answer. Usually, some simple reasoning is all we need to see if the answer makes sense. This is how we might do such a check here: notice that the mass of oxygen in the second sample is more than twice the mass in the first sample. Therefore, we should expect the mass of V in the second sample to be somewhat more than twice what it is in the first. The answer we obtained, 2.867 g V, is more than twice 1.274 g V, so our answer seems to be reasonable.

PRACTICE EXERCISE 1.1

If you have ever worn silver jewellery in a natural hot pool, you will have noticed that it turned black fairly rapidly. This is due to the formation of silver sulfide, Ag_2S , from reaction of the silver with H_2S . Analysis of a sample of Ag_2S

showed it to be composed of 1.74 g of silver and 0.260 g of sulfur. If a second sample of the same compound contains 2.80 g of silver, what mass of sulfur does it contain?

The laws of conservation of mass and definite proportions served as the experimental foundation for the atomic theory. At the beginning of the nineteenth century, John Dalton (1766–1844), an English scientist, used the Greek concept of atoms to make sense of the laws of conservation of mass and definite proportions. Dalton reasoned that, if atoms really exist, they must have certain properties to account for these laws. He described such properties, and the following list constitutes what we now call **Dalton's atomic theory**.

1. Matter consists of tiny particles called atoms.
2. Atoms are indestructible. In chemical reactions, the atoms rearrange but they do not themselves break apart.
3. In any sample of a pure element, all the atoms are identical in mass and other properties.
4. The atoms of different elements differ in mass and other properties.
5. When atoms of different elements combine to form a given compound, the constituent atoms in the compound are always present in the same fixed numerical ratio.

Dalton's theory easily explained the law of conservation of mass. According to the theory, a chemical reaction is simply a reordering of atoms from one combination to another. If no atoms are gained or lost, and if the masses of the atoms cannot change, the mass after the reaction must be the same as the mass before. This explanation of the law of conservation of mass allows us to use a notation system of **chemical equations** to describe chemical reactions. A chemical equation contains the reactants on the left-hand side and the products on the right-hand side, separated by a forward arrow, as demonstrated in the following chemical equation for the formation of liquid water from its gaseous elements.

The law of conservation of mass requires us to have the same number of each type of atom on each side of the arrow; this being the case, the chemical equation above is described as *balanced*. We will discuss this concept in detail in the chapter on stoichiometry. Note that this chemical equation also specifies the physical states of the reactants and product. Gases, liquids and solids are abbreviated as (g), (l) and (s), respectively, after each reactant and product.

The law of definite proportions can also be explained by Dalton's theory. According to the theory, a given compound is always composed of atoms of the same elements in the same numerical ratio. Suppose, for example, that elements *X* and *Y* combine to form a compound in which the number of atoms of *X* equals the number of atoms of *Y* (i.e. the atom ratio is 1 to 1). If the mass of a *Y* atom is twice that of an *X* atom, then every time we encounter a sample of this compound, the mass ratio (*X* to *Y*) would be 1 to 2. This same mass ratio would exist regardless of the size of the sample so, in samples of this compound, elements *X* and *Y* are always present in the same proportion by both number and mass.

Strong support for Dalton's theory came when Dalton and other scientists studied elements that can combine to give at least two different compounds. For example, sulfur and oxygen can combine to form either sulfur dioxide, SO_2 , or sulfur trioxide, SO_3 depending on the reaction conditions. The former contains one atom of sulfur and two atoms of oxygen, while the latter contains one atom of sulfur and three atoms of oxygen. Although they have similar chemical formulae, they are different chemically; for example, at room temperature, SO_2 is a colourless gas while SO_3 , which melts at 16.8°C , is a solid or liquid, depending on the temperature of the room. If we analyse samples of SO_2 and SO_3 in which the masses of sulfur are the same, we obtain the results shown in table 1.1.

TABLE 1.1 Mass composition of sulfur dioxide and sulfur trioxide

Compound	Mass of sulfur	Mass of oxygen
SO_2	1.00 g	1.00 g
SO_3	1.00 g	1.50 g

Note that the ratio of the masses of oxygen in the two samples is one of small whole numbers.

$$\frac{\text{mass of oxygen in sulfur trioxide}}{\text{mass of oxygen in sulfur dioxide}} = \frac{1.50 \text{ g}}{1.00 \text{ g}} = \frac{3}{2}$$

Similar observations are made when we study other elements that form more than one compound with each other. These observations form the basis of the **law of multiple proportions**, which states that: Whenever two elements can combine to form more than one compound, the different masses of one element that combine with the same mass of the other element are in the ratio of small whole numbers.

Dalton's theory explains the law of multiple proportions in a very simple way. A molecule of sulfur trioxide contains 1 sulfur and 3 oxygen atoms, and a molecule of sulfur dioxide contains 1 sulfur and 2 oxygen atoms (figure 1.6). If we had just one molecule of each, our samples would each contain 1 sulfur atom and, therefore, the same mass of sulfur. Then, comparing the oxygen atoms, we find they are in a numerical ratio of 3 to 2. But because oxygen atoms all have the same mass, the mass ratio must also be 3 to 2. The law of multiple proportions was not known before Dalton presented his theory, and its discovery demonstrates science in action. Experimental data suggested to Dalton the existence of atoms, and the atomic theory suggested the relationships that we now call the law of multiple proportions. When found by experiment, the existence of the law of multiple proportions added great support to the atomic theory. In fact, for many years, it was one of the strongest arguments in favour of the existence of atoms.

FIGURE 1.6

Compounds containing oxygen and sulfur demonstrate the law of multiple proportions. Represented here are molecules of sulfur trioxide, SO_3 , and sulfur dioxide, SO_2 . Each contains one sulfur atom, and therefore the same mass of sulfur. The oxygen ratio is 3 to 2, both by atoms and by mass.

1.3 The structure of the atom

LEARNING OBJECTIVE 1.3 Describe the structure of the atom.

Even though absolute proof of the existence of atoms was not available around the turn of the twentieth century, scientists were nevertheless interested in the structure of the atom. While Dalton's theory said that atoms were indestructible and could not be broken apart, experiments around this time showed this was not necessarily true. In particular, the discovery of radiation in the form of X-rays by Wilhelm Röntgen (1845–1923) in 1895 (see figure 1.7) and radioactivity by Antoine Henri Becquerel (1852–1908, pictured in figure 1.8) in 1896 led scientists to believe that the atom was composed of discrete particles, as both forms of radiation involve the release of particles from atoms, thought at that time to be indivisible.

Further evidence for the presence of discrete particles in atoms came from experiments with gas discharge tubes, such as that shown in figure 1.9. When the tube was filled with a low-pressure gas and a high voltage was applied between the electrodes, negatively charged particles flowed from the negative electrode (cathode) to the positive electrode (anode).

FIGURE 1.7

**FIGURE 1.8**

Antoine Henri Becquerel (1852–1908), a French physicist, discovered radioactivity and was awarded the 1903 Nobel Prize in physics.

**FIGURE 1.9**

Diagram of a gas discharge tube

Because they emanated from the cathode, the particles were called cathode rays. In 1897, the British physicist JJ Thomson passed cathode rays through a magnetic field using the modified discharge tube shown in figure 1.10. The magnetic field caused the path of the cathode rays to bend. Analysis of this effect allowed Thomson to determine the charge to mass ratio of the components of cathode rays, what we now know as electrons.

In 1909, the American chemist Robert Millikan determined the charge on an individual electron by measuring the rates at which charged oil drops fell between electrically charged plates. This, combined with Thomson's results, allowed calculation of the mass of an electron as 9.09×10^{-31} kg. The knowledge that atoms were electrically neutral meant that the electron must have a positively charged counterpart, but its exact nature was not known by the early years of the twentieth century. It was the work of the New Zealand-born scientist Ernest Rutherford (1871–1937) that shed light not only on the positively charged component of the atom, but also on the structure of the atom itself. Around 1909, Rutherford, who had already been awarded the Nobel Prize in chemistry in 1908 for his work on the theory of radioactivity, devised his famous gold foil experiment depicted in figure 1.11. Rutherford took a sheet of gold about $0.4 \mu\text{m}$ thick

(μm is the abbreviation for micrometre, which is $1 \times 10^{-6} \text{ m}$), which corresponds to the thickness of just a few thousand atoms, and bombarded it with a stream of positively charged **alpha particles**. Alpha particles are the nuclei of helium atoms.

FIGURE 1.10

Diagram of the apparatus used by JJ Thomson to determine the charge to mass ratio of the electron. The cathode ray beam passes between the poles of a magnet and between a pair of metal electrodes that can be given electric charges. The magnetic field tends to bend the beam in one direction (to point 2) while the charged electrodes bend the beam in the opposite direction (to point 3). By adjusting the charge on the electrodes, the two effects can be made to cancel each other (point 1). The amount of charge on the electrodes required to balance the effect of the magnetic field can be used to calculate the charge to mass ratio.

FIGURE 1.11

Schematic view of Rutherford's gold foil experiment. When a beam of positively charged alpha particles was 'shot' at a thin gold foil, most of them passed straight through the foil. Some, however, were deflected straight back towards the source.

Most of the particles went straight through the foil essentially undisturbed, some were deflected through various angles, and about 1 in 8000 was deflected almost straight back towards the source. Of this observation, Rutherford said, ‘It was almost as incredible as if you had fired a fifteen-inch [38.1-centimetre] [artillery] shell at a piece of tissue paper and it came back and hit you’. To explain his observations, Rutherford proposed a new model of the atom. He suggested that every atom has a tiny electrically charged central core, which he called the **nucleus**, that constitutes most of the mass of the atom. He later determined the charge on this to be positive, due to particles, which he called **protons**, and the number of these in the nucleus determines the identity of the atom. The electrical neutrality of the atom requires that there is the same number of electrons in an atom as there are protons in the nucleus, and these surround the central core, as shown schematically in figure 1.12.

FIGURE 1.12

Diagram (not to scale) showing the nucleus and the volume occupied by the surrounding electrons. If this were drawn to scale, the nucleus would be invisible.

Electrons occupy a volume that is huge compared with the size of the nucleus, but each electron has such a small mass that alpha particles are not deflected by the electrons. Consequently, an alpha particle is deflected only when it passes very near a nucleus, and it bounces straight back only when it collides head-on with a nucleus. Because most of the volume of an atom is essentially empty space, most alpha particles pass through the foil without being affected. From the number of particles deflected and the pattern of deflection, Rutherford calculated that the positive nucleus occupies less than 0.1% of the total atomic volume. We now know that the percentage of the atomic volume is far less than this — to give you some idea of the relative volumes, an atom the size of a sports stadium would have a nucleus the size of a pea. When Rutherford calculated the nuclear mass based on the number of protons in the nucleus, the value always fell short of the actual mass. In fact, Rutherford found that only about half of the nuclear mass could be accounted for by protons. This led him to suggest that there was another particle in the nucleus that had a mass close to or equal to that of a proton, but with no electric charge. This suggestion initiated a search that finally ended in 1932 with the discovery of the **neutron** by a British physicist named James Chadwick (1891–1974). Because they are found in the nucleus, protons and neutrons are sometimes called **nucleons**. Table 1.2 summarises the **subatomic particles** present in this model of the atom.

TABLE 1.2 Physical data for the electron, proton and neutron

Particle	Symbol	Charge (C)	Mass (kg)	Mass (u)
electron	e^-	-1.6022×10^{-19}	9.1094×10^{-31}	5.4858×10^{-4}
proton	p	$+1.6022 \times 10^{-19}$	1.6726×10^{-27}	1.0073
neutron	n	0	1.6749×10^{-27}	1.0087

Note: The charge is measured in coulombs (C). The final column gives the mass in atomic mass units (u); $1\text{ u} = 1.66054 \times 10^{-27}\text{ kg}$ ($\frac{1}{12}$ the mass of the ^{12}C atom).

Over the intervening years, it has been shown that protons and neutrons are themselves composed of still smaller particles called quarks. The existence of quarks has helped us understand how the atomic nucleus can stay together despite the presence of positively charged protons in close proximity. However, quarks are very unstable outside the confines of the atomic nucleus and are of more interest to physicists than chemists.

How big, or small, is an atom?

The introduction to this chapter stated that atoms are tiny. But just how small is 'tiny'? In order to give you some idea of the atomic scale, we're going to count all the individual atoms in a New Zealand 10-cent piece (the copper-coloured coin in figure 1.13). If we started today, counting at one atom per second, how long do you think this would take? Days? Months? Years? Decades? Have a guess before you read any further.

FIGURE 1.13 How long would it take to count all the atoms in a New Zealand 10-cent coin?

In order to calculate the number of atoms that we'll be counting, we need to know that a 10-cent piece is predominantly made up of iron (steel), with a thin copper coating, and that it weighs 3.30 g.

We'll assume that a year is 365.25 days and therefore contains 31 557 600 seconds. If you're an average Australasian, you can expect to live for about 80 years, which translates to around 2 500 000 000 (two-and-a-half billion) seconds. So if you started counting at one atom per second on the day you were born, by the time you reached 80, you'd have counted about two-and-a-half billion atoms. But that's not nearly enough.

The oldest known living animal was a clam found in Iceland in 2006. Counting the rings on its shell showed it was 507 years old when it was dredged from the seabed (a process that unfortunately killed it). Counting one atom per second for this length of time would get us to about 16 billion atoms. But we're not there yet.

The oldest living thing on Earth is thought to be a patch of seagrass in the Mediterranean Sea that has been dated at around 200 000 years old. An atom a second for that length of time gives us about 6.3 trillion (6 300 000 000 000) atoms. You might think we'd be getting close to counting all the atoms in the 10-cent piece by now, but you'd be wrong. We're not even 1% of the way there. In fact, we're not even anywhere near 1%. We're obviously going to be counting for a while.

The Earth is thought to be about 4.6 billion years old. So let's assume that we've been around since the formation of the Earth, and we've been diligently counting the atoms in the 10-cent piece at one atom per second. After this time, we'd be old, out of breath, and we would have counted around 145 quadrillion (145 000 000 000 000 000) atoms. Surely we must have counted all the atoms by now?

Nope! Still not even close. In fact, the atoms that we've counted by this time would weigh around 13 micrograms, probably just enough for us to see with the naked eye, but nowhere near the number in our 10-cent piece. Even if we counted a thousand atoms per second from the time of the formation of the Earth, we would still be only about 0.5% of the way there.

There are approximately 35 500 000 000 000 000 000 000 atoms in a New Zealand 10-cent piece and, at an atom per second, it would take us about 1 quadrillion years, or roughly 85 000 times the age of the universe, to count these. This is a number of truly incomprehensible magnitude. More incredible still, if we stacked these atoms one on top of another, the resulting chain would go around the Earth about 125 000 times.

To examine how atoms are constructed, we will consider the simplest possible atom, hydrogen, with the **chemical symbol** H. A hydrogen atom consists of a single proton in the nucleus, as well as a single electron. We designate this as ${}^1_1\text{H}$. We use this terminology for any chemical element X as follows.

The **atomic number (Z)** is the number of protons in the nucleus. The **mass number (A)** is the number of protons in the nucleus plus the number of neutrons (N) in the nucleus.

Note that the atomic number is also equal to the number of electrons in a *neutral* atom (i.e. one in which the number of protons and the number of electrons is the same). A chemical element is defined by its atomic number; all atoms having the same atomic number are atoms of the same element. Therefore, the symbol ${}^1_1\text{H}$ tells us that an atom of hydrogen contains 1 proton ($Z = 1$), 1 electron and 0 neutrons ($A = 1$).

If we were to analyse a sample of hydrogen atoms, we would find that roughly 1 atom in every 6600 would have approximately twice the mass of a ${}^1_1\text{H}$ atom. These heavier atoms belong to an isotope of hydrogen called deuterium. **Isotopes** are atoms of an element with the same number of protons (i.e. the same value of Z) but different numbers of neutrons (i.e. different values of A). Deuterium atoms are symbolised as ${}^2_1\text{H}$, meaning that there is 1 proton ($Z = 1$) and 1 neutron ($A = 2$) in the nucleus.

The ${}^1_1\text{H}$ atom is sometimes called protium to distinguish it from deuterium. In chemical terms, deuterium atoms behave essentially identically to hydrogen atoms, but there are some important differences in reactivity when they are bonded to other atoms. Protium and deuterium are examples of **stable isotopes**. This means that the nuclei of these atoms do not undergo any decay processes and are stable indefinitely. In addition, hydrogen also has a third isotope called tritium, ${}^3_1\text{H}$, which has 1 proton and 2 neutrons in the nucleus. It is the least abundant isotope of hydrogen, with only 1 to 10 atoms of tritium in every 10^{18} atoms of hydrogen. Tritium is **radioactive**, meaning that its nucleus is unstable and undergoes spontaneous decay to give an atom of helium, He, a process we will look at in greater detail in the chapter on nuclear chemistry. Helium atoms are characterised by having 2 protons in the nucleus ($Z = 2$). Helium has two stable isotopes, ${}^3_2\text{He}$ and ${}^4_2\text{He}$, with 1 and 2 neutrons, respectively, in the nucleus. The element with 3 protons in the nucleus, lithium ($Z = 3$), has the stable isotopes ${}^6_3\text{Li}$ and ${}^7_3\text{Li}$ with 3 and 4 neutrons, respectively. Any atom of a specified A and Z is called a **nuclide**. A **radionuclide** is a radioactive nuclide.

WORKED EXAMPLE 1.2

The composition of atoms

The following short-lived radioactive isotopes can be incorporated into simple compounds such as water, glucose and ammonia, which are then used in a medical imaging technique called positron emission tomography (PET). Determine the number of protons, neutrons and electrons in each isotope.

- (a) ${}^{11}_6\text{C}$
- (b) ${}^{13}_7\text{N}$
- (c) ${}^{15}_8\text{O}$

Analysis

The number of protons is equal to the atomic number (Z), the number of neutrons is found from Z and the mass number (A), and the number of electrons in a neutral atom must equal the number of protons.

Solution

- (a) C is the chemical symbol for carbon. The subscript 6 is Z , which is the number of protons in the nucleus. The

superscript 11 is A . We find the number of neutrons by subtracting Z from A : $A - Z = 11 - 6 = 5$ neutrons. Because this is a neutral atom, the number of electrons must equal the number of protons. ${}^{11}_6\text{C}$ has 6 protons, 5 neutrons and 6 electrons.

- (b) N is the symbol for nitrogen. $Z = 7$ and $A = 13$. Z tells us that the nucleus contains 7 protons. Subtracting Z from A , we find that there are 6 neutrons in this isotope. Finally, the atom is neutral, so there are 7 electrons.
- (c) Oxygen, O, has $Z = 8$. A neutral atom of ${}^{15}_8\text{O}$ has 8 protons, 8 electrons and $15 - 8 = 7$ neutrons.

Is our answer reasonable?

In all cases, the number of protons is equal to the number of electrons, as required for neutral atoms. We have followed the rules for calculating the number of neutrons and have carried out the calculations properly. Our answers should therefore be correct.

PRACTICE EXERCISE 1.2

Determine the number of protons and neutrons in each of the following stable isotopes.

- (a) ${}^{27}_{13}\text{Al}$
- (b) ${}^{139}_{57}\text{La}$
- (c) ${}^{14}_7\text{N}$

Inclusion of the atomic number in this terminology is almost redundant when the chemical symbol is included, so it is common to see a shorthand version that excludes this. Thus, we often write ${}^1_1\text{H}$ as simply ${}^1\text{H}$, as we know that all atoms of hydrogen have $Z = 1$. Using the same shorthand version, deuterium would be written as ${}^2\text{H}$ and tritium as ${}^3\text{H}$.

Atomic mass

Table 1.2 noted that the ${}^{12}\text{C}$ isotope is used as the basis by which **atomic mass** is measured. The **atomic mass unit (u)** is the mass equal to $\frac{1}{12}$ the mass of one atom of ${}^{12}\text{C}$. Therefore, $1\text{ u} = 1.660\,539\,066\,60 \times 10^{-27}\text{ kg}$, and the masses of all atoms are measured relative to this. The atomic mass unit is also known as the Dalton (Da), particularly in biochemistry. In calculations in this text, we will generally round the value of u so that $1\text{ u} = 1.660\,54 \times 10^{-27}\text{ kg}$.

Using this scale, we find that the mass of a single ^{19}F atom is 18.998 403 2 u and that of a single ^{31}P atom is 30.973 762 u. In other words, a single ^{19}F atom weighs $18.998\,403\,2 \times 1.660\,54 \times 10^{-27}$ kg and a single ^{31}P atom weighs $30.973\,762 \times 1.660\,54 \times 10^{-27}$ kg. Because both fluorine and phosphorus have only one naturally occurring isotope, we can be sure that any fluorine atom we chose from a macroscopic sample of fluorine would have a mass of 18.998 403 2 u, while any phosphorus atom chosen from a macroscopic sample of phosphorus would have a mass of 30.973 762 u. We therefore say that the atomic mass of fluorine is 18.998 403 2 u and the atomic mass of phosphorus is 30.973 762 u. In total, there are 19 elements which consist of only a single stable isotope; these are Be, F, Na, Al, P, Sc, Mn, Co, As, Y, Nb, Rh, I, Cs, Pr, Tb, Ho, Tm and Au. The majority of elements in the periodic table comprise two or more isotopes, and the mass of a single atom chosen at random from a macroscopic sample of these elements would not be constant — it would depend on which isotope was chosen. We therefore define the atomic mass of these elements as the average mass per atom of a naturally occurring sample of atoms of the element. Consider, for example, the element gallium, Ga. There are two naturally occurring isotopes of Ga, namely $^{69}_{31}\text{Ga}$ and $^{71}_{31}\text{Ga}$, each of which contains 31 protons in the nucleus. Nuclei of the former contain 38 neutrons while those of the latter contain 40. Any naturally occurring sample of gallium will be composed of 60.11% of the $^{69}_{31}\text{Ga}$ isotope and 39.89% of the $^{71}_{31}\text{Ga}$ isotope. Given the atomic masses of these isotopes ($^{69}_{31}\text{Ga} = 68.9256$ u, $^{71}_{31}\text{Ga} = 70.9247$ u), we can calculate the average atomic mass of Ga by taking the sum of the atomic mass of each isotope multiplied by its abundance as follows.

$$\text{average atomic mass of Ga} = (0.6011 \times 68.9256 \text{ u}) + (0.3989 \times 70.9247 \text{ u}) = 69.72 \text{ u}$$

The average atomic mass of Ga, 69.72 u, is just less than the average of the masses of the two isotopes (69.9252 u) because the lighter $^{69}_{31}\text{Ga}$ isotope is more abundant than the heavier $^{71}_{31}\text{Ga}$ isotope. Figure 1.14 illustrates the range of isotopic compositions found in four elements, one of which is tin, the element with the largest number of stable isotopes.

FIGURE 1.14

The natural abundances of the isotopes of chlorine (Cl), chromium (Cr), germanium (Ge) and tin (Sn), illustrate the diversity of isotopic distributions. The mass number and relative abundance of each isotope are indicated.

While the distribution of isotopes in samples of most elements on Earth is essentially constant, there are 14 elements (H, Li, B, C, N, O, Mg, Si, S, Cl, Ar, Br, Tl and Pb) which show substantial variation in their isotopic compositions, depending on the source of the element. Consider, for example, hydrogen.

As we have seen, this element has three isotopes, ^1H , ^2H and ^3H , the last of which we will neglect in this discussion because of its negligible abundance. If we analysed samples of atmospheric methane and methane from a natural gas well, we would find that the proportion of the ^2H isotope in the hydrogen atoms of the former would be greater than that in the latter, and hence the average atomic mass of H in the two samples would be different. Therefore, instead of quoting a single value for the average atomic mass of hydrogen, a range of values of atomic mass is given [1.007 84 u, 1.008 11 u], which corresponds to the lowest and highest values measured in natural samples. Table 1.3 gives the range of atomic mass values for these 14 elements, together with the conventional atomic masses which are used for routine work or when the source of the sample is unknown.

TABLE 1.3 Atomic mass ranges and conventional atomic masses for H, Li, B, C, N, O, Mg, Si, S, Cl, Ar, Br, Tl and Pb

Element name	Symbol	Atomic number	Atomic mass range (u)	Conventional atomic mass (u)
hydrogen	H	1	[1.007 84, 1.008 11]	1.008
lithium	Li	3	[6.938, 6.997]	6.94
boron	B	5	[10.806, 10.821]	10.81
carbon	C	6	[12.0096, 12.0116]	12.011
nitrogen	N	7	[14.006 43, 14.007 28]	14.007
oxygen	O	8	[15.999 03, 15.999 77]	15.999
magnesium	Mg	12	[24.304, 24.307]	24.305
silicon	Si	14	[28.084, 28.086]	28.085
sulfur	S	16	[32.059, 32.076]	32.06
chlorine	Cl	17	[35.446, 35.457]	35.45
argon	Ar	18	[39.792, 39.963]	39.948
bromine	Br	35	[79.901, 79.907]	79.904
thallium	Tl	81	[204.382, 204.385]	204.38
lead	Pb	82	[206.14, 207.94]	207.2

These atomic mass ranges are only important in very high precision work, and in this text, we will therefore use the conventional atomic masses listed in table 1.3 in any calculations involving these 14 elements.

WORKED EXAMPLE 1.3

Calculating average atomic masses from isotopic abundances

The element neodymium, Nd, is well known for its use in extremely strong permanent magnets. Naturally occurring neodymium is a mix of stable isotopes and very long-lived radioactive isotopes in the following proportions.

The atomic masses of the isotopes are as follows.

Use this information to calculate the average atomic mass of neodymium.

Analysis

In any macroscopic sample of neodymium, 27.15% of the total mass is contributed by atoms of ^{142}Nd , 12.17% by atoms of ^{143}Nd , 23.80% by atoms of ^{144}Nd , 8.29% by atoms of ^{145}Nd , 17.19% by atoms of ^{146}Nd , 5.76% by atoms of ^{148}Nd and 5.64% by atoms of ^{150}Nd . This means that, when we calculate the mass of the hypothetical 'average atom' of Nd, we have to weight it according to both the masses of the isotopes and their relative abundance. (Keep in mind, of course, that such an atom does not really exist. This is just a simple way to see how we can calculate the average atomic mass of this element.)

Solution

We will calculate 27.15% of the mass of an atom of ^{142}Nd , 12.17% of the mass of an atom of ^{143}Nd , 23.80% of the mass of an atom of ^{144}Nd , 8.29% of the mass of an atom of ^{145}Nd , 17.19% of the mass of an atom of ^{146}Nd , 5.76% of the mass of an atom of ^{148}Nd and 5.64% of the mass of an atom of ^{150}Nd . Adding these contributions gives the mass of the 'average atom' of Nd. Therefore:

$$\begin{aligned}\text{average atomic mass of Nd} &= (0.2715 \times 141.907\,723\,\text{u}) + (0.1217 \times 142.909\,814\,3\,\text{u}) \\ &\quad + (0.2380 \times 143.910\,087\,3\,\text{u}) + (0.0829 \times 144.912\,573\,6\,\text{u}) \\ &\quad + (0.1719 \times 145.913\,116\,9\,\text{u}) + (0.0576 \times 147.916\,893\,\text{u}) \\ &\quad + (0.0564 \times 149.920\,891\,\text{u}) \\ &= 144.242\,\text{u}\end{aligned}$$

Is our answer reasonable?

The lightest isotope has a mass of roughly 142 u, while that of the heaviest is around 150 u. Taking an unweighted average of these would give an answer of 146 u. However, given that the 3 lightest isotopes of Nd make up more than 60% of the total isotopic abundance, we would expect the weighted average to be somewhat less than 146 u. Our calculated average atomic mass, 144.242 u, is consistent with this. Hence, we can feel confident our answer is correct.

PRACTICE EXERCISE 1.3

Neon has three naturally occurring isotopes. ^{20}Ne has a mass of 19.9924 u and is 90.48% abundant, ^{21}Ne has a mass of 20.9938 u and is 0.27% abundant, and ^{22}Ne

has a mass of 21.9914 u and is 9.25% abundant. Using these data, calculate the average atomic mass of neon.

CHEMICAL CONNECTIONS

Ulcers, isotopes and the Nobel Prize

The 2005 Nobel Prize for physiology or medicine was awarded to two Australian doctors, Robin Warren and Barry Marshall, for 'their discovery of the bacterium *Helicobacter pylori* (figure 1.15) and its role in gastritis and peptic ulcer disease'. In the 1980s, they were the first to show that infection by a bacterium was the cause of duodenal and gastric ulcers, rather than the prevailing belief at the time that stress and lifestyle were responsible. This discovery allowed what was previously a widespread chronic, painful and debilitating condition to be easily treated with antibiotics.

FIGURE 1.15

A diagram of the main features of the *Helicobacter pylori* bacterium

Dr Marshall carried out a famous experiment on himself, in which he drank a brew containing *Helicobacter pylori* and became very ill with damage to his stomach, which he then treated successfully with antibiotics, thus supporting his hypothesis that the bacterium was the cause. He also developed an elegantly simple test, based on isotopic labelling, for the presence of the *Helicobacter pylori* bacterium in the stomach.

The isotopic labelling test is enabled by the fact that carbon has three naturally occurring isotopes: the stable isotopes ^{12}C (~99% abundant) and ^{13}C (~1% abundant), and the radioactive isotope ^{14}C (trace amounts). Enriching the amount of either ^{13}C or ^{14}C in a carbon-containing molecule allows the molecule, or its reaction products, to be traced because the isotopic distribution will be different to that found naturally.

The *Helicobacter pylori* bacterium produces an enzyme called urease which converts a molecule of urea, $\text{CO}(\text{NH}_2)_2$, to carbon dioxide, CO_2 , and ammonia, NH_3 , according to the following equation.

The test for *Helicobacter pylori* involves the patient swallowing a sample of urea in which the carbon atom has been labelled with either ^{13}C or ^{14}C . After a few minutes, a sample of the patient's breath is taken, which is then analysed for elevated levels of $^{13}\text{CO}_2$ or $^{14}\text{CO}_2$. As an elevated level in the breath sample can only have originated from the labelled urea, a positive test confirms the presence of urease, and therefore *Helicobacter pylori*, in the stomach. Antibiotics can then be prescribed.

This example shows that, even if you're not studying to be a chemist, knowledge of chemistry is vitally important in other fields of science.

1.4 The periodic table of the elements

LEARNING OBJECTIVE 1.4 Explain the basis of the periodic table of the elements.

We have already seen that the elements H, He and Li can be ordered on the basis of increasing atomic number ($Z = 1, 2$ and 3 , respectively). If we continue such an ordering, we obtain the **periodic table of the elements**. The periodic table we use today is based primarily on the efforts of a Russian chemist, Dmitri Ivanovich Mendeleev (1834–1907, pictured in figure 1.16), and a German physicist, Julius Lothar Meyer (1830–1895). Working independently, these scientists developed similar periodic tables only a few months apart in 1869. Mendeleev is usually given the credit, however, because he published his version first.

The extraordinary thing about the work of Mendeleev and Meyer was that they knew nothing of the structure of the atom, so were unaware of the concept of atomic number, which is the basis of the modern periodic table. What they did know, however, were the atomic masses of many of the elements. Bear in mind also that not all of the elements we know today had been discovered at this time. Mendeleev was preparing a chemistry textbook for his students at the University of St Petersburg and, looking for some pattern among the properties of the elements, he found that, when he arranged them in order of increasing atomic mass, similar chemical properties were repeated over and over at regular intervals. For instance, the elements lithium (Li), sodium (Na), potassium (K), rubidium (Rb) and caesium (Cs), are soft metals that react vigorously with water. Similarly, the elements that immediately follow each of these also constitute a set with similar chemical properties. Thus, beryllium (Be), follows lithium; magnesium (Mg), follows sodium; calcium (Ca), follows potassium; strontium (Sr), follows rubidium; and barium (Ba), follows caesium. All of these elements form compounds with oxygen having a 1 : 1 metal to oxygen ratio. Mendeleev used such observations to construct his periodic table, which is illustrated in figure 1.17.

FIGURE 1.16

Dmitri Ivanovich Mendeleev, the developer of the periodic table

FIGURE 1.17

Mendeleev's original periodic table, taken from the German chemistry journal *Zeitschrift für Chemie*, 1869, volume 12, pages 405–6

Ueber die Beziehungen der Eigenschaften zu den Atomgewichten der Elemente. Von D. Mendelejeff. – Ordnet man Elemente nach zunehmenden Atomgewichten in verticale Reihen so, dass die Horizontalreihen analoge Elemente enthalten, wieder nach zunehmendem Atomgewicht geordnet, so erhält man folgende Zusammenstellung, aus der sich einige allgemeinere Folgerungen ableiten lassen.

			Ti = 50	Zr = 90	? = 180
			V = 51	Nb = 94	Ta = 182
			Cr = 52	Mo = 96	W = 186
			Mn = 55	Rh = 104,4	Pt = 197,4
			Fe = 56	Ru = 104,4	Ir = 198
		Ni = Co = 59	Pd = 106,6	Os = 199	
H = 1			Cu = 63,4	Ag = 108	Hg = 200
	Be = 9,4	Mg = 24	Zn = 65,2	Cd = 112	
	B = 11	Al = 27,4	? = 68	Ur = 116	Au = 197?
	C = 12	Si = 28	? = 70	Sn = 118	
	N = 14	P = 31	As = 75	Sb = 122	Bi = 210?
	O = 16	S = 32	Se = 79,4	Te = 128?	
	F = 19	Cl = 35,5	Br = 80	I = 127	
Li = 7	Na = 23	K = 39	Rb = 85,4	Cs = 133	Tl = 204
		Ca = 40	Sr = 87,6	Ba = 137	Pb = 207
		? = 45	Ce = 92		
		?Er = 56	La = 94		
		?Yt = 60	Di = 95		
		?In = 75,6	Th = 118?		

At first glance, Mendeleev's original table looks little like the 'modern' table given in figure 1.18. However, a closer look reveals that the rows and columns have been interchanged. The elements in Mendeleev's table are arranged in order of increasing atomic mass. When the sequence is broken at the right places and stacked, the elements fall naturally into columns.

Mendeleev placed elements with similar properties in the same row even when this left occasional gaps in the table. For example, he placed arsenic, As, in the same row as phosphorus because they had similar chemical properties, even though this left gaps in other rows. In a stroke of genius, Mendeleev reasoned, correctly, that the elements that belonged in these gaps had simply not yet been discovered. In fact, on the basis of the location of these gaps, Mendeleev could predict, with astonishing accuracy, the properties of the yet-to-be-found elements, and his predictions helped serve as a guide in the search for them.

The elements tellurium, Te, and iodine, I (note that the German word for 'iodine' is *jod*, which has the abbreviation J in Mendeleev's original table), caused Mendeleev some problems. According to the best estimates at that time, the atomic mass of tellurium was greater than that of iodine. Yet, if these elements were placed in the table according to their atomic masses, they would not fall into the proper rows required by their properties. Therefore, Mendeleev switched their order, believing that the atomic mass of tellurium had been incorrectly measured (it had not), and in so doing violated his ordering sequence based on atomic mass.

The table that Mendeleev developed is the basis of the one we use today, but one of the main differences is that Mendeleev's table lacks the elements helium (He), neon (Ne), argon (Ar), krypton (Kr), xenon (Xe) and radon (Rn). In Mendeleev's time, none of these elements had yet been discovered because they are relatively rare and because they have virtually no tendency to undergo chemical reactions. When these elements were finally discovered, beginning in 1894, another problem arose. Two more elements, argon, Ar, and potassium, K, did not fall into the rows required by their properties if they were placed in the table in the order required by their atomic masses. Another switch was necessary and another exception had been found. It became apparent that atomic mass was not the true basis for the periodic repetition of the properties of the elements. With Rutherford's discovery of the structure of the atom, it became apparent

that the elements in the periodic table were arranged in order of increasing atomic *number*, not atomic *mass*, and when this was realised it became obvious that Te and I, and Ar and K, were in fact in the correct positions.

The modern periodic table

The periodic table in use today is shown in figure 1.18. The horizontal rows are called **periods** and are numbered 1 to 7, while the vertical columns are called **groups** and are numbered 1 to 18. The elements are arranged in order of increasing atomic number across each period, and a new period begins after each group 18 element. On the periodic table, the atomic masses are given (generally to four significant figures) below each chemical symbol.

FIGURE 1.18

The periodic table of the elements. At the time of writing, 118 elements are known. Atomic masses in parentheses refer to the longest lived isotope of the element. The elements outlined in table 1.3, which have a range of atomic masses, have square brackets around their conventional atomic masses in the periodic table.

While the atomic mass usually increases with atomic number, you can see the exceptions we mentioned previously (Te and I; Ar and K) as well as Co and Ni. While the isotopic composition and, therefore, the atomic masses of most elements are well established, there are some unstable elements of which all the isotopes undergo spontaneous radioactive decay. Given that the isotopic composition of such elements cannot therefore be known, it is usual to simply quote the mass number of the longest lived isotope of the element, and these are given in parentheses in the periodic table. Note that there are discontinuities in the periodic table between elements 56 and 72, and between elements 88 and 104, and these two sets of elements are given below the table itself. The elements from 57 to 71 are called the **lanthanoids** (or, less commonly, the **rare earth elements**). Elements 89 to 103 are called the **actinoids**. The lanthanoids and actinoids are generally situated below the rest of the periodic table, simply to save space and to make the table easier to read; you can see a version of the table in which all the elements, including the lanthanoids and actinoids, are ordered according to atomic number in figure 4.38. Note that the lanthanoid and actinoid

elements are chemically distinct from the rest of the elements in the periodic table, and do not belong to any of the groups 1 to 18. The lanthanoids and actinoids are sometimes called the **f-block elements**, and similar terminology is also used elsewhere in the table; elements in groups 1 and 2 are called the **s-block elements**, elements in groups 3 to 12 are called the **d-block elements**, and elements in groups 13 to 18 are called the **p-block elements**. As we will see, *s*, *p*, *d* and *f* refer to orbitals, particular regions in space in the atom where electrons have a high probability of being found. The *d*-block elements are also called **transition metals**.

Individual groups within the periodic table are also known by particular names, although this practice is less prevalent than in the past. Group 1 elements are called **alkali metals**, group 2 elements are called **alkaline earth metals**, group 15 elements are called **pnictogens**, group 16 elements are called **chalcogens**, group 17 elements are called **halogens** and group 18 elements are called **noble gases**. Of these, only the terms halogens and noble gases are in common usage.

All elements on the periodic table belong to one of three categories — metals, nonmetals and metalloids — and the groupings are shown by the different colours on the periodic table in figure 1.18. **Metals** are generally good conductors of heat and electricity, are malleable (can be beaten into a thin sheet) and ductile (can be drawn out into a wire), and have the usual metallic lustre. Elements that do not have these characteristics are called **nonmetals**, and the majority of these are gases at room temperature and pressure. The properties of **metalloids** lie somewhere between the metals and nonmetals. The most notable property of these elements is the fact that they tend to be semiconductors, and metalloids such as silicon, Si, and germanium, Ge, have therefore found wide use in silicon chips and transistors. Note that the classification of the recently prepared elements Lv, Ts and Og is somewhat arbitrary, as weighable quantities of these have not yet been obtained.

Naming the elements

All of the elements in the periodic table have one- or two-letter abbreviations of their names. The abbreviations of many elements are simply the first one or two letters of their names (e.g. carbon, C; oxygen, O; lithium, Li) but there are quite a number of elements for which the derivation of the abbreviation is not quite so obvious: for example, potassium, K, tin, Sn, lead, Pb, and iron, Fe. Such apparent anomalies occur because of the way that the elements were historically named. Nowadays, when a new element is discovered, the discoverer usually gets to suggest a name for the element, which is then ratified by IUPAC, the International Union of Pure and Applied Chemistry.

Of all the elements on the periodic table, carbon (C), sulfur (S), iron (Fe), copper (Cu), arsenic (As), silver (Ag), tin (Sn), antimony (Sb), gold (Au), mercury (Hg), lead (Pb) and bismuth (Bi) were known to ancient civilisations so the date of their ‘discovery’ is not known. Of these, the element symbols Fe, Cu, Ag, Sn, Sb, Au, Hg and Pb were derived from the Latin names *ferrum*, *cuprum*, *argentum*, *stannum*, *stibium*, *aurum*, *hydrargyrum* and *plumbum*. The earliest known discovery of an element was that of phosphorus, P. It was isolated in 1669 by the German alchemist Hennig Brand from the distillation of about 5000 L of urine (he was apparently trying to make silver or gold — unsuccessfully, of course!) and was named after the Greek word *phosphoros*, meaning ‘bringer of light’, as the element glows in the dark (see figure 1.19). Elements have been named after countries (germanium, Ge, francium, Fr, americium, Am, polonium, Po) and even after the places they were first discovered; the Swedish town of Ytterby has the distinction of having four elements (erbium, Er, ytterbium, Yb, yttrium, Y, and terbium, Tb) named after it, as these were first found in mineral deposits close to the town. Surprisingly few elements have been named after people; at present, only 17 people have been immortalised on the periodic table, and they are listed in table 1.4.

FIGURE 1.19

Phosphorus, the first element whose date of discovery is known, was isolated in 1669 by alchemist Hennig Brand as he tried to make silver or gold by distilling urine.

TABLE 1.4 People after whom elements have been named

Name	Brief biography	Element named
Vasilii Yefrafovich von Samarski-Bykhovets (1803–1870)	Chief of staff of the Russian Corps of Mining Engineers	samarium, Sm (element 62)
Johan Gadolin (1760–1852)	Finnish chemist; first person to isolate a lanthanoid element	gadolinium, Gd (element 64)
Pierre Curie (1859–1906) Marie Curie (1867–1934)	Husband and wife scientific team; Pierre (French) and Marie (Polish by birth); jointly awarded the Nobel Prize in physics in 1903. Marie Skłodowska-Curie received her second Nobel Prize in 1911, this time in chemistry for her work in radioactivity.	curium, Cm (element 96)
Albert Einstein (1879–1955)	Most famous scientist of the twentieth century, if not all time; German by birth; awarded the Nobel Prize in physics in 1921	einsteinium, Es (element 99)
Enrico Fermi (1901–1954)	Italian physicist; made great advances in the study of nuclear reactions; awarded the Nobel Prize in physics in 1938	fermium, Fm (element 100)
Dmitri Mendeleev (1834–1907)	Russian chemist; renowned for the development of the periodic table	mendelevium, Md (element 101)
Alfred Nobel (1833–1896)	Swedish inventor of dynamite and patron of the Nobel Prizes	nobelium, No (element 102)
Ernest Lawrence (1901–1958)	American inventor of the cyclotron; awarded the Nobel Prize in physics in 1939	lawrencium, Lr (element 103)
Ernest Rutherford (1871–1937)	New Zealand physicist/chemist; made seminal contributions to understanding the structure of the atom; awarded the Nobel Prize in chemistry in 1908	rutherfordium, Rf (element 104)
Glenn Seaborg (1912–1999)	American chemist; first prepared many of the elements beyond uranium in the periodic table; awarded the Nobel Prize in chemistry in 1951	seaborgium, Sg (element 106)
Niels Bohr (1885–1962)	Danish physicist; studied electronic energy levels within atoms, which aided our understanding of the atom; awarded the Nobel Prize in physics in 1922	bohrium, Bh (element 107)
Lise Meitner (1878–1968)	Austrian physicist; made fundamental discoveries concerning nuclear fission; controversially never awarded a Nobel Prize	meitnerium, Mt (element 109)
Wilhelm Röntgen (1845–1923)	German physicist; discoverer of X-rays; awarded the inaugural Nobel Prize in physics in 1901	röntgenium, Rg (element 111)
Nicolaus Copernicus (1473–1543)	Polish astronomer; proposed that the sun, rather than the Earth, was the centre of the solar system	copernicium, Cn (element 112)
Georgii Flerov (1913–1990)	Russian physicist; made significant discoveries in the syntheses of elements beyond uranium	flerovium, Fl (element 114)
Yuri Oganessian (1933–)	Russian physicist; has made important advances in the syntheses of superheavy elements	oganesson, Og (element 118)

1.5 Electrons in atoms

LEARNING OBJECTIVE 1.5 Detail the role of electrons in atoms.

While we have touched briefly on the concept of electrons, we have to this point concentrated primarily on the nucleus of the atom and the way in which the number of protons in the nucleus determines the chemical identity of the atom. However, many of the chemical properties of an atom and, most importantly, its chemical reactivity are determined primarily by the electrons.

One of the most interesting things about electrons is that we cannot really say *exactly* where they are at any particular time, so we usually talk about their *most probable* locations. Electrons occupy regions of space called **orbitals** in atoms. Each orbital has a characteristic electron distribution and energy. For example, the lowest energy state of a hydrogen atom, the **ground state**, occurs when the single electron occupies an orbital in which its most probable distance from the nucleus is 5.29×10^{-11} m. If we were to take snapshots of the position of the electron in this orbital over time, we would find a spherical distribution. If the ground-state hydrogen atom absorbs a specific amount of energy, the electron can be promoted to a higher energy orbital to form an **excited state** in which the electron lies, on average, further from the nucleus. Such a process is called an **electronic transition**, and the electron distribution in the higher energy orbital is dumbbell shaped. Similarly, the electron in an excited-state hydrogen atom can move to a lower energy orbital through the emission of energy, often in the form of light. Indeed, as we shall see in the chapter on atomic energy levels, such processes are the basis behind both neon and sodium vapour lights. Orbitals have definite energies, so the energy of any electron is dictated by the energy of the orbital it occupies; therefore, an electron in an atom can have only certain well-defined energies. This is a fundamental principle of the science of quantum mechanics called **quantisation**, a phenomenon first proposed by the German physicist Max Planck (1858–1947; Nobel Prize in physics, 1918) in 1900. We will learn more about the quantisation of energy in the chapter on atomic energy levels.

Electrons have a single negative charge, and the overall charge on any chemical species is determined by the number of electrons relative to the number of protons; for example, the oxide ion, O^{2-} , has a 2– charge because there are two more electrons (10) than protons (8) in the ion. Similarly, the Li^+ ion contains three protons and two electrons, so it has a single positive charge. In addition to their negative charge, all electrons have an intrinsic property called **spin**. This can have one of two values, which are commonly called ‘spin up’ and ‘spin down’ and are often depicted as follows.

$\uparrow$ (spin up)
 $\downarrow$ (spin down)

Each orbital within an atom can contain a maximum of two electrons, one of which must be spin up and the other spin down.

Chemists are interested in electrons because they constitute the chemical bonds that hold atoms together in molecules. Covalent chemical bonds usually consist of one, two or three pairs of electrons shared between atoms, each pair containing electrons of opposite spin. For a molecule to undergo a chemical reaction, usually these bonds must be broken and new ones made; this requires a reorganisation of the electron pairs between the reactant and product molecules, and the ease with which this can be done determines how fast the reaction occurs. Reactions in which one or more electrons are formally transferred between chemical species are also known; such reactions, known as **redox reactions**, are important in a huge number of chemical and biochemical processes; in fact, as you are reading this, iron ions and oxygen molecules are busy exchanging electrons in your blood to transport oxygen around your body.

Because of their importance in both chemical structure and chemical reactivity, electrons occupy a central place in chemistry. In the remaining chapters of this text, we will learn more of the properties of atoms and molecules that are predominantly dictated by electrons.

We have learned much about the atom in the years since Rutherford’s seminal experiment. Indeed, so far we have detailed only the very basics of atomic structure; later chapters will outline some of the amazing complexity of the atom. For the moment, it is sufficient for you to appreciate that the atom is composed of a positively charged central nucleus containing protons and neutrons, which is surrounded by negatively charged electrons that can undergo transitions only between well-defined energy levels. And with only 118 different types of these building blocks, we can construct the universe.

SUMMARY

1.1 Define atoms, molecules, ions, elements and compounds.

Atoms are the fundamental building blocks of all matter. Uncharged collections of atoms bonded together in a definite structure are called molecules. These are held together by covalent bonds that share electrons between adjacent atoms. Ions are charged chemical species that may be derived from both atoms and molecules. Cations are positively charged, while anions are negatively charged. Elements comprise only a single type of atom, while compounds are made up of two or more chemical elements. All of these different chemical entities can be involved as reactants in chemical reactions, in which they are transformed to products.

1.2 Explain how the concept of atoms developed.

All matter is composed of atoms. The existence of atoms was proposed on the basis of the following.

- The law of conservation of mass — mass is conserved in chemical reactions.
- The law of definite proportions — elements are combined in the same proportions by mass in any particular compound.
- The law of multiple proportions — when two elements can combine to form more than one compound, the different masses of one element that combine with the same mass of the other element are in the ratio of small whole numbers.

Dalton's atomic theory was the first to propose the existence of atoms on the basis of scientific observations. The basic tenets of his theory are as follows.

1. Matter consists of tiny particles called atoms.
2. Atoms are indestructible. In chemical reactions, the atoms rearrange but they do not themselves break apart.
3. In any sample of a pure element, all the atoms are identical in mass and other properties.
4. The atoms of different elements differ in mass and other properties.
5. When atoms of different elements combine to form a given compound, the constituent atoms in the compound are always present in the same fixed numerical ratio.

Dalton's theory allows us to use chemical equations, in which reactants and products are separated by a forward arrow, to describe chemical reactions. Such equations are balanced when they contain the same number of each type of atom on each side of the arrow.

1.3 Describe the structure of the atom.

Although Dalton proposed the atom to be indivisible, experiments in the late nineteenth century showed this was not the case. The negatively charged electron was the first subatomic particle to be discovered, while Rutherford's gold foil experiment, in which a thin gold sheet was bombarded with alpha particles, gave evidence for a small, positively charged nucleus. The positive charge is due to subatomic particles called protons, and the number of these in the nucleus determines the identity of the atom in question. The third component of the atom, the neutron, was predicted by Rutherford and found by Chadwick. The atom

thus comprises three subatomic particles, the electron, proton and neutron, the latter two collectively being called nucleons. Each type of atom is designated by a chemical symbol, which is determined by its atomic number (Z), the number of protons in the nucleus. The mass number (A) is equal to the number of protons plus the number of neutrons in the nucleus. The terminology used to depict an atom of any element X is A_ZX . All atoms with the same Z are of the same element; however, atoms of the same element can differ in the number of neutrons in the nucleus, and this gives rise to isotopes. Isotopes can be either radioactive (i.e. they decay spontaneously) or stable. A radioactive nucleus is called a radionuclide, while a nuclide is the name given to any atomic nucleus. We can measure atomic mass in atomic mass units (u), where 1 u is equal to $\frac{1}{12}$ of the mass of one atom of ${}^{12}\text{C}$; that is, $1\text{ u} = 1.660\,539\,066\,60 \times 10^{-27}\text{ kg}$. The atomic mass of any element is the weighted average of the masses of the isotopes of the element.

1.4 Explain the basis of the periodic table of the elements.

The periodic table of the elements contains the 118 known elements arranged in order of increasing atomic number, and was developed by both Mendeleev and Meyer. The horizontal rows are called *periods* and the vertical columns *groups*. Elements in the same group tend to have similar chemical properties. The periodic table is divided into sections according to the electron configuration of the elements, namely the *s*-block elements, the *p*-block elements, the *d*-block elements and the *f*-block elements. The *f*-block elements are divided into the lanthanoids (also sometimes called the rare earth elements) and the actinoids, while the *d*-block elements are also called the transition metals. The elements of the periodic table can be classified as metals, nonmetals or metalloids.

1.5 Detail the role of electrons in atoms.

Electrons occupy regions of space called orbitals. The lowest energy arrangement of electrons in the orbitals of an atom is called the ground state. Electrons can be promoted to higher energy orbitals by absorption of energy to give excited states; conversely, electrons in higher energy orbitals can move to lower energy orbitals with the emission of energy, often as light. Such processes are called electronic transitions. The energies of electrons in atoms are determined by the energies of the orbitals within the atom, so electrons in atoms can have only certain well-defined energies. This is called quantisation, a fundamental principle of quantum mechanics. Electrons have a single negative charge, and one of two possible spins. An orbital in an atom can hold a maximum of two electrons, which must be of opposite spin. Covalent bonds comprise one, two or three pairs of electrons. Chemical reactions often involve reorganising these electrons in bond-making and bond-breaking processes. Redox reactions involve the transfer of one or more electrons between chemical species.

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation
The law of conservation of mass	1.2	The total mass of reactants present before a reaction starts equals the total mass of products after the reaction is finished. We can use this law to check whether we have accounted for all the substances formed in a reaction.
The law of definite proportions	1.2	If we know the mass ratio of the elements in one sample of a compound, the ratio will be the same in a different sample of the same compound.
The law of multiple proportions	1.2	When two elements can combine to form more than one compound, the different masses of one element that combine with the same mass of the other element are in a ratio of small whole numbers.
Atomic mass	1.3	The average mass per atom of a naturally occurring sample of atoms of the element. This is measured relative to $\frac{1}{12}$ the mass of the ^{12}C isotope ($1.660\,539\,066\,60 \times 10^{-27}$ kg).
Periodic table of the elements	1.4	This is a table of the chemical elements arranged in order of increasing atomic number. We can use the periodic table to figure out whether a particular element is a metal, nonmetal or metalloid, predict its chemical reactivity, determine its number of protons and electrons, obtain its atomic mass and so on. In fact, all of chemistry is contained within the periodic table.

KEY TERMS

actinoids Elements 89 to 103 of the periodic table.

alkali metals The elements in group 1 (except hydrogen) of the periodic table.

alkaline earth metals The elements in group 2 of the periodic table.

alpha particle The nucleus of a helium atom (^4_2He).

anion A negatively charged ion.

atom A neutral particle having one nucleus; the smallest representative sample of an element.

atomic mass The average mass (in u) of the atoms of the isotopes of a given element as they occur naturally.

atomic mass unit (u) The mass equal to $\frac{1}{12}$ of the mass of one atom of ^{12}C . $1\text{ u} = 1.660\,539\,066\,60 \times 10^{-27}$ kg.

atomic number (Z) The number of protons in a nucleus.

cation A positively charged ion.

chalcogens The elements in group 16 of the periodic table.

chemical equation A form of notation used to describe chemical reactions, in which the reactants and products of the reaction are separated by a forward arrow, with the reactants appearing on the left-hand side.

chemical formula A formula written using chemical symbols and subscripts that describes the composition of a chemical compound or element.

chemical reaction A process involving transformation of chemical species into different chemical species, usually involving the making and/or breaking of chemical bonds.

chemical symbol A one- or two-letter symbol for an element.

compound A chemical substance containing two or more elements in a definite and unchanging proportion.

covalent bond A chemical bond in which two atoms share one or more pairs of electrons.

d-block elements Collective name for the elements in groups 3 to 12 of the periodic table.

Dalton's atomic theory Matter consists of tiny, indestructible particles called atoms and all atoms of one element are identical. The atoms of different elements have different masses. Atoms combine in definite ratios of atoms when they form compounds.

electron A subatomic particle (e , ${}_{-1}^0e$), with a charge of -1 and mass of 5.4858×10^{-4} u (9.1094×10^{-31} kg), that is outside an atomic nucleus; the particle that moves when an electric current flows.

electronic transition The movement of electrons between different energy states.

element A chemical species consisting of atoms of a single type.

excited state Any state in which a chemical system is not in its lowest possible energy state.

f-block elements A collective name for the lanthanoid and actinoid elements.

ground state The lowest possible energy state of a chemical system.

group A vertical column of elements in the periodic table.

halogens The elements in group 17 of the periodic table.

ion A charged chemical species.

isotopes Atoms of the same element having different numbers of neutrons in their nuclei.

lanthanoids Elements 57 to 71 of the periodic table.

law of conservation of mass No detectable gain or loss in mass occurs in chemical reactions. Mass is conserved.

law of definite proportions In a given chemical compound, the constituent elements are always combined in the same proportion by mass.

law of multiple proportions Whenever two elements can combine to form more than one compound, the different masses of one element that combine with the same mass of the other are in a ratio of small whole numbers.

mass number (A) The numerical sum of the protons and neutrons in an atom of a given isotope.

matter Anything that has mass and occupies space.

metalloids Elements with properties that lie between those of metals and nonmetals, and that are found in the periodic table around the diagonal line running from boron, B, to astatine, At.

metals Elements that are good conductors of heat and electricity, are malleable (can be beaten into a thin sheet) and ductile (can be drawn out into a wire), and have the usual metallic lustre.

molecule An uncharged collection of atoms bonded together in a definite structure.

neutron A subatomic particle (n , ${}_0^1n$), with a charge of 0 and a mass of 1.0086 u ($1.6749 \times 10^{-27}\text{ kg}$), that exists in all atomic nuclei except those of the ${}^1\text{H}$ isotope.

noble gases The elements in group 18 of the periodic table.

nonmetals Nonductile, nonmalleable, nonconducting elements.

nucleon A proton or a neutron.

nucleus The dense core of an atom that comprises protons and, for every atom except ${}^1_1\text{H}$, neutrons.

nuclide A particular atom of specified atomic number and mass number.

orbital A three-dimensional wave describing a bound electron.

p-block elements A collective name for the elements in groups 13 to 18 of the periodic table.

period A horizontal row of elements in the periodic table.

periodic table of the elements A table in which symbols for the elements are displayed in order of increasing atomic number and arranged so that elements with similar properties lie in the same column.

pnictogens The elements in group 15 of the periodic table.

product The chemical species obtained as the result of a chemical reaction.

proton A subatomic particle (${}_1^1p$), with a charge of +1 and a mass of 1.0073 u ($1.6726 \times 10^{-27}\text{ kg}$), that is found in atomic nuclei.

quantisation A phenomenon whereby the energy of a chemical system is not continuous but is restricted to certain definite values.

radioactive Able to emit various atomic radiations or gamma rays.

radionuclide A radioactive isotope.

rare earth elements An alternative name for the lanthanoid elements.

reactant A chemical species that is transformed in a chemical reaction.

redox reaction A reaction involving the transfer of one or more electrons between chemical species.

s-block elements A collective name for the elements in groups 1 and 2 of the periodic table.

spin The intrinsic angular momentum of electrons and protons.

stable isotopes Isotopes that do not undergo any decay processes.

subatomic particles Electrons, protons and neutrons.

transition metals The elements in groups 3 to 12 of the periodic table.

REVIEW QUESTIONS

The essential concepts in brief

L01

- 1.1 Define the following terms: matter, atom, covalent bond, ion, cation, anion, element, compound, chemical formula, reactant, chemical reaction, product.

The atomic theory

L02

- 1.2 Name and state the three laws of chemical combination discussed in this chapter.
- 1.3 Balanced chemical equations have the same number of atoms of each type on either side of the arrow. Which of the three laws discussed in this chapter require this to be the case, and why?
- 1.4 Why was it important that Lavoisier's experiments into the chemical reactions of elements with oxygen were carried out in a closed jar?
- 1.5 How did Dalton's theory explain the law of conservation of mass?

The structure of the atom

L03

- 1.6 How did the discovery of X-rays and radioactivity support the idea that atoms were not indivisible, but were composed of discrete particles?
- 1.7 Why did most of the alpha particles in Rutherford's gold foil experiment pass straight through the foil undeflected? Name the force that resulted in the deflection of some of the alpha particles.
- 1.8 Which component particles contribute most to the mass of an atom? Where in an atom are these particles situated?
- 1.9 When we calculate the mass of an atom, we generally neglect any contribution to this from electrons in the atom. Why is this?
- 1.10 Define the term 'nucleon'.
- 1.11 What is an isotope? Why do isotopes of an element exhibit similar chemical behaviour?
- 1.12 Consider the symbol ${}_Z^AX$, where X stands for the chemical symbol for an element. What information is given by (a) A and (b) Z ?

- 1.13 Write the symbols (mass number, atomic number and chemical symbol) of the following isotopes. (Consult a table of atomic numbers or a periodic table, as needed.)

- (a) an isotope of gold which contains 118 neutrons
(b) an isotope of fluorine which contains 9 neutrons
(c) an isotope of neodymium which contains 83 neutrons
(d) an isotope of osmium which contains 108 neutrons

The periodic table of the elements

L04

- 1.14 What is the chemical symbol for each of the following elements?

- (a) potassium
(b) sodium
(c) arsenic
(d) yttrium
(e) tin
(f) antimony
(g) tungsten
(h) gold
(i) mercury
(j) lead

- 1.15 What is the name of each of the following elements?

- (a) Be
(b) Ru
(c) Pu
(d) Tc
(e) V
(f) Po
(g) Ge
(h) Es
(i) Rf
(j) Ag

- 1.16 On what basis did Mendeleev construct his periodic table? On what basis are the elements arranged in the modern periodic table?

- 1.17** The element francium, Fr, is one of the rarest elements that occurs naturally on Earth. It is formed by radioactive decay of heavier elements and there is thought to be only 20–30 g of francium present on Earth at any one time. From its position in the periodic table, would you expect this element to undergo a vigorous reaction with water? Outline your reasoning.
- 1.18** Why did Mendeleev leave gaps in his periodic table?
- 1.19** Among the first 92 elements, there are four sets of elemental neighbours (Ar and K; Co and Ni; Te and I; Th and Pa) in which the element with the greater (average) atomic mass has the smaller atomic number. Given that the atomic number reflects the number of protons in the nucleus, discuss how this anomaly can occur.
- 1.20** On the basis of their positions in the periodic table, why is it not surprising that ^{90}Sr , a dangerous radioactive isotope of strontium, replaces calcium in newly formed bones?
- 1.21** When nickel-containing ores are refined, commercial amounts of palladium and platinum are also often obtained. Why is this not unexpected?
- 1.22** Why would you reasonably expect cadmium to be a contaminant in zinc but not in silver?
- 1.23** All of the elements with atomic numbers greater than 92 have been prepared by humans and do not, with the exception of minute amounts of Np and Pu, occur naturally. Explain why it is very unlikely that a completely new element with an atomic number of less than 92 will ever be discovered.
- 1.24** In each of the following sets of elements, state which fits the description in parentheses.
- Sm, Cu, Nb, Ba, Ga (*s*-block element)
 - Bi, Mt, Co, Mg, H (*p*-block element)
 - At, P, Zr, Ca, Se (transition metal)
 - Rg, S, Sc, Eu, Al (lanthanoid element)
 - Yb, Cr, Au, Np, Cl (actinoid element)
- 1.25** Calculations show that a rod of platinum 10 cm long and 1 cm in diameter can theoretically be drawn out into a wire nearly 28 000 km long. What is this property of metals called?
- 1.26** Gold can be hammered into sheets so thin that some light can pass through them. Which property of gold allows such thin sheets to be made?
- 1.27** Name the elements that exist as diatomic gases (gases that exist as molecules containing two atoms) at 25 °C (room temperature) and 1.013×10^5 Pa (atmospheric pressure).
- 1.28** Which two elements exist as liquids at room temperature and atmospheric pressure?
- 1.29** Weighable amounts of the very heavy elements, with atomic numbers greater than 112, have not yet been prepared, and so their bulk physical properties are as yet unknown. Which element, Fl (element 114) or Lv (element 116), would be more likely to exhibit properties of a metalloid?
- 1.30** Sketch the shape of the periodic table and mark off those areas where we find each of the following.
- metals
 - nonmetals
 - metalloids

Electrons in atoms

L05

- 1.31** What is the name given to the most probable region of space in which an electron might be found?
- 1.32** When electrons of opposite spin occupy an orbital, we say that their spins are paired. Molecules with odd numbers of electrons, therefore, cannot have all of the electron spins paired, and we say that they have unpaired spins. Which of the following molecules *must* have unpaired spins: N_2 , F_2 , CO , NO , NO_2 ?
- 1.33** An atom in an excited state has a higher energy than the same atom in its ground state. Given that neon lights involve neon atoms in excited states, suggest a method by which the excited-state atoms might lose the excess energy they have.
- 1.34** Quantisation is very important on the atomic scale but, in the large scale of our everyday lives, we barely notice it. Why do you think this might be so?

REVIEW PROBLEMS

- 1.35** Methane is the simplest of a series of compounds collectively called the alkanes, which consist of only carbon and hydrogen and have the general chemical formula $\text{C}_n\text{H}_{2n+2}$. For every 1.000 g of C in a sample of methane, there is 0.336 g of hydrogen. Which of the following compositions corresponds to that of methane? **L02**
- 7.317 g carbon, 8.295 g hydrogen
 - 2.618 g carbon, 5.228 g hydrogen
 - 3.884 g carbon, 1.305 g hydrogen
 - 6.911 g carbon, 4.003 g hydrogen
 - 9.352 g carbon, 7.417 g hydrogen
- 1.36** The reaction of carbon with oxygen can give rise to both carbon monoxide, CO , and carbon dioxide, CO_2 , the former generally being formed under conditions where there is a limited supply of oxygen. Carbon monoxide can be formed from complete reaction of 1.000 g of carbon and 1.332 g of oxygen, while carbon dioxide requires 1.000 g of carbon and 2.664 g of oxygen. Which of the following compositions refer to CO , which refer to CO_2 , and which refer to neither? **L02**
- 2.650 g carbon, 3.530 g oxygen
 - 1.482 g carbon, 3.948 g oxygen
 - 3.167 g carbon, 5.701 g oxygen
 - 0.375 g carbon, 0.999 g oxygen
 - 4.713 g carbon, 6.278 g oxygen
- 1.37** Germanium tetrachloride is a dense liquid that is used in the production of fibre-optic cables. Any sample of germanium tetrachloride is composed of germanium and chlorine in the mass ratio of 1.00 : 1.95. If a sample of germanium tetrachloride contains 5.00 g of germanium, what mass of chlorine does it contain? **L02**
- 1.38** A compound of phosphorus and chlorine used in the manufacture of a flame-retardant treatment for fabrics contains 1.20 g of phosphorus for every 4.12 g of chlorine. Suppose a sample of this compound contains 6.22 g of chlorine. What mass of phosphorus does it contain? **L02**
- 1.39** With reference to problem 1.37, if 2.00 g of germanium combined completely with chlorine to form germanium tetrachloride, what mass of germanium tetrachloride would be formed? **L02**
- 1.40** Refer to the data about the phosphorus–chlorine compound in problem 1.38. If 12.5 g of phosphorus combined completely with chlorine to form this compound, what mass of the compound would be formed? **L02**
- 1.41** Reaction of arsenic with fluorine can result in the formation of two compounds containing only arsenic and fluorine. Molecules of one of these compounds contain one atom of As and three atoms of F, with the mass ratio of As to F being 1 : 0.761. Molecules of the second compound of arsenic and fluorine contain one atom of As and five atoms of F. What mass of fluorine would be combined with each 1.000 g of arsenic in this compound? **L02**

- 1.42** Tin forms two compounds with chlorine. In one of them (compound 1), there are two Cl atoms for each Sn atom; in the other (compound 2), there are four Cl atoms for each Sn atom. When combined with the same mass of tin, what would be the ratio of the masses of chlorine in the two compounds? In compound 1, 0.597 g of chlorine is combined with each 1.000 g of tin. What mass of chlorine would be combined with 1.000 g of tin in compound 2? **LO2**
- 1.43** The atomic mass unit is defined in terms of the mass of the ^{12}C atom. Given that 1 atomic mass unit corresponds to 1.66054×10^{-24} g, calculate the mass of 1 atom of ^{12}C in grams. **LO3**
- 1.44** Use the mass corresponding to the atomic mass unit given in problem 1.43 to calculate the mass of 1 atom of sulfur. **LO3**
- 1.45** One of the earliest anaesthetics — its first recorded use was in 1844 — was a compound called nitrous oxide, or, more commonly, laughing gas. Molecules of nitrous oxide are composed of two atoms of nitrogen and one atom of oxygen. In this compound, 1.7513 g of nitrogen is combined with 1.0000 g of O. If the atomic mass of O is 16.00 u, use the above information to calculate the atomic mass of the nitrogen. **LO3**
- 1.46** Element *X* forms a compound with oxygen in which there are two atoms of *X* for every three atoms of O. In this compound, 1.125 g of *X* is combined with 1.000 g of oxygen. Use the average atomic mass of oxygen to calculate the average atomic mass of *X*. Use your calculated atomic mass to identify element *X*. **LO3**
- 1.47** If an atom of ^{12}C had been assigned a relative mass of 24.0000 u, determine the average atomic mass of hydrogen relative to this mass. **LO3**
- 1.48** The radioactive ^{14}C isotope is used as the basis of radiocarbon dating. An atom of ^{14}C has a mass that is 1.166 94 times that of a ^{12}C atom. What is the atomic mass of this isotope of carbon expressed in atomic mass units? **LO3**
- 1.49** Antimony, Sb, has two stable isotopes. ^{121}Sb has a mass of 120.9038 u and an abundance of 57.36%, while ^{123}Sb has a mass of 122.9042 u and an abundance of 42.64%. Use these data to calculate the average atomic mass of antimony. **LO3**
- 1.50** When calculating the mass of a PCl_3 molecule, it would be usual to add the atomic mass of one P atom to three times the average atomic mass of chlorine. This would give an answer of 137.333 u. However, in precise work, it is important to use the actual atomic masses of all the elements in a molecule. With this in mind, given that phosphorus has a single stable isotope and chlorine has two, there will be four different possible masses of a PCl_3 molecule. Use the following data to calculate these four masses. ^{31}P has a mass of 30.973 u, ^{35}Cl has a mass of 34.969 u and ^{37}Cl has a mass of 36.966 u. **LO3**
- 1.51** Use the periodic table to determine the numbers of protons, electrons and neutrons present in the atoms of each of the following isotopes. **LO3,4**
- ^{103}Rh
 - ^{79}Br
 - ^{132}Ba
 - ^{257}Rf
- 1.52** From the elements Os, Ga, Xe, Rb, Tb, Ba, Bk and B, choose one that fits each of the following descriptions. **LO4**
- a metalloid
 - a lanthanoid
 - an actinoid
 - a transition metal
 - a group 1 metal
- 1.53** Write the names and chemical symbols for three examples of each of the following. **LO4**
- nonmetals
 - alkaline earth metals
 - lanthanoids
 - chalcogens

ADDITIONAL EXERCISES

- 1.54** An atom of an element has 25 protons in its nucleus. **LO2,3,4**
- Is the element a metal, a nonmetal or a metalloid?
 - On the basis of the average atomic mass, write the symbol for the element's most abundant isotope.
 - How many neutrons are in the isotope you described in (b)?
 - How many electrons are in an atom of this element?
 - How many times heavier than ^{12}C is the average atom of this element?
- 1.55** The elements *X* and *Y* form a compound having the formula XY_4 . When these elements react, it is found that 1.00 g of *X* combines with 0.684 g of *Y*. When 1.00 g of *X* combines with 0.154 g of O, it forms a compound containing two atoms of O for each atom of *X*. Use these data to calculate the atomic masses of *X* and *Y*, and therefore determine the identity of the compound XY_4 . **LO2,3**
- 1.56** An iron nail is composed of four isotopes with the percentage abundances and atomic masses given in the following table. Calculate the average atomic mass of iron.

Isotope	Percentage abundance	Atomic mass (u)
^{54}Fe	5.80	53.9396
^{56}Fe	91.72	55.9349
^{57}Fe	2.20	56.9354
^{58}Fe	0.28	57.9333

- 1.57** Manganese forms a number of compounds with oxygen. One of these contains two Mn atoms and three O atoms. This compound has a mass ratio of manganese to oxygen of 1.000 : 0.4370. Another compound containing only manganese and oxygen comprises these elements in the mass ratio of 1.000 : 1.019. What is the probable formula of the second manganese–oxygen compound? **LO2**
- 1.58** One atomic mass unit corresponds to a mass of 1.66054×10^{-24} g, and the atomic masses of cobalt, Co, and fluorine, F, are 58.933 194 u and 18.998 403 2 u, respectively. Use these data to calculate the mass, in grams, of one atom of cobalt and one atom of fluorine. Use these two answers to determine how many atoms of Co are in a 58.933 194 g sample of cobalt and how many atoms of F are in a 18.998 403 2 g sample of fluorine. Compare your answers. Without actually performing any calculations, how many atoms do you think would be in a 30.973 762 g sample of phosphorus? **LO3**
- 1.59** The diameter of a typical atom is of the order of 10^{-10} m, while the diameter of its nucleus is approximately 10^{-15} m. Use these data to calculate the volume of both an atom and its nucleus. Hence, determine what fraction of the volume of a typical atom is occupied by its nucleus. The volume (*V*) of a sphere is given by the formula $V = \frac{4}{3}\pi r^3$ where *r* is the radius. **LO3**
- 1.60** The atomic mass of the ^{12}C isotope is defined as exactly 12 u. Given that this isotope is used as the basis of the atomic mass unit, why do atomic masses not all have round number values? **LO2,3**

1.61 Given below are the formulae of various ions. How many electrons are present in each of these ions? **L01,3,4,5**

- (a) F^-
- (b) O_2^-
- (c) CO_3^{2-}
- (d) Na^+
- (e) PO_4^{3-}
- (f) ClO_4^-

1.62 We will see in later chapters that the elements in groups 16 and 17 of the periodic table often form negatively charged ions in which they have the same number of electrons as the closest group 18 element. Conversely, the elements in groups 1 and

2 of the periodic table often form positively charged ions in which they have the same number of electrons as the closest group 18 element. With this in mind, predict the formulae of the simplest ions formed by the following elements. **L01,4,5**

- (a) O
- (b) F
- (c) Li
- (d) Be
- (e) K
- (f) Br
- (g) I
- (h) Sr

The language of chemistry

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 2.1** use measurements and units in calculations
 - 2.2** represent substances and processes using common chemistry conventions
 - 2.3** apply basic chemical nomenclature.
-

Chemie. Matū. كيمياء. Chimie. χημεία. Kemi. 화학. Chimica. Química. Химия. วิชาเคมี. 化学. रसायन विज्ञान. রসায়ন. Kemia. Sunadarai.

Different languages, but the same word: Chemistry.

In the chapter on the atom, we included a brief outline of the meanings of some commonly used chemical terms. This was necessary because chemistry uses many words that are unfamiliar to those who haven't been trained in the subject. In fact, to some of you, this text probably appeared to be written in a foreign language, just like many of the above words, when you first looked at it, and this analogy is quite apt — chemistry does have a language all of its own, just like any specialist discipline, and this language must be learned in order to understand the subject. However, the language of chemistry is not limited to words; chemists also use diagrams, symbols, abbreviations, formulae, numbers, equations and pictures to impart information.

You will gain an appreciation of all of these during your first-year chemistry course, but in this chapter we will concentrate on three important concepts that are part of the overall language of chemistry:

- measurement, numbers and units
- representations of chemical reactions and chemical species
- nomenclature — the way in which chemical species are named.

An understanding of these concepts is crucial in order to be able to understand chemistry. We will begin by looking at the importance of something we perhaps take for granted — measurement.

2.1 Measurement

LEARNING OBJECTIVE 2.1 Use measurements and units in calculations.

Chemistry is a science of measurement. Whenever we weigh a certain mass of a particular substance, evaluate the rate of a chemical reaction or determine the cell potential of an electrochemical cell, we are making measurements. Measurements always have a unit and always have an associated uncertainty. A measurement that is missing either of these is meaningless.

SI units

On 15 April 1999, Korean Air Cargo Flight 6316 from Shanghai to Seoul crashed shortly after takeoff, killing the three crew members and five people on the ground. No evidence of an explosion or mechanical failure was found, and no distress call was made. The resulting investigation found that the crash was most likely caused by confusion over units, specifically metres and feet. The plane was instructed by Air Traffic Control to climb to an altitude of 1500 metres after takeoff, but the First Officer relayed this as 1500 feet

to the captain, who, thinking he was at a much higher altitude than he was meant to be, put the plane into a dive from which it could not recover. The confusion is perhaps explained by the fact that China uses metres as its unit of aviation altitude, while most of the rest of the world, somewhat surprisingly, uses feet.

In February 2001, workers at America's Teaching Zoo, located at Moorpark College in Los Angeles, USA, awoke to find that Clarence, a Galapagos Tortoise that had arrived on loan from the Los Angeles Zoo the previous day, had escaped from his enclosure by pushing over one of its poles. It turned out that Moorpark College, when told that the tortoise weighed '250', had assumed that this meant 250 pounds and constructed the enclosure accordingly. In fact, Clarence tipped the scales at 250 kg, more than double the weight planned for. Fortunately, being 250 kg, Clarence didn't get far and was soon rehoused in a more suitable structure.

These examples illustrate the significance of units in our modern world. A **unit** is a specific standard quantity of a particular property, against which all other quantities of that property can be measured. For example, we can measure all lengths with respect to the length of 1 metre, and metre is therefore a unit of length. Humans have recognised the importance of units of measurement for thousands of years. One of the earliest documented units of measurement was the *cubit*, a unit of length used in ancient Egypt equal to the distance between the tip of the middle finger and the elbow (see figure 2.1). In fact, many units used by the ancient Egyptians were based on parts of the human body, such as the digit, the palm, the hand and the span. Obviously people come in all different shapes and sizes, so this system was far from satisfactory. Over time, a jumble of measuring systems and standards developed. For example, it is believed that in around the year 1100, England's King Henry I defined the *yard* as the distance from the end of his nose to the tip of his thumb, while 200 years later King Edward II decreed that three barleycorns laid end to end constituted an *inch*.

It was in France, following the French Revolution in 1789, that a serious attempt was first made to develop an international system of units. On 22 June 1799, two pieces of platinum, one weighing exactly 1 kilogram and the other exactly 1 metre in length, were deposited in the Archives de la République in Paris, marking the introduction of what is commonly known as the metric system and what scientists call **SI (Système International) units**. The SI has a set of base units for seven measured quantities. These are given in table 2.1 along with their definitions, which no longer involve reference to physical objects, but instead use fixed defining constants.

FIGURE 2.1

The cubit is one of the oldest known units of measurement. It was defined as the distance between the tip of the middle finger and the elbow. Such a loosely defined unit could only result in the vaguest of measurements. Today we have a system of precisely defined units.

TABLE 2.1 The seven SI base units

Measurement	Unit	Symbol	Definition
time	second	s	The second is defined by taking the fixed numerical value of the caesium frequency, $\Delta\nu_{\text{Cs}}$, the unperturbed ground-state hyperfine transition frequency of the caesium 133 atom, to be 9 192 631 770 when expressed in the unit Hz, which is equal to s^{-1} .
length	metre	m	The metre is defined by taking the fixed numerical value of the speed of light in vacuum, c , to be 299 792 458 when expressed in the unit m s^{-1} , where the second is defined in terms of the caesium frequency $\Delta\nu_{\text{Cs}}$.

(continued)

TABLE 2.1 (continued)

Measurement	Unit	Symbol	Definition
mass	kilogram	kg	The kilogram is defined by taking the fixed numerical value of the Planck constant, h , to be $6.626\,070\,15 \times 10^{-34}$ when expressed in the unit J s, which is equal to $\text{kg m}^2 \text{s}^{-1}$, where the metre and the second are defined in terms of c and $\Delta\nu_{\text{Cs}}$.
electric current	ampere	A	The ampere is defined by taking the fixed numerical value of the elementary charge, e , to be $1.602\,176\,634 \times 10^{-19}$ when expressed in the unit C, which is equal to A s, where the second is defined in terms of $\Delta\nu_{\text{Cs}}$.
thermodynamic temperature	kelvin	K	The kelvin is defined by taking the fixed numerical value of the Boltzmann constant, k , to be $1.380\,649 \times 10^{-23}$ when expressed in the unit J K^{-1} , which is equal to $\text{kg m}^2 \text{s}^{-2} \text{K}^{-1}$, where the kilogram, metre and second are defined in terms of h , c and $\Delta\nu_{\text{Cs}}$.
amount of substance	mole	mol	One mole contains exactly $6.022\,140\,76 \times 10^{23}$ elementary entities. This number is the fixed numerical value of the Avogadro constant, N_{A} , when expressed in the unit mol^{-1} and is called the Avogadro number. The amount of substance, symbol n , of a system is a measure of the number of specified elementary entities. An elementary entity may be an atom, a molecule, an ion, an electron, any other particle or specified group of particles.
luminous intensity	candela	cd	The candela is defined by taking the fixed numerical value of the luminous efficacy of monochromatic radiation of frequency $540 \times 10^{12} \text{ Hz}$, K_{cd} , to be 683 when expressed in the unit lm W^{-1} , which is equal to cd sr W^{-1} , or $\text{cd sr kg}^{-1} \text{m}^{-2} \text{s}^3$, where the kilogram, metre and second are defined in terms of h , c and $\Delta\nu_{\text{Cs}}$.

Source: Adapted from *The International System of Units (SI)* 2019, 9th edn, International Bureau of Weights and Measures.

A working knowledge of the units and symbols given in table 2.1 is essential in chemistry. However, as you can see, the precise definitions are complicated, and it is not necessary to memorise them; they are given for interest only. Note that we will meet the Planck constant, the Boltzmann constant and the Avogadro constant, all of which are used in the above definitions, in the chapters on atomic energy levels, chemical reactions and stoichiometry, and chemical thermodynamics, respectively.

We are all familiar with the SI units for length, **metre (m)**, mass, **kilogram (kg)**, and time, **second (s)**. The SI unit of temperature, **kelvin (K)**, has absolute zero ($-273.15\text{ }^{\circ}\text{C}$), the coldest possible temperature, as its zero point. Temperature is more commonly measured in degrees Celsius ($^{\circ}\text{C}$) — a temperature in Celsius may be converted to kelvin by adding 273.15. This means that the freezing point of water, $0\text{ }^{\circ}\text{C}$, is equal to 273.15 K, while the boiling point of water, $100\text{ }^{\circ}\text{C}$, is 373.15 K. Note that a temperature *difference* of 1 kelvin (we do not say 1 degree kelvin) is the same as a temperature difference of 1 degree Celsius.

The SI unit of amount of substance, a concept that will be discussed in the chapter on chemical reactions and stoichiometry, is the **mole (mol)**, while the unit of electrical current, the **ampere (A)**, will be discussed when we study electrochemistry in the chapter on oxidation and reduction. The SI unit of luminous intensity (the brightness of the radiation emitted by phosphorescent and fluorescent compounds, for example) is the **candela (cd)**.

SI units for *any* physical quantity can be derived from these seven base units. For example, there is no SI base unit for area, but we know that to calculate the area of, for example, a rectangular room we multiply its length by its width (i.e. its length in one dimension by its length in the other). Therefore, the SI unit for area is derived by multiplying the unit for length (m) by the unit for length (m) to give m^2 (metre squared, or square metre). We describe m^2 as a *derived unit*. Table 2.2 lists commonly used derived units, including those that are important in chemistry. Note that the SI gives special names to some derived units.

TABLE 2.2 Commonly used SI derived units

Measurement	Expression in terms of simpler quantities	Unit	Expression in terms of SI base units
area	length $\times$ width ^(a)	square metre	m ²
volume	length $\times$ width $\times$ height ^(a)	cubic metre	m ³
speed, velocity	distance ^(b) /time	metre per second	m s ⁻¹
acceleration	velocity/time	metre per second squared	m s ⁻²
density	mass/volume	kilogram per cubic metre	kg m ⁻³
specific volume	volume/mass	cubic metre per kilogram	m ³ kg ⁻¹
force	mass $\times$ acceleration	newton, N	N = kg m s ⁻²
pressure	force/area	pascal, Pa	Pa = N m ⁻² = kg m ⁻¹ s ⁻²
energy	force $\times$ distance ^(b)	joule, J	J = N m = kg m ² s ⁻²
power	energy/time	watt, W	W = J s ⁻¹ = kg m ² s ⁻³
electric charge	electric current $\times$ time	coulomb, C	C = A s
electric potential	energy/electric charge	volt, V	V = J C ⁻¹ = kg m ² s ⁻³ A ⁻¹
frequency	1/time	hertz, Hz	Hz = s ⁻¹
catalytic activity	amount of substance/time	katal, kat	kat = mol s ⁻¹

(a) Width and height are simply length in different directions.

(b) Distance is another name for length.

The units for area and volume, square metre and cubic metre, respectively, are probably familiar to you, as are their symbols, m² and m³. However, while you are also probably familiar with the unit of velocity (metre per second) you may perhaps wonder how the symbol m s⁻¹ (which, despite its appearance, is still pronounced ‘metre per second’) is obtained. To obtain a velocity, we divide length by time, and to obtain the *unit* for velocity we divide the *unit* of length (m) by the *unit* of time (s).

$$\text{velocity} = \frac{\text{distance}}{\text{time}}$$

$$\text{unit of velocity} = \frac{\text{unit of distance}}{\text{unit of time}} = \frac{\text{metre}}{\text{second}} = \frac{\text{m}}{\text{s}}$$

We can write the symbol for the resulting unit in two ways: as m/s, or, as we shall do throughout this text, as m s⁻¹. Recall that x^{-1} is simply another way of writing $\frac{1}{x}$, and so, when we write m s⁻¹, this is the same as $\text{m} \times \frac{1}{\text{s}} = \text{m/s}$.

$$\frac{\text{m}}{\text{s}} = \text{m} \times \frac{1}{\text{s}} = \text{m} \times \text{s}^{-1} = \text{m s}^{-1}$$

Similarly, we obtain an acceleration by dividing velocity by time, and the unit is then derived from the unit of velocity (m s⁻¹) divided by the unit of time (s). The unit is therefore $\frac{\text{m s}^{-1}}{\text{s}} = \text{m s}^{-2}$ (metre per second squared), where s⁻² is the same as $\frac{1}{\text{s}^2}$. This illustrates a very important concept that is used throughout this text when we perform calculations: *units undergo the same kinds of mathematical operations as the numbers to which they are attached*. We demonstrate this in worked example 2.1.

WORKED EXAMPLE 2.1

Deriving SI units

Surface tension is a property of liquids that, for example, allows small insects to walk on water. As we will see in the chapter on condensed phases, it is a measure of the resistance of a liquid to an increase in surface area. We can obtain values of surface tension by dividing force by distance. What is the SI derived unit of surface tension? How can we express that unit in terms of SI base units?

Analysis

As we obtain surface tension values by dividing force by distance, we will obtain the unit of surface tension by dividing the units of force by the units of distance. To obtain the unit in terms of SI base units, we will need to convert the derived unit of force (see table 2.2) to SI base units.

Solution

The SI unit of force is the newton (N) and the SI unit of distance is the metre (m). Therefore, the unit of surface tension is obtained as follows.

$$\text{surface tension} = \frac{\text{force}}{\text{distance}}$$

$$\text{unit of surface tension} = \frac{\text{unit of force}}{\text{unit of distance}} = \frac{\text{N}}{\text{m}} = \text{N m}^{-1}$$

From table 2.2, we can see that the newton (N) is a derived unit, with $\text{N} = \text{kg m s}^{-2}$. We can therefore rewrite N m^{-1} as follows.

$$\text{N m}^{-1} = \text{kg m s}^{-2} \times \text{m}^{-1} = \text{kg s}^{-2}$$

Thus, the unit of surface tension expressed in SI base units is kg s^{-2} .

PRACTICE EXERCISE 2.1

The momentum p of an object of mass m and velocity u is given by the equation $p = mu$. What is the SI derived unit of momentum?

Sometimes it is inconvenient to use SI base or derived units. For example, if we were to use metres to measure the tiny length of an atomic radius or the enormous distance to the nearest star, we would end up with a very small or very large number, respectively. The SI system addresses this problem by the use of prefixes that divide or multiply the unit by a particular power of ten. For example, the prefix *centi* means the following unit is divided by 100, while the prefix *kilo* signifies that the following unit is multiplied by 1000. Table 2.3 lists the SI prefixes.

TABLE 2.3 Decimal prefixes for SI units

Prefix	Symbol	Factor
yotta	Y	10^{24}
zetta	Z	10^{21}
exa	E	10^{18}
peta	P	10^{15}
tera	T	10^{12}
giga	G	10^9
mega	M	10^6
kilo	k	10^3
hecto	h	10^2
deca	da	10^1

deci	d	10^{-1}
centi	c	10^{-2}
milli	m	10^{-3}
micro	μ	10^{-6}
nano	n	10^{-9}
pico	p	10^{-12}
femto	f	10^{-15}
atto	a	10^{-18}
zepto	z	10^{-21}
yocto	y	10^{-24}

Each prefix has an associated symbol, which is placed immediately before the base unit. Therefore, km refers to kilometre, a unit of 10^3 m (pronounced KILO-metre, not kil-OM-etre), while cm (centimetre) is a unit of 10^{-2} m.

The use of powers of ten for the SI prefixes simplifies the manipulation of units. In fact, the French initially attempted to put time on a decimal basis, and for a few years following the French Revolution, the day in France was divided into 10 hours, each consisting of 100 minutes, each of which was made up of 100 seconds. The week also consisted of 10 days. Obviously, this did not catch on.

WORKED EXAMPLE 2.2

Using SI prefixes

PG5 is one of the largest synthetic molecules ever prepared and characterised. The synthesis of PG5 requires around 170 000 bond-forming reactions, and the molecule has a diameter of 10 nm. Could we use an optical microscope to see a molecule of PG5, given that this instrument cannot observe objects smaller than 2×10^{-7} m?

Analysis

We need to convert 10 nm to metres, and compare it with 2×10^{-7} m. The SI symbol n stands for nano and means 10^{-9} , so we will use this conversion factor.

Solution

We know from table 2.3 that $1 \text{ nm} = 1 \times 10^{-9} \text{ m}$, and therefore $10 \text{ nm} = 10 \times 10^{-9} \text{ m} = 1 \times 10^{-8} \text{ m}$. This is less

than $2 \times 10^{-7} \text{ m}$ and hence we will not be able to see a molecule of PG5 using an optical microscope.

Is our answer reasonable?

We can check our result by converting the size of the smallest visible object ($2 \times 10^{-7} \text{ m}$) to nanometres so that it can be compared directly with the size of the PG5 molecule; $2 \times 10^{-7} \text{ m}$ is equal to $200 \times 10^{-9} \text{ m}$, or 200 nm. The PG5 molecule is 10 nm in diameter; the smallest object that can be seen under the microscope is 200 nm, so again we conclude that the PG5 molecule will not be visible.

PRACTICE EXERCISE 2.2

- Give the abbreviation for each of the following.
 - microgram
 - micrometre
 - nanosecond
- How many metres correspond to each of the following?
 - 1 nm
 - 1 cm
 - 1 pm
- What symbol is used to represent each of the following?
 - 10^{-2} g
 - 10^6 m
 - 10^{-6} s

Non-SI units

Although SI units have been officially adopted in nearly all countries, many non-SI units remain in common usage throughout the world. For example, we saw earlier that temperatures are much more likely to be measured in degrees Celsius (or degrees Fahrenheit in the USA) than in the SI unit kelvin. Even chemists are not immune to this; we often use the litre, a unit of volume equal to 1000 cm^3 , rather than the more correct (but inconveniently large) m^3 . The millilitre, which is equal to 1 cm^3 , is also often used. Various non-SI units of pressure (atmosphere, millimetre of mercury, torr, bar), rather than the SI unit pascal, are still regularly seen in the chemical literature. As long as use of non-SI units persists, it will occasionally be necessary for you to be able to convert between non-SI and SI units. To do this, we need to know the conversion factor between the units. We can then obtain an equation to convert between the two. This is illustrated in worked example 2.3.

WORKED EXAMPLE 2.3

Unit conversions

The laws of cricket were originally written in the days of 'imperial' units, with measurements stipulated in yards (yd) and feet (ft). Law 6.1 states that a cricket pitch is 22 yd in length. How long is a cricket pitch in metres given that $1\text{ m} = 1.0936\text{ yd}$?

Analysis

We are told that 1 m corresponds to 1.0936 yd ; we can write this as follows.

$$\frac{1.0936\text{ yd}}{1\text{ m}} = 1.0936\text{ yd m}^{-1}$$

However, as we are given the measurement in yd and need to convert this to m, we require the conversion factor in terms of (m yd^{-1}) . We obtain this knowing the following.

$$\frac{1\text{ m}}{1.0936\text{ yd}} = 0.9144\text{ m yd}^{-1}$$

We can now solve the problem by multiplying this conversion factor by 22 yd.

Solution

$$22\text{ yd} \times 0.9144\text{ m yd}^{-1} = 20.12\text{ m}$$

Is our answer reasonable?

We know that 1 m is slightly longer than 1 yd , so we would expect our numerical answer to be slightly less than 22, which it is. Notice also that the units in our solution are consistent: $\text{yd} \times \text{m yd}^{-1} = \text{m}$.

PRACTICE EXERCISE 2.3

Carry out the following conversions involving pressure units.

1. Convert 3.62 bar to Pa ($1\text{ Pa} = 1 \times 10^{-5}\text{ bar}$).
2. Convert $391\text{ millimetres of mercury (mmHg)}$ to Pa ($1\text{ Pa} = 7.50 \times 10^{-3}\text{ mmHg}$).

3. Convert $7.89 \times 10^3\text{ Pa}$ to atmosphere (atm) ($1\text{ Pa} = 9.87 \times 10^{-6}\text{ atm}$).

The use of non-SI units in measuring pressure and volume can cause particular problems in chemistry. One of the most important equations in chemistry, which we will meet in the chapter on gases, is the ideal gas equation, $pV = nRT$ where p = pressure, V = volume, n = amount of substance and T = temperature. R is called the gas constant and, providing that all the other variables in the equation are measured in SI or derived SI units (Pa, m^3 , mol and K), it has a value of $8.314\text{ J mol}^{-1}\text{ K}^{-1}$. However, as stated above, pressures are often measured in atmosphere, millimetres of mercury, torr, and bar, while volumes are usually measured in litres, rather than m^3 . This means that the value of R depends on the units used, as shown in worked example 2.4.

WORKED EXAMPLE 2.4

The gas constant

Calculate the value and the units of the gas constant R if 1.000 mol of a gas occupies a volume of 22.414 L at 1.000 atm pressure and 273.15 K .

Analysis

We are given the values of all the variables in the ideal gas equation except the gas constant. We must then rearrange the ideal gas equation to make R the subject, plug in all the

values and solve. We obtain the units of the final answer from this equation also.

Solution

We rearrange the ideal gas equation $pV = nRT$, to make R the subject, by dividing both sides of the equation by nT to give the following.

$$R = \frac{pV}{nT}$$

We now plug in the given values to obtain the value and units of R .

$$R = \frac{pV}{nT} = \frac{1.000 \text{ atm} \times 22.414 \text{ L}}{1.000 \text{ mol} \times 273.15 \text{ K}}$$

$$= 8.206 \times 10^{-2} \text{ atm L K}^{-1} \text{ mol}^{-1}$$

Is our answer reasonable?

You can see immediately that both the pressure and amount of substance have numerical values of 1.000, which can be ignored in the calculation. At a very rough approximation, we can see that the answer will lie somewhere in the region of $\frac{20}{200}$ (0.1) to $\frac{20}{300}$ (0.066), which it does.

PRACTICE EXERCISE 2.4

Determine the value and units of the gas constant R for the following systems of units.

(a) 1.000 mol of a gas occupies a volume of $22.414 \times 10^{-3} \text{ m}^3$ at 1.000 atm pressure and 273.15 K.

(b) 1.000 mol of a gas occupies a volume of $22.414 \times 10^{-3} \text{ m}^3$ at 1.013 25 bar pressure and 273.15 K.

(c) 1.000 mol of a gas occupies a volume of $22.414 \times 10^{-3} \text{ m}^3$ at 760 mmHg pressure and 273.15 K.

Notice that the method of unit conversion described in worked example 2.3 can also be used for conversion between SI units. For example, suppose we wanted to express 418 cm^3 in m^3 ; we would need the conversion factor in terms of $\text{m}^3 \text{ cm}^{-3}$. From the unit prefix ‘c’, we know that:

$$1 \text{ cm} = 1 \times 10^{-2} \text{ m}$$

$$\text{Therefore, } 1 \text{ cm}^2 = (1 \times 10^{-2} \text{ m})^2 = 1 \times 10^{-4} \text{ m}^2$$

$$\text{and } 1 \text{ cm}^3 = (1 \times 10^{-2} \text{ m})^3 = 1 \times 10^{-6} \text{ m}^3$$

The conversion factor is therefore:

$$\frac{1 \times 10^{-6} \text{ m}^3}{\text{cm}^3} = 1 \times 10^{-6} \text{ m}^3 \text{ cm}^{-3}$$

We then carry out the conversion as follows.

$$418 \text{ cm}^3 \times 1 \times 10^{-6} \text{ m}^3 \text{ cm}^{-3} = 418 \times 10^{-6} \text{ m}^3$$

Dimensional analysis

One of the questions most commonly asked by students is ‘What equations do I need to learn for the final exam?’ If you read this text from start to end (or indeed, if you just go to the glossary of equations in appendix M), you will find a large number of equations, all of which are important to the subject of chemistry in one sense or another, and you might think that it is necessary for you to learn them all by heart. You’ll be happy to know that this is not the case.

Dimensional analysis involves using the units of a physical quantity to derive the equation used to determine its value. Earlier in this chapter we stated that ‘*units undergo the same kinds of mathematical operations as the numbers to which they are attached*’. We then went on to illustrate this in worked example 2.1 when we determined the units of surface tension (N m^{-1}) through knowledge of the fact that surface tension is equal to force (N) divided by length (m). We will now look at this principle more closely, using the following equations, which will be covered in more detail in the chapter on chemical reactions and stoichiometry.

$$M = \frac{m}{n} \quad \text{and} \quad c = \frac{n}{V}$$

The equation on the left relates molar mass (M), mass (m) and amount of substance (n), while the equation on the right involves concentration (c), amount of substance (n) and volume (V). These are two

of the most used equations in chemistry and, without doubt, these equations are the two most often written incorrectly. Yet, all you need to know to determine the correct forms of these equations are the units of molar mass (M), g mol^{-1} , and concentration (c), mol L^{-1} .

The unit of molar mass, g mol^{-1} , is obtained by dividing a physical quantity having the unit gram by a physical quantity having the unit mole. These physical quantities are mass (m) and amount (n), respectively. Knowing this allows us to write the equation relating mass, amount, and molar mass as follows.

$$\text{molar mass unit (g mol}^{-1}\text{)} = \frac{\text{gram}}{\text{mole}}$$

$$\text{Therefore, molar mass} = \frac{\text{physical quantity measured in gram}}{\text{physical quantity measured in mole}} = \frac{\text{mass}}{\text{amount}} = \frac{m}{n}$$

And there you have it — the equation is given by the units. The correct units of molar mass (g mol^{-1}) are obtained *only* if we divide mass (measured in g) by amount (measured in mol). *No other combination of mass and amount will give the correct units of molar mass.*

A similar situation occurs in the case of concentration. The unit of concentration is mol L^{-1} , and is therefore obtained by dividing a physical quantity having the unit mole by a physical quantity having the unit litre. We know that mole is the unit of amount (n) and litre is the unit of volume (V). Therefore, we can write:

$$\text{concentration unit (mol L}^{-1}\text{)} = \frac{\text{mole}}{\text{litre}}$$

$$\text{Therefore, concentration} = \frac{\text{physical quantity measured in mole}}{\text{physical quantity measured in litre}} = \frac{\text{amount}}{\text{volume}} = \frac{n}{V}$$

Again, no other combination of amount and volume will give the correct units of concentration.

Dimensional analysis assists you not only in remembering the correct form of an equation, but also in ensuring you have rearranged an equation correctly. Consider, for example, rearranging the above equation for concentration, to make n the subject. The correct rearrangement, obtained by multiplying both sides of the equation by V , gives the following.

$$n = c \times V$$

We can easily check this because we know that the units on both sides of the equation must be the same. On the left-hand side, we have units of mol and on the right-hand side we have units of $\text{mol L}^{-1} \times \text{L} = \text{mol}$. Therefore, we can be confident that we have rearranged the equation correctly.

If we had arranged the variables incorrectly, for example, $n = \frac{c}{V}$ or $n = \frac{V}{c}$, we could quickly see from the units that we had made a mistake; $\frac{c}{V}$ gives units of $\text{mol L}^{-1}/\text{L} = \text{mol L}^{-2}$, while $\frac{V}{c}$ gives units of $\text{L}/\text{mol L}^{-1} = \text{L}^2 \text{mol}^{-1}$. Neither can be correct as they do not give the units of mol.

This is always a good check whenever you rearrange an equation; *if the units are not the same on both sides of the rearranged equation, you have made a mistake.*

There are situations where dimensional analysis might, at first glance, appear not to work. Consider, for example, the ideal gas equation, $pV = nRT$, which we encountered earlier in this chapter. Given that pressure (p) is measured in Pa, volume (V) in m^3 , amount (n) in mol and temperature (T) in K, and the gas constant (R) has units of $\text{J mol}^{-1} \text{K}^{-1}$, we can work out the units on both sides of the equation.

- The units of pV (left-hand side) are $\text{Pa} \times \text{m}^3 = \text{Pa m}^3$.
- The units of nRT (right-hand side) are $\text{mol} \times \text{J mol}^{-1} \text{K}^{-1} \times \text{K} = \text{J}$.

This does not appear to be correct, as it looks as though we have different units on each side of the equation. However, remember that both Pa and J are derived units; from table 2.2 we can see that $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ and $1 \text{ Pa} = 1 \text{ kg m}^{-1} \text{ s}^{-2}$. Therefore:

$$\text{Pa m}^3 = \text{kg m}^{-1} \text{ s}^{-2} \times \text{m}^3 = \text{kg m}^2 \text{ s}^{-2} = \text{J}$$

We can see that the units on both sides of the equation are, in fact, the same.

Dimensional analysis is not limited to these relatively simple equations. It works for *any* equation. This is because the numbers and the units on both sides of an equation must be the same. As worked example 2.5 shows, dimensional analysis can also be used to determine the correct form of an equation if you know the units of all the constituent components.

WORKED EXAMPLE 2.5

Dimensional analysis

As we will see in the chapter on solutions and solubility, an aqueous salt solution will boil at a temperature slightly greater than 100 °C, depending on how much salt the solution contains. The magnitude of this boiling point elevation (ΔT) can be calculated from some combination of the molal boiling point elevation constant (K_b) and the molality (b) of the solution. Given that the units of b are mol kg^{-1} and those of K_b are $\text{K mol}^{-1} \text{ kg}$, what equation should be used to calculate ΔT when this is measured in K?

Analysis

We need to combine the units of b and K_b to give units of K in our final answer. The three possibilities are shown below.

$$\Delta T = \frac{K_b}{b} \quad \Delta T = \frac{b}{K_b} \quad \Delta T = K_b b$$

We need to determine the final units for ΔT that result from each of these three possibilities. The correct equation will give final units of K.

Solution

We insert the appropriate units into each of the three expressions above.

$$\frac{K_b}{b} \text{ has units of } \frac{\text{K mol}^{-1} \text{ kg}}{\text{mol kg}^{-1}} = \text{K mol}^{-2} \text{ kg}^2$$

$$\frac{b}{K_b} \text{ has units of } \frac{\text{mol kg}^{-1}}{\text{K mol}^{-1} \text{ kg}} = \text{K}^{-1} \text{ mol}^2 \text{ kg}^{-2}$$

$$K_b b \text{ has units of } \text{K mol}^{-1} \text{ kg} \times \text{mol kg}^{-1} = \text{K}$$

Therefore, the correct equation to calculate the boiling point elevation is $\Delta T = K_b b$.

Is our answer reasonable?

Given that there is only one way of combining the units of K_b and b to give units of K, we can be confident our answer is correct.

PRACTICE EXERCISE 2.5

Deduce the correct form of each of the following equations by considering the units of all the components of the equation.

- Obtain an equation for mass (m , g) in terms of molar mass (M , g mol^{-1}) and amount (n , mol).
- Obtain an equation for heat (q , J) in terms of specific heat capacity (c , $\text{J g}^{-1} \text{ K}^{-1}$), mass (m , g) and temperature change (ΔT , K).

- Obtain an equation for the speed of light (c , m s^{-1}) in terms of energy (E , J), Planck's constant (h , Js) and wavelength (λ , m).

Precision and accuracy

Whenever we make a measurement, we want it to be both accurate and precise. These words are often used interchangeably in English, but in fact they have rather different meanings. A measurement's **accuracy** refers to how close the value is to the correct value, while **precision** signifies how reproducible a particular measurement is when made a number of times. As we will see in the next section, the precision of a measurement determines the number of significant figures to which the measurement may be quoted. The concepts of accuracy and precision are illustrated in figure 2.2.

FIGURE 2.2

The difference between precision and accuracy in the game of golf. Golfer 1 hits shots that are precise (because they are tightly grouped), but the accuracy is poor as the balls are not near the target (the 'true' value). Golfer 2 needs help — the shots are neither precise nor accurate. Golfer 3 wins with shots that are precise (tightly grouped) and accurate (in the hole).

PRACTICE EXERCISE 2.6

Four workers weigh a 5.000 g mass three times on several different sets of kitchen scales and obtain the following results.

- (a) Worker A: 5.022 g, 4.976 g, 5.008 g
(b) Worker B: 4.836 g, 5.033 g, 4.723 g

- (c) Worker C: 5.230 g, 5.231 g, 5.232 g
(d) Worker D: 4.632 g, 4.835 g, 4.926 g

Which set of data has the best precision? Which has the best accuracy?

Uncertainties and significant figures

Every measurement has an associated uncertainty, which results from the limitations of the methods we use to make the measurement. Consider the two thermometers in figure 2.3, which display the same temperature. The divisions on the left thermometer are 1°C apart and it is therefore certain, barring any imperfections in the manufacture of the thermometer, that the temperature is greater than 24°C and less than 25°C . It can be estimated that the top of the fluid column falls about 0.3 of the way between the divisions for 24°C and 25°C , so the measurement can be recorded as 24.3°C . However, we cannot say that the temperature is exactly 24.3°C , as the last figure is only an estimate, and the left thermometer might be read as 24.2°C by one observer and 24.4°C by another. The thermometer on the right is graduated in divisions of 0.1°C and may therefore be read to a greater precision than the other thermometer. Reading the thermometer on the right, it is now certain, again assuming no flaws in the thermometer, that the temperature lies between 24.3°C and 24.4°C , and another figure in the measurement can be estimated by noting that the top of the fluid lies about 0.2 of the way between the divisions. Therefore, the temperature according to the thermometer on the right would be stated as 24.32°C . By convention in science, all figures in a measurement up to and including the first estimated figure are recorded. The figures recorded according to this convention are called **significant figures**. The thermometer on the right can be read to a greater precision, and the measurement made contains a correspondingly larger number (4) of significant figures. The number of significant figures in a measurement is equal to the number of digits known for certain, plus one that is estimated. Therefore, there will always be uncertainty in the last significant figure of any measurement. In the above example, the final figures of both 24.3°C (the measurement on the left thermometer) and 24.32°C (the measurement on the right thermometer) are uncertain.

It is usually easy to determine the quantity of significant figures in a number — simply count the figures. However, it is often not necessarily obvious how many significant figures a number contains when zeros are present at its beginning or end; for example, does the number 0.0023 contain two (23), four (0023) or five (0.0023) significant figures? Does the number 3000 contain one (3) or four (3000) significant figures?

Such problems can (and should) be avoided by writing numbers in **scientific notation**, which immediately shows how many significant figures are present. Scientific notation expresses numbers in terms of powers of 10; for example, the number 15 becomes 1.5×10^1 in scientific notation, 362 becomes 3.62×10^2 , and so on. In scientific notation, 0.0023 is written as 2.3×10^{-3} , and it can be seen that the number contains only two significant figures. Similarly, the more precise number 0.00230 would be

FIGURE 2.3

Thermometers with different scales give readings with different precision. The thermometer on the left has divisions that are 1°C apart, allowing the temperature to be estimated to the nearest 0.1°C . The thermometer on the right has divisions every 0.1°C , permitting estimation of the temperature to 0.01°C .

written as 2.30×10^{-3} , and this then has three significant figures. A measurement quoted as 2.3×10^{-3} implies that the actual value lies somewhere between 2.2×10^{-3} and 2.4×10^{-3} , whereas a more precise measurement of 2.32×10^{-3} now suggests limits of 2.31×10^{-3} and 2.33×10^{-3} ; in all cases, it is the final digit that is uncertain. The question of how many significant figures the number 3000 contains is somewhat more complicated. In the absence of any context we only know that the 3 is significant for certain, as we have no information to be able to make a judgement on the zeros, and we would therefore say that 3000 contains 1 significant figure. However, if 3000 was part of a series of measurements that included the numbers 2998, 3001 and 3002, we would say that, in this context, 3000 contains 4 significant figures. With respect to this, any ambiguity can be avoided simply by expressing the number in scientific notation; 3×10^3 contains 1 significant figure, and 3.000×10^3 contains 4 significant figures. Figure 2.4 summarises the rules for using significant figures.

FIGURE 2.4 Rules for significant figures

1. All nonzero digits in a number are significant.
2. Whether a zero in a number is significant or not depends on its position in the number.
 - (a) A zero *is significant* if it is positioned:
 - (i) between two nonzero digits:
 704 has three significant figures
 5.02 has three significant figures
 173.05 has five significant figures
 - (ii) at the end of a number that includes a decimal point:
 0.500 has three significant figures (**0.500**)
 25.160 has five significant figures (**25.160**)
 3.00 has three significant figures (**3.00**)
 - (b) A zero *is not significant* when it is positioned before the first nonzero digit in a number. In these cases, the zero before the decimal point can be omitted without any loss of information, while any subsequent zeros before the first nonzero digit are merely placeholders:
 0.009 21 has three significant figures (**0.009 21**)
 0.025 01 has four significant figures (**0.025 01**)
 - (c) A zero *may be significant* when it is positioned at the end of a number without a decimal point. In order to decide whether or not such a zero is significant, context is required. In the absence of context, such zeros should be assumed to be not significant. To avoid ambiguity, numbers should be written in scientific notation:
 - (i) 1000 may, depending on context, have one, two, three or four significant figures and should be written as:
 1×10^3 for one significant figure
 1.0×10^3 for two significant figures
 1.00×10^3 for three significant figures
 1.000×10^3 for four significant figures
 - (ii) 590 may, depending on context, have either two or three significant figures and should be written as:
 5.9×10^2 for two significant figures
 5.90×10^2 for three significant figures.

Note that some numbers are *exact*, and by definition have an infinite number of significant figures. Examples of exact numbers include those used in counting; if you count 10 objects, you have exactly 10 objects. Numbers that are part of the definitions of units are also considered to be exact. For example, there are exactly 1000 millimetres in 1 metre, and 60 seconds in 1 hour. Exact numbers have no uncertainty.

The number of significant figures in a measurement is the same regardless of the units. For example, a length of 2.3×10^{-3} m can be expressed in millimetres (2.3 mm) or nanometres (2.3×10^6 nm), but in each case the values must have the same number of significant figures, as the precision of the measurement does not depend on the units in which it is expressed.

As we shall see below, the number of significant figures to which the answer to any calculation can be expressed depends on the number of significant figures in the data used. It is therefore strongly recommended that, whenever you are recording or manipulating numerical scientific data, you express all numbers in scientific notation. This will help avoid any possible ambiguities and allow you (and others) to see the precision of your data at a glance.

WORKED EXAMPLE 2.6

Significant figures

Determine the number of significant figures in the following numbers.

- (a) 0.051 532
- (b) 0.780 20
- (c) 530.06
- (d) 800

Analysis

We need to use the rules in figure 2.4 to determine the number of significant figures in each part of the question. We can then check our answers by writing the numbers in scientific notation.

Solution

Rule 1 in figure 2.4 gives us the minimum number of significant figures in each number. We simply count the nonzero digits.

- (a) 0.051 532 has at least five significant figures.
- (b) 0.780 20 has at least three significant figures.
- (c) 530.06 has at least three significant figures.
- (d) 800 has at least one significant figure.

We then use rule 2 in figure 2.4 to determine whether or not the zeros in the numbers are significant.

- (a) None of the zeros in 0.051 532 is significant as they are all positioned before the first nonzero digit (rule 2(b)(i)).

- (b) The leading zero is not significant (rule 2(b)(i)). The zero between 8 and 2 is significant (rule 2(a)(i)) and the final zero is significant (rule 2(a)(ii)).

- (c) Both zeros are significant (rule 2(a)(i)).

- (d) In the absence of context, we assume the zeros are not significant.

Therefore:

- (a) 0.051 532 has five significant figures
- (b) 0.780 20 has five significant figures
- (c) 530.06 has five significant figures
- (d) 800 has one significant figure.

Is our answer reasonable?

The main question in significant figures comes with zeros. Are they significant, or are they placeholders? In the number 0.051 532, all the zeros are placeholders, and writing this in scientific notation (5.1532×10^{-2}) makes this clear — none of the zeros appear in the scientific notation of this number, so they cannot be significant. The numbers in (b) and (c) contain zeros that are significant, and so they appear in the scientific notation (7.8020×10^{-1} and 5.3006×10^2 , respectively). In (d), in the absence of context, we would write the number in scientific notation with no zeros as 8×10^2 . Bear in mind that, given the appropriate context, 800 could also be 8.0×10^2 or 8.00×10^2 . Taking the rules in figure 2.4 into account, our answer is reasonable.

PRACTICE EXERCISE 2.7

How many significant figures do the following numbers contain?

- (a) 9.010 101 0
- (b) 0.000 470 0
- (c) 6 000 300.01
- (d) 20

As we saw with the example of the thermometers in figure 2.3, whenever we make a measurement using any type of scientific apparatus, the uncertainty in that measurement will depend on the precision of the apparatus used; the more precise the apparatus, the more significant figures a measurement made using it will contain. For example, consider two 20 mL pipettes, one of which has an uncertainty of ± 0.1 mL and the other an uncertainty of ± 0.05 mL ($\pm$ means ‘plus or minus’). We would quote the former pipette as measuring (20.0 ± 0.1) mL and the latter as measuring (20.00 ± 0.05) mL. The former pipette therefore delivers between 19.9 mL and 20.1 mL, while the latter pipette is more precise, and delivers between 19.95 mL and 20.05 mL whenever it is used. This type of uncertainty is called an **absolute uncertainty**; it has the same units as the quantity being measured. The absolute uncertainty of any piece of apparatus is generally given to be plus or minus half of the smallest division on its scale (see figure 2.5).

Because an absolute uncertainty must always be compared with the actual measurement made in order for us to be able to gauge its relative magnitude, it is often useful to quote the **percentage uncertainty** of a piece of apparatus. In this case, we would calculate the percentage uncertainty of the more precise of the two pipettes as follows.

$$\text{percentage uncertainty} = \frac{\text{absolute uncertainty}}{\text{value of the measurement}} \times 100\% = \frac{0.05 \text{ mL}}{20.00 \text{ mL}} \times 100\% = 0.25\%$$

As we shall see below, percentage uncertainties are important when we are working with measurements in a way that requires us to do calculations involving either multiplication or division.

It should be noted that there are two types of uncertainties in any measurement. Random uncertainties refer to the reproducibility of a measurement, and are generally taken account of in the quoted uncertainty of the apparatus used to make the measurement. These are what give rise to the total uncertainty that we report at the end of a calculation. Systematic uncertainties usually result from deficiencies in the measuring equipment or from human error; for example, when using a pipette which delivers only 19.00 mL rather than the stated 20.00 mL, or using a pH meter that has been incorrectly calibrated. These uncertainties can be eliminated through careful experimental technique.

FIGURE 2.5

The 0.1 mL gradations on this pipette imply an uncertainty of ± 0.05 mL.

Uncertainties and significant figures in calculations

We have shown above how to determine the number of significant figures in an individual number. But when we use numbers in a calculation, how many significant figures does the answer contain? And how do uncertainties in numerical measurements translate to an uncertainty in the final answer when these measurements are used in calculations? More often than not, you will be relying on your calculator to carry out calculations; this will generally give an answer containing many more significant figures than are justified and will tell you nothing about the uncertainty in that answer. You therefore need to make use of some rules to appreciate what sort of precision you should give in your final answer.

To determine the appropriate number of significant figures in the answer of a calculation, the following rules apply.

- When a numerical measurement is multiplied by a constant, the number of significant figures in the answer will be the same as that in the numerical measurement.
- When two or more numerical measurements are multiplied or divided, the number of significant figures in the answer should not be greater than the number of significant figures in the least precise measurement.
- When two or more numerical measurements are added or subtracted, the answer should have the same number of decimal places as the measurement with the smallest number of decimal places.

Note that in worked examples and the end-of-chapter exercises we often encounter multi-step calculations. These would often be carried out all in one step on a calculator, and the answer would then be rounded according to the rules given above. However, for illustrative purposes in these examples, we generally carry out each step individually, round each intermediate answer, and then use this rounded answer in the next step of the calculation. This can then result in a discrepancy between the final answers obtained from the one-step and multi-step calculations. One way to minimise the magnitude of this discrepancy is to carry an extra significant figure through each calculation step, and then round the final answer. Worked example 2.7 illustrates these three approaches and shows that, in all cases, any discrepancy is small. Your university may have a preferred way for you to work, and of course you should follow their direction.

WORKED EXAMPLE 2.7

Rounding in multi-step calculations

Analysis of a sample of gas showed that it contained only the elements O and N, in a mass ratio of 40.00 g : 14.01 g, respectively. A separate sample of this gas contained 2.791 g of N.

Calculate the mass of O that this sample contained by:

- (a) carrying out the calculation in a single step and rounding the final answer
- (b) carrying out the calculation as two separate steps and rounding both the intermediate and final answers

- (c) carrying out the calculation as two separate steps as in (b) and carrying an extra significant figure through from the intermediate answer.

Analysis

We know the mass ratio of O to N in the first sample of gas, and we know this ratio must be the same in the second sample. Given the mass of N in the second sample, and knowing the O to N ratio, we can calculate the mass of O.

Solution

We know the following.

$$\frac{\text{mass of O (sample 1)}}{\text{mass of N (sample 1)}} = \frac{\text{mass of O (sample 2)}}{\text{mass of N (sample 2)}}$$

Therefore:

$$\text{mass of O (sample 2)} = \frac{\text{mass of O (sample 1)}}{\text{mass of N (sample 1)}} \times \text{mass of N (sample 2)}$$

- (a) Carrying out the calculation in a single step and rounding the answer.

$$\text{mass of O} = \frac{40.00 \text{ g}}{14.01 \text{ g}} \times 2.791 \text{ g} = 7.969 \text{ g}$$

- (b) Carrying out the calculation as two separate steps and rounding both the intermediate and final answers.

Step 1: Calculate the O to N ratio.

$$\text{O to N ratio} = \frac{40.00 \text{ g}}{14.01 \text{ g}} = 2.855$$

Step 2: Multiply the ratio by the mass of N.

$$\text{mass of O} = 2.855 \times 2.791 \text{ g} = 7.968 \text{ g}$$

- (c) Carrying out the calculation as two separate steps as in (b) and carrying an extra significant figure through from the intermediate answer.

Step 1: Calculate the O to N ratio.

$$\text{O to N ratio} = \frac{40.00 \text{ g}}{14.01 \text{ g}} = 2.8551$$

Step 2: Multiply the ratio by the mass of N.

$$\text{mass of O} = 2.8551 \times 2.791 \text{ g} = 7.969 \text{ g}$$

Is our answer reasonable?

The three answers are essentially the same, differing by only 1 in the final figure. This would be expected for a calculation only involving two steps; obviously the more steps in a calculation, the greater the possible discrepancy between the answers. However, you will generally find that any discrepancy occurs in only the final figure of the answer.

We can further illustrate the effect of rounding by considering the following examples involving multiplication, division and subtraction. If we calculate the following equation on a ten-digit calculator, the answer is 13.497 093 75, a number with ten figures. But how many of these figures are significant?

$$\frac{3.14 \text{ kg} \times 2.751 \text{ m}}{0.64 \text{ s}}$$

The numbers in the numerator (top line) contain three and four significant figures, respectively, while the denominator (bottom line) contains two significant figures, and so it makes no sense to have an answer that is many orders of magnitude more precise than any of the numbers from which it is derived. The rule above for multiplication and division states that we can have only as many significant figures in our final answer as there are in the least precise measurement. Therefore, in this example, we can express our answer to only two significant figures, so our final answer is as follows.

$$\frac{3.14 \text{ kg} \times 2.751 \text{ m}}{0.64 \text{ s}} = 13 \text{ kg m s}^{-1}$$

Here, we have carried out the calculation as a single step and rounded at the end. Note that, if we carried out the multiplication first as a separate step, rounded, and then carried out the division, our answer would be as follows.

$$\text{Step 1: } 3.14 \text{ kg} \times 2.751 \text{ m} = 8.64 \text{ kg m}$$

$$\text{Step 2: } \frac{8.64 \text{ kg m}}{0.64 \text{ s}} = 14 \text{ kg m s}^{-1}$$

If we calculate the sum of the lengths below, a calculator will give the numerical answer as 169.807. However, using the rule for addition and subtraction, we must give the answer to only a single decimal place, as 125.2 m has the fewest decimal places. Therefore, our answer is 169.8 m.

$$\begin{array}{r} 3.247 \text{ m} \\ 41.36 \text{ m} \\ +125.2 \text{ m} \\ \hline 169.8 \text{ m} \end{array}$$

Different rules apply when working with logarithms, as we will do extensively when considering pH in the chapter on acids and bases.

- *The logarithm of a number can have the same number of figures to the right-hand side of the decimal point as there are significant figures in the number.*

For example, the number 0.003 21 has three significant figures (this becomes more obvious when it is written in scientific notation as 3.21×10^{-3}). Using a calculator to determine the logarithm gives $-2.493\ 494\ 967\ 6$. This should then be quoted as -2.493 .

The reverse is also true; *the antilogarithm of a number has the same number of significant figures as there are figures to the right of the decimal point.* Hence, using a calculator, we find that the antilogarithm of -4.18 is $6.606\ 934\ 48 \times 10^{-5}$. This should be quoted to two significant figures, namely 6.6×10^{-5} .

The above rules for logarithms apply to both common ($\log_{10}$) and natural ($\ln$ or $\log_e$) logarithms.

While significant figures and uncertainties are related, the rules for determining the uncertainty in the answer of a calculation are somewhat different from those for significant figures. They are as follows.

- *When two or more numerical measurements are added or subtracted, the uncertainty in the final answer is the sum of the absolute uncertainties in the measurements.*

Before we see an example of this, we should recall that an absolute uncertainty is one that has the same units as the measurement. We will now consider adding two volumes, 21.05 mL and 18.55 mL. If the absolute uncertainty in each of the measurements is ± 0.05 mL, then the uncertainty in the final answer is ± 0.1 mL. We can explain this as follows. A volume of (21.05 ± 0.05) mL implies that the true value lies between $(21.05 - 0.05)$ mL and $(21.05 + 0.05)$ mL; in other words, between 21.00 mL and 21.10 mL. Likewise, a volume of (18.55 ± 0.05) mL implies that the true value lies between $(18.55 - 0.05)$ mL and $(18.55 + 0.05)$ mL; in other words, between 18.50 mL and 18.60 mL. Thus, when we add the two measurements, the smallest possible answer we could obtain is $(21.00 \text{ mL} + 18.50 \text{ mL}) = 39.50 \text{ mL}$ and the largest possible answer we could obtain is $(21.10 \text{ mL} + 18.60 \text{ mL}) = 39.70 \text{ mL}$. Adding 21.05 mL and 18.55 mL gives 39.60 mL, and so we would quote the final answer as (39.6 ± 0.1) mL — in other words it could range from 39.5 mL to 39.7 mL, owing to the uncertainty in each reading.

Notice that our final answer appears to have dropped a significant figure — it has 3 significant figures, where the initial measurements contained 4. This is a result of the magnitude of the uncertainty. As it is generally only the final figure in a measurement that has any uncertainty, we usually only quote uncertainties to a single figure. Therefore, the uncertainty we obtain from adding 0.05 and 0.05 is not 0.10, but 0.1. As this must refer to the final figure in the answer, we cannot quote the answer as (39.60 ± 0.1) mL — it must be (39.6 ± 0.1) mL. You may quite often find that the uncertainty dictates the precision of the answer.

- *When two or more numerical measurements are multiplied or divided, the uncertainty in the final answer is the sum of the percentage uncertainties in the measurements.*

As an example of this, consider calculating the density (ρ) of gold by dividing its mass (m) by its volume (V). Suppose that a (5.000 ± 0.005) g sample of gold occupies a volume of (0.2588 ± 0.005) mL. We would calculate the density using the following equation.

$$\rho = \frac{m}{V} = \frac{5.000 \text{ g}}{0.2588 \text{ mL}} = 19.32 \text{ g mL}^{-1}$$

To calculate the uncertainty in the answer, we must calculate the percentage uncertainties in the two measurements, and then add them. The reasoning for this is similar to that given above — the mass spans the possible values 4.995 g to 5.005 g, and the volume ranges from 0.2583 mL to 0.2593 mL. Therefore, the smallest and largest possible values of the density, as dictated by these uncertainties, are:

$$\rho = \frac{m}{V} = \frac{4.995 \text{ g}}{0.2593 \text{ mL}} = 19.26 \text{ g mL}^{-1} \quad \text{and} \quad \rho = \frac{m}{V} = \frac{5.005 \text{ g}}{0.2583 \text{ mL}} = 19.38 \text{ g mL}^{-1}$$

However, treatment of the uncertainties here is not as simple as in the case of addition and subtraction. When measurements are added or subtracted, they must have the same units, and so the absolute uncertainties, which must also therefore have the same units, can be added. When measurements are multiplied or divided, then they do not necessarily need to have the same units, and we cannot then add the absolute uncertainties. We solve this problem by converting the absolute uncertainties to percentage uncertainties, which are dimensionless (i.e. they have no units). These can then be added, and in the final step the total percentage uncertainty is converted back to an absolute uncertainty. Thus, in the above example, we convert the absolute uncertainties to percentage uncertainties as follows.

$$\% \text{ uncertainty in measurement} = \frac{\text{absolute uncertainty in measurement}}{\text{value of measurement}} \times 100$$

$$\text{Therefore \% uncertainty in mass} = \frac{0.005 \text{ g}}{5.000 \text{ g}} \times 100 = 0.1\%$$

$$\text{And \% uncertainty in volume} = \frac{0.0005 \text{ mL}}{0.2588 \text{ mL}} = 0.2\%$$

Therefore, the total % uncertainty is $0.1\% + 0.2\% = 0.3\%$.

We convert the total % uncertainty to an absolute uncertainty as follows.

$$\text{absolute uncertainty in calculated value} = \frac{\text{total \% uncertainty} \times \text{calculated value}}{100}$$

$$\text{Therefore absolute uncertainty in density} = \frac{0.3 \times 19.32 \text{ g mL}^{-1}}{100} = 0.06 \text{ g mL}^{-1}$$

You will note that $\pm 0.06 \text{ g mL}^{-1}$ represents the spread of values in the final answer that we calculated previously.

PRACTICE EXERCISE 2.8

Give the answers to the following calculations to the correct number of significant figures.

- (a) $5.891 + 3.990 + 15 + 31.62$
- (b) 2.81×1.052
- (c) $4.71 \times (3.308 + 4.1)$

- (d) the total mass of two beakers of water, each of which weighs 22.30 g
- (e) $\log(7.014 \times 3.93)$
- (f) $\frac{7.17}{15.3} \times (310 + 87.4)$

PRACTICE EXERCISE 2.9

Perform the following calculations involving measurements. Give the answers to the correct number of significant figures, and use the appropriate units.

- (a) $47.8817 \text{ g} + 35.6 \text{ g}$
- (b) $17.10 \text{ mL} - 5.6 \text{ mL}$

- (c) $14.134 \text{ g} - 0.0891 \text{ g}$
- (d) $21.8 \text{ g} + 6.21 \text{ g} + 0.773 \text{ g}$
- (e) $\frac{12.0131 \text{ g}}{13.8 \text{ mL}}$
- (f) $2.64 \text{ m} \times 1.031 \text{ m} \times 1.1 \text{ m}$

PRACTICE EXERCISE 2.10

A student wanted to prepare 100 mL of a 1.000 g L^{-1} solution of NaCl and devised the following method. The student weighed 0.100 g of solid NaCl on a balance and transferred

this to a 100 mL volumetric flask. Sufficient water was then added, with stirring, to give a final volume of 100 mL according to the mark on the volumetric flask.

Given that the uncertainties in the balance and volumetric flask were $\pm 0.001\text{ g}$ and $\pm 1\text{ mL}$, respectively, calculate the final uncertainty in the concentration of the NaCl solu-

tion. Did the student succeed in preparing a 1.000 g L^{-1} solution? If not, what was the concentration, including the uncertainty, of the solution?

CHEMICAL CONNECTIONS

The National Measurement Institute

The National Measurement Institute (NMI) is the Australian government's national authority on measurement. It is the peak body responsible for providing unit and measurement standards and services in Australia, and for maintaining its measurement system. This covers physical, chemical, biological, legal and trade measurement.

We mentioned earlier in this chapter that the unit of mass is the kilogram (kg). The kilogram was the last base unit of the SI system of measurement still related to a physical artefact — a platinum–iridium weight nicknamed 'Big K' held at the Bureau International des Poids et Mesures (BIPM, the International Bureau of Weights and Measures) in Paris. In 2019, after serving science for over a century, Big K was retired, and the kilogram was redefined in

terms of universal constants of nature (see table 2.1). This change addressed a potential drift of as much as 1 part in 10^9 per year in Big K. The new definition of the kilogram uses Einstein's famous equation $E = mc^2$, which links mass to energy through the fixed value for the speed of light c , and the equation $E = h\nu$, which links energy to the accurate measurement of frequency ν , through the fixed value of Planck's constant h .

National standards laboratories, such as NMI in Australia and the Measurement Standards Laboratory (MSL) of New Zealand, still send their national 1 kg references (see figure 2.6) to BIPM in Paris to be calibrated (at the $20\text{ }\mu\text{g}$ level!), but instead of being calibrated against Big K they are now measured against values obtained from ongoing international scientific collaborations, which turn the new definition of the kilogram into a practical standard.

FIGURE 2.6

Australia's Copy No. 44 of 'Big K', the international prototype of the kilogram. Prior to 2019, the kilogram was defined in terms of the mass of 'Big K', a block of 90% platinum — 10% iridium alloy.

While measurement might seem a somewhat esoteric field, it is fundamental to every aspect of our modern economy. For example, national mass standards support all mass-related measurements from highly precise micro-gram amounts used in pharmaceutical research to high-tonnage agricultural or mining exports.

A key aim of NMI is to promote uniform measurement policy and practice in the sphere of international trade. For example, an area in which NMI has been active is the honey industry, particularly in relation to high-value monofloral honeys such as Manuka. New Zealand and Australia

export thousands of tonnes of high-value honeys each year. The market value of these honeys is premised on their type, place of origin and bioactivity. Like many premium products, the brand value of these honeys is at risk from fraudulent practices such as substitution, dilution and false labelling. NMI works extensively with the Australian and New Zealand governments, and industries in both countries, to develop a range of chemical and biological measurement capabilities (figure 2.7) that help protect both countries' high-value honeys from fraud.

FIGURE 2.7 NMI has developed a range of tests to ensure the origin, authenticity and quality of Manuka honey.

In partnership with the New Zealand Ministry of Primary Industries, NMI has developed a legal, chemical definition for New Zealand Manuka honey by identifying and measuring unique marker compounds using Liquid Chromatography Mass Spectrometry. NMI has also set up a specialist nuclear magnetic resonance-based honey

characterisation capability to help monitor honey on the Australian market for adulteration and to form part of a comprehensive chemical character library for unique Australian honeys. Mass spectrometry and nuclear magnetic resonance spectroscopy are discussed in the chapter on structure determination.

2.2 Representations of molecules and reactions

LEARNING OBJECTIVE 2.2 Represent substances and processes using common chemistry conventions.

The language of chemistry is not only about the meaning of words, but also about how we can represent chemical species using particular combinations of letters, numbers, symbols and pictures (see figure 2.8). In this section we will describe some of the many different ways in which we can depict molecules, as well as the bond-making and bond-breaking processes that occur in chemical reactions.

FIGURE 2.8

Different ways of representing the chemical species methane include: (a) chemical formula (b) structural formula (c) 3-D structural formula (d) ball-and-stick model (e) space-filling model.

Chemical formulae

The simplest way to describe the composition of any substance is to write its **chemical formula**. This shows the number of each type of atom present in a substance. A chemical formula contains elemental symbols to represent atoms and subscripted numbers to indicate the number of atoms of each type. It may be as simple as water, H_2O , or as complicated as $\text{C}_{30}\text{H}_{34}\text{AuBClF}_3\text{N}_6\text{O}_2\text{P}_2\text{PtW}$, the compound which currently holds the record for containing the most elements. As we have seen in the introductory chapter on the atom, each chemical element is described by a one- or two-letter symbol, and these form the basis for all chemical formulae. The simplest chemical formulae describe pure elements and are usually just their elemental symbols as listed on the periodic table; for example, helium is He, silicon is Si and copper is Cu. Such formulae imply that the bulk elements are composed of either individual atoms which do not interact (such as He) or 'infinite' three-dimensional arrays of bonded atoms (such as Si and Cu). However, this is not the case for some elements, and we must write more complex chemical formulae for these. For example, seven elements (hydrogen, nitrogen, oxygen, fluorine, chlorine, bromine and iodine) occur naturally neither as individual atoms nor as three-dimensional arrays but as molecules containing two atoms (diatomic molecules). To signify this, their chemical formulae are written as H_2 , N_2 , O_2 , F_2 , Cl_2 , Br_2 and I_2 , respectively. Some other elements occur as larger molecules; a phosphorus molecule contains four P atoms and a sulfur molecule contains eight S atoms so their chemical formulae are P_4 and S_8 , respectively. A chemical formula that refers to a discrete molecule is often called a **molecular formula** as it describes the types and numbers of atoms present in the molecule. Note that a subscripted numeral refers to the atom immediately preceding it, or, if it follows a group of atoms enclosed in parentheses, to the entire group of enclosed atoms. For example, the chemical formula BH_3 shows that the compound contains one boron atom and three hydrogen atoms, whereas the chemical formula $\text{B}(\text{OH})_3$ shows that the compound contains one boron atom, three oxygen atoms and three hydrogen atoms.

Chemical compounds contain more than one element. Therefore, there is potentially more than one way to write the formula of any compound. For example, hydrogen chloride is a diatomic molecule with one atom each of hydrogen and chlorine. Its chemical formula might therefore be written as HCl or ClH . To avoid possible confusion, chemists have standardised the writing of chemical formulae. For **binary compounds** (compounds containing only two elements) the guidelines listed in figure 2.9 apply.

FIGURE 2.9

Guidelines for writing the chemical formulae of binary compounds

1. With the exception of hydrogen, the element further to the left in the periodic table appears first. Examples are KCl , PCl_3 , Al_2S_3 and Fe_3O_4 .
2. If hydrogen is present, it appears last except when the other element is from group 16 or 17 of the periodic table. For example, we write hydrogen last in LiH , NH_3 , B_2H_6 and CH_4 , but first in H_2O_2 , H_2S , HCl and HI .
3. If both elements are from the same group of the periodic table, the lower one appears first; for example, SiC and BrF_3 .
4. If the compound is ionic, we write the cation (the positively charged ion) first, followed by the anion (the negatively charged ion). Examples are NaBr and MgCl_2 .

Writing chemical formulae for compounds containing more than two elements requires some knowledge of the bonding within the compound. As we will discuss in greater detail in the chapter on chemical bonding and molecular structure, chemical compounds can be divided broadly into two classes — ionic compounds and covalent compounds — which are distinguished by the type of bonding. Ionic compounds are composed solely of ions, and the attractive forces between ions of opposite charge result in the formation of 'infinite' three-dimensional lattices. On the other hand, covalent compounds are characterised

by bonding involving the sharing of electrons between adjacent atoms. To write the chemical formula of an ionic compound containing more than two elements, we again write the cation followed by the anion. For example, the formula of sodium nitrate, which contains positively charged sodium ions, Na^+ , and negatively charged nitrate ions, NO_3^- , is NaNO_3 . Note that the ordering of the elements in the NO_3^- ion conforms to the rules given above. Note also that we must always ensure that the total charge on the ionic compound is zero, so the number of Na^+ and NO_3^- ions must be the same, and we never include the individual ionic charges in the overall formula.

Writing the chemical formula for calcium nitrate is a little more complicated. The formula of the calcium ion is Ca^{2+} , while that of the nitrate ion is NO_3^- . We can see that, to achieve an overall charge of zero, we will require one Ca^{2+} ion and two NO_3^- ions, and it is with the latter that a potential problem arises. We signify the presence of two NO_3^- ions, as we do for any ion, by using a subscripted '2' immediately following the ion. However, you can see that, if we do this, we will have two subscripted numbers immediately adjacent to each other, thereby leading to possible confusion. In cases such as this, we enclose the ion in parentheses, and place the subscripted '2' outside the parentheses. Putting the cation first, we therefore write the chemical formula as $\text{Ca}(\text{NO}_3)_2$.

As stated above, it is understood that the subscripted '2' refers to the entire group of atoms within the parentheses; that is, the correct chemical formula, $\text{Ca}(\text{NO}_3)_2$, implies one Ca^{2+} ion and two NO_3^- ions. The incorrect chemical formula, CaNO_{32} , implies one Ca, one N and 32 O atoms.

To illustrate the difference between the use of subscripted numbers and numbers of normal case, consider the following chemical equation, which describes solid $\text{Al}_2(\text{SO}_4)_3$ dissolving in water to form its constituent ions.

Note that subscripts are used only when we are referring to the number of constituent atoms or ions *within an element or compound*; in other words, they appear in chemical formulae only. Conversely, normal case numbers are used as coefficients to describe the number of atoms, ions or molecules present *in a particular chemical equation*. This will be covered in much greater detail in the chapter on chemical reactions and stoichiometry.

PRACTICE EXERCISE 2.11

Write the chemical formulae for the compounds resulting from all possible combinations of the following cations and anions (16 compounds in total).

If calcium nitrate, a white crystalline solid with the chemical formula $\text{Ca}(\text{NO}_3)_2$, is exposed to moist air, it absorbs water and forms a **hydrate**. This hydrate is also a white crystalline solid but it has the chemical formula $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$. This process can be reversed by heating the hydrate under vacuum to remove the water molecules, which results in the formation of **anhydrous** $\text{Ca}(\text{NO}_3)_2$, which is what we started with. (Anhydrous simply means that the compound contains no water molecules.) The formation of hydrates is relatively common among ionic compounds, and it is usual to write the water molecules in such compounds at the end of the chemical formula, with the number of water molecules indicated by a normal case number. This provides an exception to the rules given above.

The majority of covalent compounds are carbon-based organic compounds, the chemical formulae of which are often written with carbon first, followed by hydrogen and then the remaining elements in alphabetical order (e.g. $\text{C}_2\text{H}_6\text{O}$, $\text{C}_4\text{H}_9\text{BrO}$, CH_3Cl).

The major shortcoming of a chemical formula is that it tells us little or nothing about the structure of the compound in question. To obtain this information, we require structural formulae.

Structural formulae

Chemists are interested in the way in which atoms are bonded together to form molecules. While molecular formulae are useful in telling us the chemical makeup of molecules, they only rarely give us any idea of which atom is bonded to which. For example, the molecular formula of water is always written as H_2O , but this tells us nothing about how the atoms are arranged in the molecule. We cannot tell from the molecular formula alone which of the three possible arrangements of atoms below is the correct one for H_2O .

Structural formulae attempt to show the way in which the atoms in a molecule are covalently bonded together, thereby giving us some structural information. The chemical symbols are still used for each element present, but now the constituent atoms are placed in the order in which they are bonded together and the bonds between neighbouring atoms are represented as lines. A single line represents a single bond, which, as we will see in the chapter on chemical bonding and molecular structure, consists of a pair of electrons. Consider for example the ammonia molecule, NH_3 . We can show the way in which the four atoms are bonded together in this molecule by drawing the structural formula as follows.

From this depiction, it is obvious that the nitrogen atom is bonded to three H atoms by single bonds. It is also common to see ammonia depicted as shown.

This gives us the same structural information as the previous diagram (the N atom is bonded to three H atoms by single bonds), but shows the molecule apparently adopting a slightly different geometry. This illustrates an important point about structural formulae: *structural formulae do not necessarily show the correct geometry of a compound*, simply because it is difficult to accurately represent three-dimensional molecules in two dimensions. While both of the depictions correctly show all of the bonds in the molecule, neither is strictly correct from a structural point of view as they do not show the actual three-dimensional arrangement of the atoms. Both of them also neglect the fact that there is a pair of electrons on the N atom which does not participate in bonding. This is termed a lone pair of electrons. While such electrons are often ignored in depictions of molecules (their presence is usually implied by the chemical formula), they can have significant structural consequences. Where necessary, they can be shown as follows.

In later chapters, you will find it can be important to show lone pairs on atoms, especially when you draw organic reaction mechanisms, which show the movement of electrons in bond-making and bond-breaking processes. Even with the inclusion of the lone pair, this is still not an accurate depiction of the ammonia molecule in a three-dimensional sense, but it shows the correct connections between the constituent atoms of the molecule. We will see later how to introduce three-dimensional elements into structural formulae.

It is in the world of organic chemistry that structural formulae are particularly useful. While many covalent inorganic compounds tend to be small molecules in which a single central atom is joined to 2, 3, 4, 5 or 6 surrounding atoms, organic molecules tend to exist as rings and chains, and have a huge variety of possible geometries. This is due to the unusual propensity of carbon atoms to bond to themselves, a property called **catenation**, which can lead to the formation of massive molecules. Each carbon atom in a molecule can form bonds to as many as four other carbon atoms, which means that even relatively small organic molecules have many different possible ways in which the constituent atoms can be bonded together. Structural formulae allow us to depict these possibilities.

Carbon is a tetravalent element, meaning that it prefers to form a total of four bonds within a molecule. These bonds may be single (one pair of electrons), double (two pairs of electrons) or triple (three pairs of electrons). This means that there are four different ways that a carbon atom can form a total of four bonds: four single bonds, two double bonds, a double bond and two single bonds, or a triple bond and a single bond. Hydrogen, on the other hand, is monovalent, meaning that it usually forms only one single bond to another atom and, in an organic molecule, this is most often to a carbon atom. This can be illustrated by the propane molecule, which has the chemical formula C_3H_8 . Given that each C atom must form four bonds and each hydrogen atom must form one, there is only one possible way of attaching all the elements; this is shown in the structural formula below.

We can see from this that the three carbon atoms of a propane molecule link to form a chain in which each carbon at the end of the chain (called a **terminal carbon**) is singly bonded to three hydrogen atoms, and the inner carbon is singly bonded to two hydrogen atoms. Notice that the structural formula of propane contains more information than the chemical formula. Both formulae identify the number of atoms (three C atoms and eight H atoms), but the structural formula also shows how the atoms are connected.

The propane molecule contains only C—C and C—H single bonds. It is also possible to have double bonds and triple bonds in organic molecules, which we designate by two and three lines respectively, as shown in figure 2.10.

FIGURE 2.10 Depictions of single, double and triple bonds between carbon atoms

The use of structural formulae can remove ambiguities inherent in chemical formulae. For example, the ethanol and dimethyl ether molecules have the same chemical formula, C_2H_6O . However, the structural formulae depicted in figure 2.11 clearly show the differences in the way the atoms are connected within the molecules.

FIGURE 2.11 Structural formulae of dimethyl ether and ethanol. Both molecules have the same chemical formula, C_2H_6O .

Molecules such as these that have the same chemical formula but different chemical structures are called **isomers**. Structural formulae are a convenient way to distinguish between isomers.

Two types of shorthand structural formulae are commonly used. The constituent atoms in **condensed structural formulae** are arranged in bonded groups, and the actual bonds are not drawn. For example, we would write the condensed structural formulae of dimethyl ether and ethanol as CH_3OCH_3 and CH_3CH_2OH respectively, which essentially gives us the same structural information as the structural formulae, but with a significant saving of space. Note that the condensed structural formulae attempt to show the order in which the atoms are bonded together, and differ from the chemical formula, which is C_2H_6O in both cases. Condensed structural formulae can also be drawn for more complex molecules such as 2-methylpropane, C_4H_{10} .

The condensed structural formula of this molecule can be written as $\text{CH}_3\text{CH}(\text{CH}_3)\text{CH}_3$, $(\text{CH}_3)_2\text{CHCH}_3$ or $(\text{CH}_3)_3\text{CH}$, all of which are equivalent. In these examples, any $-\text{CH}_3$ group in parentheses is understood to be bonded to the middle carbon of the longest carbon chain.

We can also use **line structures**, in which C atoms are not drawn explicitly, to depict molecules. Line structures are constructed according to the guidelines in figure 2.12.

FIGURE 2.12 Guidelines for drawing line structures

1. All bonds except C—H bonds are shown as lines.
2. C—H bonds and H atoms attached to carbon are not shown in the line structure.
3. Single bonds are shown as one line; double bonds are shown as two lines; triple bonds are shown as three lines.
4. Carbon atoms are not labelled. All other atoms are labelled with their elemental symbols.

Following the guidelines in figure 2.12, we would then write the line structure of propane, C_3H_8 , as follows.

In this diagram a carbon atom is implied at each end of the chain and at the kink in the chain. The carbon atoms are singly bonded to each other and, as there are no other elemental symbols in the structure, it is assumed that each carbon atom bonds to the appropriate number of hydrogen atoms so that it forms a total of four bonds. This means the terminal carbon atoms will bond to three hydrogen atoms and the central carbon atom will bond to two hydrogen atoms. We illustrate how to draw line structures further in worked example 2.8.

WORKED EXAMPLE 2.8

Drawing line structures

Construct line structures for compounds with the following structural formulae.

methyl *tert*-butyl ether
(an antiknock ingredient
in petrol)

propan-2-ol
(rubbing alcohol)

isoprene
(sourced from nature
to produce rubber)

Analysis

We are asked to convert the structural formulae above to line structures. To do this, we simply apply the guidelines given previously.

Solution

Using guidelines 1 and 2, we remove all C—H bonds and H atoms attached to C atoms from the structure, thereby leaving the carbon-based framework of each molecule (remember that Me = $-\text{CH}_3$). Guideline 3 states that double bonds remain as two lines. This gives us the following.

The final guideline tells us to remove the labels for all C atoms. This gives the following answer.

Is our answer reasonable?

To check that the line structures represent the correct substances, count the number of intersections and line ends, which should equal the number of C atoms in the compound. The first line structure has five, the second has three and the third has five, matching the chemical formulae. Therefore, our answers appear correct.

You should be familiar with line structures, and you should be able to convert from a structural formula to a line structure, and from a line structure to a structural formula. To do the latter, keep in mind that carbon atoms are not shown in a line structure, so the first step is to place a C at every line intersection or kink and at the end of every line. Then add singly bonded hydrogen atoms (—H) until every carbon atom has four bonds.

WORKED EXAMPLE 2.9

Converting line structures

Draw the structural formulae and determine the chemical formulae of the molecules in the following line structures.

Analysis

We know that line structures show all structural features except carbon atoms and C—H bonds. We can therefore convert a line structure into a structural formula in two steps. First, place a C at any unlabelled line end and at each line intersection or kink. Second, add hydrogen atoms until each carbon atom has four bonds. The chemical formula is then obtained by counting the number of atoms of each element.

Solution

Begin by placing a C at each intersection, kink and line end.

The second structure has four carbon atoms. The two terminal carbon atoms have just one bond, so each needs three hydrogen atoms. The carbon with the double bond to oxygen already has its complete set of four bonds. The other inner carbon atom has a bond to C and a bond to O, so it needs two hydrogen atoms. This gives the structural formula below, and the chemical formula $C_4H_8O_2$.

The third structure contains a triple bond. The terminal carbon atom needs one hydrogen atom, but the other carbon atom of the triple bond already has four bonds. The next carbon atom has two bonds, one to carbon and one to oxygen. Two hydrogen atoms are needed to give this atom four bonds, and this gives the structural formula below, and the chemical formula C_3H_4O .

Now add hydrogen atoms until each carbon atom has a total of four bonds. Each carbon atom in the first structure already has two bonds, so each needs two hydrogen atoms. This gives the structural formula below, and the chemical formula $C_2H_4Cl_2$.

Is our answer reasonable?

Check the consistencies of the structural formulae by counting the number of bonds associated with each carbon

atom. If you have converted the line structure correctly, each carbon atom will have four bonds.

PRACTICE EXERCISE 2.12

Convert the following line structures into structural and chemical formulae.

While line structures are the basis for the depiction of most molecules in the chemical literature, it is common to see variations on the rules we have outlined previously. For example, we might see butane, C_4H_{10} , written as any of the following.

All of these are acceptable alternatives for the 'strictly correct' depiction shown below.

Notice also that in molecules with no double or triple bonds, the carbon chain can be drawn in any orientation. The following equivalent line structures can be drawn for pentane, C_5H_{12} , but the first two are the most common.

The depiction of molecules as line structures can give rise to some very interesting shapes, and some of these have served as inspirations for the synthesis of particular molecules. Consider, for example, the molecules below, all of which have been synthesised.

cubane, C_8H_8

housane, C_5H_8

basketane, $C_{10}H_{12}$

Probably the most remarkable example of molecular synthesis inspired by line structures is the series of molecules called Nanoputians, which were reported in 2003 by Dr Stephanie Chanteau and Professor James Tour from Rice University in the USA. These are molecules that, when drawn as line structures, resemble the human form. Two examples of Nanoputians (named after the Lilliputians in Jonathan Swift's *Gulliver's Travels*) are shown in figure 2.13. Had we chosen to describe these with their chemical formulae ($C_{39}H_{42}O_2$ and $C_{38}H_{44}O_2$ for NanoKid and NanoBalletDancer, respectively) we would have no idea of the delightful shapes that representations of these molecules can display.

FIGURE 2.13

Line structures of: (a) NanoKid, and (b) NanoBalletDancer

Three-dimensional structures

While the structural formulae encountered so far give more structural information than chemical formulae, they do not necessarily give a complete representation of a molecule. For example, none of the molecules shown previously are flat, but you would not know this from looking at the structural formulae. We must therefore attempt to introduce some aspects of three-dimensionality in our representations. There are a number of ways this can be done.

Three-dimensional structural formulae

The simplest way of drawing a three-dimensional structure in two dimensions is to use a structural formula or line structure as a base, and then add some perspective. This is illustrated below using the molecule 1,2-difluorocyclopropane. This is a cyclic molecule consisting of a triangle of carbon atoms, with F atoms attached to two adjacent carbons. We can draw the line structure as shown.

However, when this molecule is viewed in three dimensions from side-on, we can immediately see that the flat line structure is not an adequate representation; each carbon atom in the ring has two attached atoms, either two H atoms or an H atom and an F atom, which point either above or below the plane of the ring. This leads to two possible relative arrangements of the F atoms within the molecule — either both on the same side of the ring, or on opposite sides — and hence two possible isomers named using the prefixes *cis* and *trans* (see figure 2.14).

FIGURE 2.14

Representations of the two possible isomers of 1, 2-difluorocyclopropane. The two F atoms may be arranged so that they are on either the same or opposite sides of the ring. In the diagram, carbon atoms are represented by black balls, hydrogen atoms by white balls, and fluorine atoms by green balls.

The *cis* isomer has both F atoms on the same side of the ring. (Note that it does not matter whether they are both on the top or bottom side of the ring — the same compound results.) The F atoms are on opposite sides of the ring in the *trans* isomer. We can show this in a line structure by drawing the bonds to these atoms as wedges. A **solid wedge** ($\blacktriangleright$) represents a bond coming out of the screen or page towards the observer, while a **hashed wedge** ($\cdots\blacktriangleright$) represents a bond going back into the screen or page. A normal line is used for bonds in the plane of the screen or page. Therefore, the two isomers can be drawn as line structures as shown, and it can be easily seen that they are different compounds.

When carbon is bonded to four atoms, those atoms generally adopt a tetrahedral arrangement around the carbon atom, as this arrangement places them as far as possible away from each other. It is conventional to draw the three-dimensional nature of the four bonds around a single carbon atom as follows.

In this representation, one bond goes into the plane of the screen or page, one comes out of the plane of the screen or page, and two lie in the plane of the screen or page. We can show the three-dimensionality of molecules containing more than one carbon atom by joining these individual units together. Such three-dimensional depictions are not limited to organic compounds; transition metal complexes and main group compounds can display a wide variety of geometries, and we can use analogous diagrams to portray these. For example, the sulfur hexafluoride, SF_6 , molecule comprises a central sulfur atom surrounded by six fluorine atoms, each of which sits at a vertex of an imaginary octahedron in what is called an octahedral geometry. We would draw such an arrangement as follows.

In this case we have the two 'vertical' bonds in the plane of the screen or page, while two bonds go into the plane and two bonds come out of the plane.

While it is possible to make remarkably detailed three-dimensional drawings using only a pen and paper, it is easier to use computers to draw somewhat more realistic depictions of molecules.

Ball-and-stick models

In a **ball-and-stick model**, balls of arbitrary size represent atoms and sticks represent chemical bonds. Figure 2.15 shows a ball-and-stick model of propane. The balls are usually drawn in different colours to distinguish between different elements present in the molecule (see figure 2.16). Such models generally enable the easy visualisation of three-dimensional features of the molecule.

FIGURE 2.15

Ball-and-stick model of propane, C_3H_8

FIGURE 2.16

The colours and sizes of balls used to represent atoms in this text

Hydrogen H		Fluorine F		Sulfur S		Zinc Zn	
Boron B		Sodium Na		Chlorine Cl		Bromine Br	
Carbon C		Magnesium Mg		Iron Fe		Silver Ag	
Nitrogen N		Silicon Si		Copper Cu		Iodine I	
Oxygen O		Phosphorus P					

Space-filling models

While ball-and-stick models are useful, they are far removed from reality — chemical bonds are not sticks, and the size of atoms is by no means arbitrary. A **space-filling model** recognises that a molecule is defined by the space occupied by its electrons, and attempts to represent the relative size of atoms within a molecule by showing the size of each atom's electron cloud. Recall from Rutherford's gold foil experiment (described in the introductory chapter on the atom) that electron clouds make up nearly the entire volume of any atom. Each atom in a space-filling model is shown as a distorted sphere representing the volume occupied by its electrons. These spheres merge into one another to build up the entire molecule. A space-filling model can tell us at a glance whether the electron clouds of atoms in a molecule overlap, and therefore whether those atoms are bonded together or not. Figure 2.17 shows a space-filling model of propane; notice that the spheres of the neighbouring C atoms overlap to a significant extent, implying these atoms are bonded together. The presence of C—H bonds is also obvious from the overlap of the spheres representing C and H. Figure 2.18 shows ball-and-stick and space-filling models of several chemical compounds common in everyday life.

FIGURE 2.17 Space-filling model of propane, C_3H_8

Space-filling model				

Other representations

It is often inconvenient, if not impossible, to show every atom in a large molecule such as a protein or nucleic acid, and it is usual to draw 'cartoon' type structures of such molecules. Figure 2.19 shows such a view of haemoglobin, the iron-containing protein that carries oxygen in human blood. Instead of showing each individual atom in the molecule ($\text{C}_{2952}\text{H}_{4664}\text{N}_{812}\text{O}_{832}\text{S}_8\text{Fe}_4$ is the molecular formula of one form of the protein), the protein chains are shown as 'ribbons' which fold in particular ways depending on their chemical environment.

Stereoviews are often helpful in visualising large molecules, as they allow the image to be viewed in three dimensions, although viewing them properly requires some practice. An example of a stereoview of DNA is shown in figure 2.20. The easiest way to view stereoviews (which are three-dimensional images) is to 'go cross-eyed'. You will eventually find that, with lots of practice, a three-dimensional image appears in the middle of the two structures in figure 2.20. If you do not get it the first time, keep trying!

FIGURE 2.19

A representation of the structure of haemoglobin showing four haem groups (the ball-and-stick models). The different coloured ribbons denote different parts of the protein.

FIGURE 2.20

Stereoview of DNA

Which of our various depictions is the ‘correct’ one? The answer is ‘none of them’. Atoms are not finite, coloured spheres and bonds are not sticks attached to atoms. The representations we use in chemistry are merely attempts to visualise things that, in all probability, are impossible to depict. However, this is not to say that our representations are useless. As we will see throughout this text, we can understand many important facets of molecular structure through studying these representations. But keep in mind at all times that the representations are models; nothing more and nothing less.

Mechanistic arrows in chemical reactions

Molecules are held together by chemical bonds, and when molecules undergo chemical reactions, bonds are broken and/or bonds are made. We can depict these bond-breaking and bond-making processes by means of **mechanistic arrows**.

A two-barbed mechanistic arrow, that is, , shows the movement of a pair of electrons. The electrons move from the tail to the head of the arrow. This can represent a number of possible chemical processes, some of which are detailed below. *Note:* In order to better understand the charges on the atoms in the following examples, you should read the section on formal charges in the chapter on chemical bonding and molecular structure.

Bond breaking

Consider the following bond-breaking process.

In this case, the arrow starts at the middle of the bond. The bond breaks in a **heterolytic** fashion, with both electrons ending up on the Cl atom. This gives rise to the formation of an H^+ cation (proton) and a Cl^- anion. It is important to realise that, even though both electrons in the bond end up on the Cl^- ion, one of the electrons in the bond ‘belonged’ to the chlorine atom to begin with. Thus, the Cl atom in HCl formally gains only one electron in the bond-breaking process, thereby leaving it with a single negative charge, and by the same reasoning the H atom formally loses only one electron, thereby leaving the H atom with a single positive charge.

Bond making

Consider the following bond-making process.

Here, a bond is formed between the carbonyl O atom and the H^+ ion, with the two electrons in the bond coming from one of the lone pairs of electrons on the carbonyl O atom. This leaves a formal positive charge on the O atom.

Charge neutralisation

Consider the following charge-neutralisation process.

The positively charged carbonyl O atom can be neutralised by taking two electrons from the double bond and locating them on the carbonyl O atom. The arrow starts halfway along the bond and finishes at the O atom. This process leaves the carbonyl C atom positively charged.

In the charge-neutralisation process below, proton loss to give a neutral compound occurs by taking the two electrons from an N—H bond and locating them on the N atom. The tail of the arrow therefore is situated halfway along the N—H bond and the head points to the N atom.

These examples illustrate some important facts about double-barbed mechanistic arrows. Firstly, the tail of the arrow must be situated at a source of an electron pair: that is, either halfway along a bond or on a lone pair of electrons. Some thought will convince you that this means a double-barbed mechanistic arrow can never start at either H^+ or an H atom (a very common mistake!). Similarly, the head of the arrow must be situated in a region able to accept a pair of electrons. Thus it would be unlikely, for example, for the head of an arrow to be at an atom bearing a partial negative charge, or a negatively charged ion. It is important to remember that total charge must be conserved in any mechanistic process. Thus, in all the examples above, both sides of the equations have the same total charge. It should also be noted that we can use more than one arrow to represent multiple simultaneous bond-making and bond-breaking processes. This is illustrated below.

Here, three processes occur essentially simultaneously.

1. OH^- removes a proton from a CH_3 group, resulting in the formation of H_2O .
2. The pair of electrons which were in the C—H bond move so as to give a $\text{C}=\text{C}$ double bond.
3. The C—Br bond breaks heterolytically, with both electrons in the bond moving to the Br, to give a Br^- ion.

A single-barbed arrow, i.e. , shows the movement of a single electron. Such arrows are usually found only in reactions involving radicals, chemical species which contain one or more unpaired electrons. An example is given below, in which the Br—Br single bond is broken in a **homolytic** fashion, such that each of the bonded atoms receives an electron, giving two bromine radicals.

You will make extensive use of mechanistic arrows in the later chapters of this text, especially in writing organic reaction mechanisms.

2.3 Nomenclature

LEARNING OBJECTIVE 2.3 Apply basic chemical nomenclature.

Representing molecules as images allows us to impart a great deal of information concerning molecular structure. But molecules can also be named, and there are occasions when this is more convenient than drawing a picture. In the early days of chemistry, the list of known compounds was short, and chemists could memorise the names of all of them. New compounds were often named by their discoverer after their place of origin, physical appearance or properties. Today, more than 180 million compounds are known and millions more are synthesised each year. Chemists consequently need systematic procedures for naming chemical compounds. The International Union of Pure and Applied Chemistry (IUPAC) has established uniform guidelines for naming various types of chemical substances, and chemists increasingly use IUPAC-approved names rather than their common counterparts. In this section we will introduce the rules for **nomenclature**, the system for the naming of compounds. You will encounter many chemical names in subsequent chapters, and the basics that you learn in this section will aid your interpretation of these names. We will investigate the naming of transition metal complexes in the chapter on transition metal chemistry. You should be aware that there are some compounds that are better known by their common, unsystematic name, and not their systematic IUPAC name. The best example of this is water, the systematic name of which is oxidane. Unsystematic names for a small number of common compounds are accepted by IUPAC.

CHEMICAL CONNECTIONS

IUPAC

IUPAC is the organisation responsible for helping chemists talk to each other about their science. It does this by developing and systematising the nomenclature, symbols and terminology that are required for chemistry. The names and formulae of chemical compounds together with the units and symbols used in chemistry are central to the language of chemists, and rules are required to tell people how to put them together and work out what they mean. The rules are regularly updated, both to make them simpler, and to provide ways of naming new kinds of molecules that were not envisaged when the rules were first written.

The different sets of rules for nomenclature, symbols and terminology appear in IUPAC's 'colour' books (figure 2.21 shows the covers of the Red Book and the Blue Book).

FIGURE 2.21 The Red Book and the Blue Book are two of IUPAC's 'rule books' for nomenclature, symbols and terminology.

IUPAC's colours books are:

- the Red Book (*Nomenclature of Inorganic Chemistry*)
- the Blue Book (*Nomenclature of Organic Chemistry*)
- the Green Book (*Quantities, Units and Symbols in Physical Chemistry*)
- the Purple Book (*Compendium of Polymer Terminology and Nomenclature*)
- the Gold Book (*Chemical Terminology*)
- the Orange Book (*Analytical Nomenclature*)
- the White Book (*Biochemical Nomenclature*)
- the Silver Book (*Compendium of Terminology and Nomenclature of Properties in Clinical Laboratory Sciences*).

Information about the books and links to some of them online can be found at IUPAC's website at: www.iupac.org/what-we-do/books/color-books.

Naming inorganic compounds

The way in which we name inorganic compounds (i.e. those not composed primarily of carbon and hydrogen) depends to some extent on the exact nature of the compound in question. We will examine the different possible types of inorganic compounds in this part of the chapter. You should appreciate that what follows is, of necessity, an abbreviated version of the IUPAC rules for naming inorganic compounds. The full version may be found at the IUPAC website (www.iupac.org).

Nonmetallic binary compounds

The written name of a compound includes the names of the elements it contains and information about the number of atoms of each element present. The elements have to occur in some order, and this is set by the same guidelines as for the chemical formula as seen in figure 2.9. Names can contain elemental names, roots derived from elemental names and prefixes indicating the number of atoms of each element. Tables 2.4 and 2.5 list the more important roots and prefixes that appear in the names of nonmetallic binary compounds, compounds that contain only two elements, neither of which are metals. Figure 2.22 summarises the rules for naming nonmetallic binary compounds.

TABLE 2.4 Common roots for naming nonmetallic binary compounds		
Element	Full name	Root
As	arsenic	arsen-
Br	bromine	brom-
C	carbon	carb-
Cl	chlorine	chlor-
F	fluorine	fluor-
H	hydrogen	hydr-
I	iodine	iod-
N	nitrogen	nitr-
O	oxygen	ox-
P	phosphorus	phosph-
S	sulfur	sulf-

TABLE 2.5 Number prefixes for chemical names			
Number	Prefix	Example	Name
1	mono-	CO	carbon monoxide ^(a)
2	di-	SiO ₂	silicon dioxide
3	tri-	NI ₃	nitrogen triiodide
4	tetra-	SnCl ₄	tin tetrachloride
5	penta-	PCl ₅	phosphorus pentachloride
6	hexa-	SF ₆	sulfur hexafluoride
7	hepta-	IF ₇	iodine heptafluoride

^(a) The final 'o' of the prefix is omitted in this case.

FIGURE 2.22 Guidelines for naming nonmetallic binary compounds

1. The element closer to the left of the periodic table appears first. If both elements are from the same group of the periodic table, the lower one appears first.
2. The element that appears first retains its elemental name.

3. The second element begins with a root derived from its elemental name and ends with the suffix *-ide*. Some common roots are listed in table 2.4.
4. When there is more than one atom of a given element in the formula, the name of the element usually contains a prefix that specifies the number of atoms present (unless this can be deduced from context). Common prefixes are given in table 2.5.

Numerical prefixes are essential in naming similar binary compounds. For example, nitrogen and oxygen form the six different compounds shown as space-filling models in figure 2.23: NO, nitrogen monoxide; NO₂, nitrogen dioxide; N₂O, dinitrogen oxide; N₂O₃, dinitrogen trioxide; N₂O₄, dinitrogen tetraoxide; and N₂O₅, dinitrogen pentaoxide.

FIGURE 2.23 Space-filling models of the six compounds formed between nitrogen and oxygen

WORKED EXAMPLE 2.10

Naming binary compounds

Name the following binary compounds: SO₂, CS₂, BCl₃ and BrF₅.

Analysis

None of these compounds contains a metallic element, so we apply the guidelines for nonmetallic binary compound nomenclature.

Solution

Name the first element, use a root plus *-ide* for the second element and indicate the number of atoms with prefixes.

Therefore, we obtain:

SO₂: sulfur dioxide

CS₂: carbon disulfide

BCl₃: boron trichloride

BrF₅: bromine pentafluoride.

PRACTICE EXERCISE 2.13

Name the neutral compounds that contain:

- (a) four atoms of bromine and one atom of silicon
- (b) three atoms of oxygen and one atom of sulfur
- (c) three atoms of fluorine and one atom of chlorine.

Binary compounds of hydrogen

Hydrogen requires special consideration because, as we saw earlier, it may appear first or second in the chemical formula of a compound and, as a result, it may appear first or second in the name. This is particularly evident in the diatomic molecules that hydrogen forms with elements from groups 1 and 17, which are named according to the guidelines in figure 2.22. For example, LiH is lithium hydride, and HF is hydrogen fluoride. With elements from groups 2 and 16, hydrogen forms compounds containing two atoms of hydrogen. Except for oxygen, there is only one commonly occurring binary compound for each of these elements, so the prefix *di-* is omitted. Examples are H₂S, hydrogen sulfide, and CaH₂, calcium hydride. Oxygen forms two binary compounds with hydrogen. These have unsystematic names: one is water, H₂O (systematic name oxidane), and the other is hydrogen peroxide, H₂O₂ (systematic name dioxidane). Binary compounds of hydrogen with elements from groups 13, 14 and 15 have unsystematic names in common use; B₂H₆ is diborane (systematic name diborane(6)), CH₄ is methane (systematic name carbane), NH₃ is ammonia (systematic name azane) and PH₃ is phosphine (systematic name phosphane). In fact, carbon, boron and silicon form many different binary compounds with hydrogen, and only the simplest of these are listed here.

Ionic compounds

Binary compounds which contain metal ions are often ionic, consisting of a positively charged ion (a cation) and a negatively charged ion (an anion). We name binary ionic compounds with the cation first and the anion, which takes the suffix *-ide*, last. For example, NaCl is named sodium chloride, while KI is named potassium iodide. Compounds such as CaF₂, in which the numbers of cations and anions are not the same, do not require the actual number of cations and anions to be specified. Thus, CaF₂ is named calcium fluoride, not calcium difluoride. The reason for this is that calcium is a group 2 element, and will therefore form only a 2+ cation. This will always combine with two 1– anions to form a neutral ionic compound, and therefore we need not specify *di*fluoride. Using the same reasoning, we can see that Na₂S and MgI₂ are named sodium sulfide and magnesium iodide, respectively. Ionic compounds containing polyatomic ions such as NH₄⁺, NO₃[–] and SO₄^{2–} are again named with the cation followed by the anion, but you will need to learn both the names and the charges of the common polyatomic ions to be able to name, and write chemical formulae for, compounds containing these ions. Table 2.6 lists the more common polyatomic ions.

TABLE 2.6 Names and chemical formulae of some common polyatomic ions

Formula	Name	Formula	Name
Cations		Oxoanions	
NH ₄ ⁺	ammonium	SO ₄ ^{2–}	sulfate
H ₃ O ⁺	hydronium(oxonium)	SO ₃ ^{2–}	sulfite
Hg ₂ ²⁺	dimercury(2+)	NO ₃ [–]	nitrate
Diatomic anions		NO ₂ [–]	nitrite
OH [–]	hydroxide	PO ₄ ^{3–}	phosphate
CN [–]	cyanide	MnO ₄ [–]	permanganate
Anions containing carbon		CrO ₄ ^{2–}	chromate
CO ₃ ^{2–}	carbonate	Cr ₂ O ₇ ^{2–}	dichromate
HCO ₃ [–]	hydrogencarbonate (bicarbonate)	ClO ₄ [–]	perchlorate
CH ₃ COO [–]	acetate	ClO ₃ [–]	chlorate
C ₂ O ₄ ^{2–}	oxalate	ClO ₂ [–]	chlorite
		ClO [–]	hypochlorite

The **oxoanions** listed in table 2.6 consist of a central atom surrounded by oxygen atoms. Their names can be deduced using the rules listed in figure 2.24.

FIGURE 2.24 Guidelines for naming oxoanions

1. The name has a root taken from the name of the central atom (e.g. chlorate, ClO₃[–], and nitrite, NO₂[–]).
2. When an element forms two different oxoanions, the one with fewer oxygen atoms ends in *-ite*, and the other ends in *-ate* (e.g. SO₃^{2–}, sulfite, and SO₄^{2–}, sulfate).
3. Chlorine, bromine and iodine each form four different oxoanions that are distinguished by prefixes and suffixes. The nomenclature of these ions is illustrated for bromine, but it applies to chlorine and iodine as well: BrO[–], hypobromite; BrO₂[–], bromite; BrO₃[–], bromate; and BrO₄[–], perbromate.
4. A polyatomic anion with a charge more negative than 1– may add H⁺ to give another anion. These anions are named from the parent anion by adding the word hydrogen. For example, HCO₃[–] is hydrogencarbonate, HPO₄^{2–} is hydrogenphosphate and H₂PO₄[–] is dihydrogenphosphate.

Naming organic compounds

Organic compounds are composed primarily of carbon and hydrogen atoms, and the naming system used is based on the number of carbon atoms in the particular molecule. Not surprisingly, there are an enormous number of rules for naming organic compounds and at this stage we will restrict ourselves to the basics. Indeed, computer programs are now able to generate names from nearly any structural diagram, providing a helpful supplement to knowledge of the rules of IUPAC nomenclature.

Functional groups

The concept of functional groups underpins all of organic chemistry and makes it the systematic discipline that it is. A **functional group** is simply a group of one or more atoms within a molecule, bonded together in a particular fashion, and is usually the point of reaction within a molecule. Organic molecules are named primarily according to the functional group or groups they contain. The power of the functional group concept is that molecules containing the same functional group tend to behave in chemically similar ways, and this allows us to predict their reactivity towards particular reagents with some confidence. For example, although the two molecules below look quite different, they both contain a carbonyl functional group, $\text{C}=\text{O}$, as part of an aldehyde group, $-\text{CHO}$.

We can therefore predict that both molecules will undergo a reaction called oxidation, in which the $-\text{CHO}$ group is converted to a $-\text{COOH}$ (carboxylic acid) functional group. Similarly, both compounds will react with species called reducing agents, which will convert the $-\text{CHO}$ group to a $-\text{CH}_2\text{OH}$ (primary alcohol) group. We will learn a lot more about the specific reactions involved later in this text.

It therefore makes sense to name organic compounds according to their functional groups, and we will learn how this is done in this part of the chapter. But first, the common functional groups that you will encounter are outlined in table 2.7. Note that R is a commonly used symbol to denote either a hydrogen atom or an alkyl group (see table 2.9). You should be able to identify the presence of each of these functional groups in any molecule.

TABLE 2.7 Common functional groups

Functional group	Name of group	Found in	R =
	hydroxyl	alcohols	C
	carbonyl	aldehydes	C or H
	carbonyl	ketones	C
	carboxyl	carboxylic acids	C or H

Alcohols

The $-\text{OH}$ (hydroxyl) group is present in all alcohols. It is attached to a carbon atom, which itself may be attached to one, two or three other carbon atoms (the exception is methanol, CH_3OH , which contains only

one carbon atom). Alcohols are classified as primary (1°), secondary (2°) or tertiary (3°) according to this number, as shown in figure 2.25.

We can also classify carbon atoms within molecules according to this scheme. Thus a carbon atom attached to one carbon atom (as in a primary alcohol) is called a **primary carbon atom**, a carbon atom attached to two carbon atoms (as in a secondary alcohol) is called a **secondary carbon atom** and a carbon atom attached to three carbon atoms (as in a tertiary alcohol) is called a **tertiary carbon atom** (figure 2.25).

FIGURE 2.25 Structural formulae of primary, secondary and tertiary alcohols

WORKED EXAMPLE 2.11

Writing possible structures for alcohols

Write condensed structural formulae for the two alcohols with the molecular formula C_3H_8O . Classify each as primary, secondary or tertiary.

Analysis

We know that alcohols contain the $-\text{OH}$ group. We must therefore draw the two possible structures of the formula C_3H_8O which contain an $-\text{OH}$ group, remembering that each carbon atom in the molecule must have four bonds. In problems like this, it is generally easiest to draw the structural formula, and then convert it to the condensed form.

Solution

We have a three-carbon chain in the molecule, and so the $-\text{OH}$ group can be attached only to either the terminal carbon (it does not matter which one; the same compound results regardless of which end we attach the functional group to) or the central carbon. Therefore, we begin by drawing the carbon chain, then attach the $-\text{OH}$ group in the two possible positions, and fill in the hydrogen atoms. Doing this gives us the following two compounds.

or

1° alcohol

The compound above is a primary alcohol as the $-\text{OH}$ group is attached to a carbon atom directly bonded to only one other carbon.

or

2° alcohol

In contrast to the first structure, the above compound is a secondary alcohol, the central carbon in the chain being bonded to two other carbon atoms.

PRACTICE EXERCISE 2.14

Write condensed structural formulae for the eight alcohols that have the molecular formula $C_5H_{12}O$. Classify each as primary, secondary or tertiary.

Aldehydes and ketones

Aldehydes and ketones both contain the same functional group, the carbonyl group ($C=O$), but they differ in the way that the carbonyl group is bonded to the rest of the molecule. Aldehydes *always* have the carbon atom of the carbonyl group bonded to at least one hydrogen atom, and this means that the carbonyl group of an aldehyde must always be at the *end* of a carbon chain. Conversely, the carbon atom of the carbonyl group in ketones is *always* bonded to two other carbon atoms, and therefore can *never* be at the end of a carbon chain. We can write the aldehyde explicitly as follows.

Alternatively, we can write it as RCHO in a condensed structural formula. The differences between aldehydes and ketones are shown in figure 2.26.

FIGURE 2.26 Structural formulae and ball-and-stick models of an aldehyde and a ketone

**WORKED EXAMPLE 2.12****Writing possible structures for aldehydes**

Write condensed structural formulae for the two aldehydes with the chemical formula C_4H_8O .

Analysis

We know that the functional group in aldehydes can only be at the end of a carbon chain. In this case, we have four carbon atoms, and there are two possible ways of connecting these so that the $-\text{CHO}$ group lies at the end of a chain.

Solution

Begin by writing the $-\text{CHO}$ group and then attaching the remaining three carbon atoms. We can connect the four carbon atoms in a straight chain or a branched chain. The two possibilities are as follows.

PRACTICE EXERCISE 2.15

Write condensed structural formulae for the three ketones with the molecular formula $\text{C}_5\text{H}_{10}\text{O}$.

Carboxylic acids

The functional group found in all carboxylic acids is the carboxyl group, —COOH . We can write this explicitly as follows.

More commonly, it is written as RCOOH . As the carbon atom of a carboxyl group can bond to only one other atom, carboxyl groups are always found at the end of a carbon chain.

WORKED EXAMPLE 2.13

Writing possible structures for carboxylic acids

Write a condensed structural formula for the carboxylic acid with the molecular formula $\text{C}_3\text{H}_6\text{O}_2$.

Analysis

There is only one possible compound we can draw here. It must contain a three-carbon chain with a —COOH group on the end.

Solution

Begin by drawing the —COOH group and then attach the remaining carbon atoms. Finish by adding hydrogen atoms so that all the carbon atoms have four bonds. This gives us the compound shown below.

PRACTICE EXERCISE 2.16

Write condensed structural formulae for the four carboxylic acids that have the molecular formula $\text{C}_5\text{H}_{10}\text{O}_2$.

The nomenclature of alkanes

The names of some organic compounds have already been used in this chapter, but we have not yet learned how these names are derived. Organic compounds, as mentioned previously, are named according to their functional group. The first step in naming most organic compounds is to identify the functional group that they contain. However, we will begin by looking at a series of compounds that are not considered to contain any functional group at all: the alkanes.

Alkanes are molecules that contain only carbon and hydrogen and in which carbon atoms are joined by single bonds only. Alkanes can be divided into two classes, depending on the overall geometry of the carbon atoms. Alkanes in which the carbon atoms are joined in chains are called **acyclic alkanes** and have the general formula $\text{C}_n\text{H}_{2n+2}$. The carbon atoms in alkanes can also be joined together to form one or more rings, and such compounds are called **cycloalkanes**. All alkanes belong to a group of organic compounds called **hydrocarbons**, which are molecules composed solely of carbon and hydrogen. Alkanes are sometimes called **saturated hydrocarbons** to denote the fact that all the carbon–carbon bonds are single. As there are no functional groups in alkanes, we name them according to the length of the longest carbon chain. There are two parts to the name of an alkane: a prefix, indicating the number of carbon atoms in the chain, and the ending *–ane*. The prefixes for carbon chain lengths up to 10 carbon atoms are shown in table 2.8.

TABLE 2.8 Prefixes used in the IUPAC system for chain lengths of 1 to 10 carbon atoms

Prefix	Number of carbon atoms
meth-	1
eth-	2
prop-	3
but-	4
pent-	5
hex-	6
hept-	7
oct-	8
non-	9
dec-	10

The simplest alkane is methane, which contains one carbon atom and has the formula CH_4 . Note that the suffix and prefix are not hyphenated, but are written together as one word. The alkane with six carbon atoms in a straight chain ($\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3$) is likewise called hexane. Names for the straight-chain alkanes are straightforward, but things become more complex for alkanes in which the carbon chain is branched. In order to name such alkanes, identify the longest straight carbon chain (the **parent chain**), and then treat any groups which branch off this chain as **substituents**. The IUPAC name of an alkane with a branched chain consists of a root name that indicates the longest chain of carbon atoms in the compound, substituent names that indicate the groups bonded to the parent chain, and numbers that indicate the carbon atom to which the substituents are attached. This is illustrated below for 4-methyloctane, C_9H_{20} , in which the longest carbon chain contains eight carbon atoms (hence octane) and the $-\text{CH}_3$ (methyl) group bonded to C(4) is a substituent (hence *4-methyl*).

The substituents in alkanes are named according to the alkane from which they are derived. For example, a $-\text{CH}_3$ substituent is derived from methane, CH_4 , through the removal of one H atom. Similarly, a $-\text{C}_2\text{H}_5$ substituent is derived from ethane, C_2H_6 , by removal of one H atom. A substituent derived from an alkane by the removal of one H atom is called an **alkyl group** and is commonly represented by the symbol R. Alkyl groups are named by dropping the *-ane* from the name of the parent alkane and adding the suffix *-yl*. Therefore, a $-\text{CH}_3$ substituent is called *methyl*, and a $-\text{C}_2\text{H}_5$ substituent *ethyl*. Table 2.9 gives names and structural formulae for eight of the most common alkyl groups. Note that when alkyl substituents contain three or more carbon atoms there is more than one possible arrangement of the carbon atoms in the substituent. We differentiate between these possibilities using the prefixes *iso*, *sec*- and *tert*-. *Iso* implies the presence of a $-\text{CH}(\text{CH}_3)_2$ group at the end of the substituent carbon chain (the only possibility for a three-atom chain), while the prefixes *sec*- and *tert*- imply that the substituent is bonded to the longest carbon chain via a secondary or tertiary carbon atom, respectively. When *sec*- and *tert*- are part of a name, they are always italicised and hyphenated. However, *iso*, as used in both isopropyl and isobutyl, is not treated as a prefix like *sec*- and *tert*-, and is neither italicised nor hyphenated.

TABLE 2.9 Names, formulae and abbreviations of the most common alkyl groups

Name	Condensed structural formula	Abbreviation
methyl	$-\text{CH}_3$	Me
ethyl	$-\text{CH}_2\text{CH}_3$	Et
propyl	$-\text{CH}_2\text{CH}_2\text{CH}_3$	
isopropyl	$ \begin{array}{c} -\text{CHCH}_3 \\ \\ \text{CH}_3 \end{array} $	i-Pr
butyl	$-\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3$	Bu
isobutyl	$ \begin{array}{c} -\text{CH}_2\text{CHCH}_3 \\ \\ \text{CH}_3 \end{array} $	i-Bu

tert-butyl

t-Bu

The complete IUPAC rules for naming alkanes are given in figure 2.27.

FIGURE 2.27 Guidelines for naming alkanes

1. The name for an alkane with an unbranched chain of carbon atoms consists of a prefix showing the number of carbon atoms in the chain (table 2.8) and the ending *-ane*.
2. For branched-chain alkanes, the longest chain of carbon atoms is the parent chain, and its name becomes the root name.
3. For an alkane with one substituent, number the parent chain so that the carbon atom bearing the substituent is given the lowest possible number. For example, we number the five-carbon chain in the following compound from the right-hand end.

4. Give the substituent on the parent chain a name and a number. The number shows the carbon atom of the parent chain to which the substituent is bonded. Use a hyphen to connect the number to the name. For example, the methyl group in 3-methylpentane is attached to C(3), as shown below.

5. If there are two or more identical substituents, number the parent chain from the end that gives the lower number to the substituent closest to the end of the chain. If there are two or more identical substituents, the number of times they occur is indicated by the prefixes *di-*, *tri-*, *tetra-*, *penta-*, *hexa-* and so on. A comma is used to separate position numbers. Of the two possibilities below, we choose the one that numbers the carbon atoms to which the methyl groups are attached as 2 and 4, rather than 3 and 5.

6. If step 5 leads to more than one possibility, number the parent chain such that the first point of difference has the lowest possible number. Of the two possibilities below, we choose the one that numbers the methyl group shown in red 3 rather than 4.

7. If there are two or more different substituents, list them in alphabetical order, and (as usual) number the chain from the end that gives the lower number to the substituent encountered first or that provides the first point of difference. If there are different substituents in equivalent positions on opposite ends of the parent chain, the substituent of lower alphabetical order is given the lower number. The importance of alphabetically ordering the substituents is shown in the following example.

8. The prefixes *di-*, *tri-*, *tetra-* and so on, and the hyphenated prefixes *sec-* and *tert-* are disregarded for the purposes of placing the substituents in alphabetical order. Note that both isobutyl and isopropyl substituents are treated as beginning with the letter 'i'. Put the names of the substituents in alphabetical order first, and then insert the prefix. In the following example, the substituents are ordered as ethyl and methyl, not dimethyl and ethyl.

WORKED EXAMPLE 2.14

Writing IUPAC names for alkanes

Write IUPAC names for the following alkanes.

Analysis

We need to follow the rules for naming alkanes outlined previously. When naming alkanes, start by identifying the longest carbon chain, and then identify and number the substituents.

Solution

We will consider each alkane in turn. The longest carbon chain in (a) contains four carbon atoms and therefore will be named as a substituted butane. We then number the parent chain to give the methyl substituent the lowest possible number. This is done in either of the two equivalent ways shown below (note that the substituent is at C(2) in both cases).

We now name the substituent and specify its position on the parent chain to obtain the full name. This alkane is therefore named 2-methylbutane.

The longest carbon chain in (b) contains seven carbon atoms, and therefore it will be named as a substituted heptane. There are two substituents in this molecule: a methyl group and an isopropyl group, and therefore we must number the chain to give the substituent closest to the end of the chain the lowest number. This is shown in the following diagram, where we again have two equivalent possibilities.

To name the alkane, list the substituents in alphabetical order and specify their positions on the parent chain. As isopropyl comes before methyl, this alkane is named 4-isopropyl-2-methylheptane.

Is our answer reasonable?

The easiest way to check the answers to this type of question is to work backwards from the name we have deduced, and derive the chemical structure. If we do that in this case, we find that our answers are correct.

PRACTICE EXERCISE 2.17

Write the IUPAC names for the following alkanes.

(a)

(b)

Constitutional isomerism in alkanes

The alkanes provide an excellent example of the different ways in which a particular number of carbon and hydrogen atoms may be joined. There is only one order of attachment, and hence one way of writing CH_4 (methane), C_2H_6 (ethane) and C_3H_8 (propane). However, when we come to C_4H_{10} two orders of attachment of atoms are possible.

In one of these, butane, the four carbon atoms are bonded in an unbranched chain; in the other, 2-methylpropane, three carbon atoms are bonded in a chain, with the fourth carbon atom as a branch. Butane and 2-methylpropane are constitutional isomers. **Constitutional isomers** are compounds with the same chemical formula but a different order of attachment of the constituent atoms. Constitutional isomers can usually be distinguished by their differing physical properties; butane and 2-methylpropane provide a good example of this; butane boils at -0.5°C , while 2-methylpropane boils at -11.6°C . If we consider C_5H_{12} , we can obtain the three constitutional isomers shown below.

The number of possible constitutional isomers becomes very large very quickly. For example, the alkane with the chemical formula $\text{C}_{25}\text{H}_{52}$ has a staggering 36 797 588 possible constitutional isomers. Constitutional isomers are not unique to alkanes, and can be found throughout organic chemistry; indeed, worked examples 2.11 and 2.12 involved drawing constitutional isomers of alcohols and aldehydes, respectively.

WORKED EXAMPLE 2.15
Recognising constitutional isomers

Do the structural formulae in each of the following pairs of molecules represent the same compound or constitutional isomers?

Analysis

To determine whether these structural formulae represent the same compound or constitutional isomers, we must first find the longest chain of carbon atoms. Note that it makes no difference whether the chain is drawn straight or bent. We then number the longest chain from the end nearest the first branch and compare the lengths of each chain, and the sizes and locations of any branches. Structural formulae that have the same order of attachment of atoms represent the same compound; those which have different orders of attachment of atoms represent constitutional isomers. Note that similarities or differences between structural formulae are sometimes made clearer if they are drawn as line structures.

Solution

(a) Each structural formula has an unbranched chain of six carbon atoms. The two structures are identical and represent the same compound.

(b) Each structural formula has a chain of five carbon atoms with two branches. Although the branches are identical, they are at different locations on the chains. Therefore, these structural formulae represent constitutional isomers.

PRACTICE EXERCISE 2.18

Do the structural formulae in each of the following pairs of molecules represent the same compound or constitutional isomers?

WORKED EXAMPLE 2.16**Drawing constitutional isomers**

Draw structural formulae for the five constitutional isomers with the molecular formula C_6H_{14} .

Analysis

There are six carbon atoms in the molecule, so we can expect constitutional isomers with longest carbon chain lengths of six, five, four and possibly three. We must draw all possible isomers with these chain lengths.

Solution

The constitutional isomers of C_6H_{14} are as follows.

Note that we find that there is no way of writing C_6H_{14} with only three carbon atoms in the longest chain.

Is our answer reasonable?

There are no other possible arrangements of six carbon atoms and fourteen hydrogen atoms, each singly bonded to each other. Therefore, we can be confident our answers are correct.

PRACTICE EXERCISE 2.19

Draw the nine constitutional isomers with the formula C_7H_{16} .

CHEMICAL CONNECTIONS**Bosutinib**

In this chapter, we have looked at how to name some small organic molecules. In the case of large molecules, IUPAC names start becoming unwieldy, and we often give them trivial names instead. This is particularly true of drug molecules; for example, when we take a tablet containing *N*-(4-hydroxyphenyl)ethanamide to relieve pain, we refer to it as paracetamol. It is also generally much easier to draw the structure of a large molecule than to name it.

The molecule drawn below has the IUPAC name 4-[(2,4-dichloro-5-methoxyphenyl)amino]-6-methoxy-7-[3-(4-methylpiperazin-1-yl)propoxy]quinoline-3-carbonitrile, but is better known by its trivial name 'bosutinib'. In 2012 it was approved by the US FDA (the US Food and Drug Administration) for use as a drug against a particular type of leukaemia.

However, prior to this approval, scientists in England and the USA investigating the efficacy of this drug found some unusual results when they looked at its structure. They found that their 'bosutinib', which they had bought from a particular chemical supplier, was in fact not bosutinib at all, but a constitutional isomer of bosutinib which had the following structure.

You can see that the parts of the molecules highlighted in red are not the same. Sadly, this meant they had wasted a significant amount of time and money studying the wrong drug! This was presumed to have arisen from the use of the wrong molecule in the synthesis of bosutinib by the chemical supplier. In order to prepare authentic bosutinib, the molecule 2,4-dichloro-5-methoxyaniline is required, but the chemical supplier must have mistakenly used the constitutional isomer 3,5-dichloro-4-methoxyaniline.

2,4-dichloro-5-methoxyaniline

3,5-dichloro-4-methoxyaniline

How this mistake occurred is not known, but this story provides a very good chemical lesson that you should remember — regardless of which field of science you are in — always check to make sure that the stuff in the bottle is in fact what it says on the label!

General organic nomenclature

The principles of IUPAC nomenclature as applied to alkanes can be extended to the naming of any organic compound. The name we give to any compound with a chain of carbon atoms consists of three parts: a prefix, an infix and a suffix. Each part provides specific information about the structural formula of the compound.

1. The prefix shows the number of carbon atoms in the parent chain. Prefixes that show the presence of 1 to 10 carbon atoms in a chain were given in table 2.8.
2. The infix shows the nature of the carbon–carbon bonds in the parent chain. The three possibilities are given in table 2.10.
3. The suffix shows the class of compound to which the substance belongs, and therefore the functional group(s) present in the compound. The suffixes for the classes of compound we have already met are as shown in table 2.11.

TABLE 2.10 The three possible infixes and their meanings

Infix	Nature of carbon–carbon bonds in the parent chain
-an-	all single bonds
-en-	one or more double bonds
-yn-	one or more triple bonds

TABLE 2.11 Some suffixes and the class of compound that they designate

Suffix	Class of compound
-e	hydrocarbon
-ol	alcohol
-al	aldehyde
-one	ketone
-oic acid	carboxylic acid

We can illustrate the use of prefixes, infixes and suffixes with respect to the following four organic compounds. We will divide each name into a prefix, an infix and a suffix, and specify the information about the structural formula that is contained in each part of the name.

The prefix *prop-* means three carbon atoms in the parent chain. The infix *-en-* refers to the presence of one or more $\text{C}=\text{C}$ double bonds in the molecule, while the suffix *-e* means that the compound is a hydrocarbon, composed of only carbon and hydrogen atoms.

The prefix *eth-* means two carbon atoms in the parent chain. The infix *-an-* means there are no carbon–carbon multiple bonds in the molecule, and the suffix *-ol* means that there is an alcohol functional group in the molecule.

The prefix *pent-* means five carbon atoms in the parent chain. The infix *-an-* means there are no carbon–carbon multiple bonds in the molecule, and the suffix *-oic acid* refers to the presence of a carboxylic acid in the molecule.

The prefix *eth-* means two carbon atoms in the parent chain. The infix *-yn-* means that there are one or more $\text{C}\equiv\text{C}$ triple bonds in the molecule. The suffix *-e* means that the compound is a hydrocarbon, composed of only carbon and hydrogen atoms.

We can summarise this information in the following diagram.

Notice that, in each of these examples, there is no ambiguity about the position of the functional group. We will deal later with examples where the position is not as clear.

PRACTICE EXERCISE 2.20

Combine the proper prefix, infix and suffix to write the IUPAC name for each of the following compounds.

We have seen in this chapter that such apparently disparate topics as units, nomenclature and representations of molecules are all part of the language of chemistry. There is still much of this language for you to learn, but this chapter has introduced many of the fundamentals that you will need in order to understand and appreciate the following chapters. Indeed, it is likely that you will often need to refer back to this chapter when you come across examples of measurement, representations of molecules or nomenclature in later chapters.

SUMMARY

2.1 Use measurements and units in calculations.

All measurements have an associated unit and uncertainty. The units used for measurements are based on the set of seven SI base units, which can be combined to give various derived units. The SI base units are the metre, kilogram, second, kelvin, mole, ampere and candela. Prefixes can be used to denote multiplication of these units by powers of 10. Dimensional analysis, which uses the fact that units undergo the same kinds of mathematical operations as the numbers to which they are attached, can be used as an aid to determining the correct form of an equation. Some non-SI units are in common usage but can be converted to SI units using a conversion factor.

Uncertainties arise in any measurement from the limitations of the apparatus used to make the measurement. Some idea of the uncertainty and therefore precision in a measurement can be obtained from the number of significant figures to which the measurement is quoted.

Expressing a number in scientific notation can make it easier to determine the number of significant figures. There will always be uncertainty in the final figure of any measurement. The accuracy of a measurement shows how close to the true value the measurement is, while the precision of a measurement represents how reproducible it is.

When measurements are manipulated in equations, the following rules apply.

1. When measurements are multiplied or divided, the number of significant figures in the answer should not be greater than the number of significant figures in the least precise measurement.
2. When measurements are added or subtracted, the answer should have the same number of decimal places as the quantity with the fewest number of decimal places.

2.2 Represent substances and processes using common chemistry conventions.

The chemical formula of a substance shows the relative number of each type of atom present, but gives no structural information. The rules for writing chemical formulae of binary compounds are as follows.

1. With the exception of hydrogen, the element further to the left in the periodic table appears first.
2. If hydrogen is present, it appears last except when the other element is from group 16 or 17 of the periodic table.
3. If both elements are from the same group of the periodic table, the lower one appears first.

The chemical formulae of ionic compounds are written with the cation followed by the anion, while organic compounds have C and H first, followed by the rest of the elements in alphabetical order.

Structural formulae attempt to show particular aspects of molecular structure in both two and three dimensions. Such depictions are especially important in organic chemistry where catenation leads to an enormous number of possible carbon-based molecules. Structural formulae are drawn using one line to represent single bonds, two lines for double bonds and three lines for triple bonds. Carbon atoms at the end of a carbon chain are called terminal carbon atoms. Structural

formulae can help distinguish between isomers. Two types of shorthand structural formulae are widely used; condensed structural formulae do not include explicit depictions of bonds between atoms, while line structures remove atom labels for carbon atoms and all hydrogen atoms that are bonded to carbon atoms. Three-dimensional aspects can be introduced into structural formulae through the use of hashed and solid wedges, which show bonds going away from and coming towards the observer, respectively. Ball-and-stick models and space-filling models are two other methods where three-dimensionality may be shown. Mechanistic arrows can be used to show the movement of electrons in chemical processes. The tail of the arrow is situated at the electron source and the arrow head shows the destination.

2.3 Apply basic chemical nomenclature.

Ionic compounds are named with the cation first, followed by the anion, while oxoanions are named according to an extensive set of rules.

1. The element closer to the left of the periodic table appears first. If both elements are from the same group of the periodic table, the lower one appears first.
2. The element that appears first retains its elemental name.
3. The second element begins with a root derived from its elemental name and ends with the suffix *-ide*.
4. When there is more than one atom of a given element in the formula, the name of the element usually contains a prefix that specifies the number of atoms present.

Binary compounds containing hydrogen can be named with hydrogen either first or second, depending on the position of the other element in the periodic table, according to the above rules.

Chemical species can be named according to sets of rules prescribed by IUPAC. The rules for naming nonmetallic binary compounds are as follows.

Organic compounds are named primarily according to their functional group; those of importance in this chapter are the —OH group found in alcohols, the —CHO group found in aldehydes, the C=O group found in ketones and the —COOH group found in carboxylic acids. Alkanes belong to the group of compounds called hydrocarbons and are sometimes called saturated hydrocarbons. Those consisting solely of chains of carbon atoms are called acyclic alkanes, while those containing one or more rings of carbon atoms are called cycloalkanes. Their nomenclature is based on the longest carbon chain within the molecule, with a prefix denoting the length of that chain. Names of organic compounds generally comprise a prefix, infix and suffix. The prefix shows the number of carbon atoms in the parent chain, the infix shows the nature of the carbon-carbon bonds in the parent chain, and the suffix shows the class of compound to which the substance belongs, and therefore the functional group(s) present in the compound.

Constitutional isomers of alkanes have the same chemical formulae but different structural formulae and hence different names. These isomers generally have different physical properties.

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation
SI units	2.1	The SI base units — metre, kilogram, second, kelvin, mole, ampere and candela — are used either directly or to derive units for any measurement in chemistry.
SI prefixes	2.1	SI prefixes are used to create larger and smaller units. The prefixes help us to convert between differently sized units.
Dimensional analysis	2.1	Dimensional analysis assists in determining the correct form of an equation through knowledge of the units of all components of the equation.
Rules for significant figures in calculations	2.1	The following rules are used to round answers to the correct number of significant figures. • When measurements are multiplied or divided, the number of significant figures in the answer should not be greater than the number of significant figures in the least precise measurement. • When measurements are added or subtracted, the answer should have the same number of decimal places as the quantity with the smallest number of decimal places.
Rules for writing chemical formulae of binary compounds	2.2	The following rules are used to write the correct chemical formulae for compounds containing only two elements. 1. With the exception of hydrogen, the element further to the left in the periodic table appears first. 2. If hydrogen is present, it appears last except when the other element is from group 16 or 17 of the periodic table. 3. If both elements are from the same group of the periodic table, the lower one appears first. 4. If the compound is ionic, we write the cation first, followed by the anion.
Rules for drawing line structures	2.2	These rules are used for converting structural formulae to line structures, and can also be used to carry out the reverse operation. 1. All bonds except C—H bonds are shown as lines. 2. C—H bonds and H atoms attached to carbon are not shown in the line structure. 3. Single bonds are shown as one line; double bonds are shown as two lines; triple bonds are shown as three lines. 4. Carbon atoms are not labelled. All other atoms are labelled with their elemental symbols.
Hashed and solid wedges	2.2	These are used to introduce three-dimensional aspects into structural formulae. A solid wedge () represents a bond coming out of the screen or page, while a hashed wedge () represents a bond going back into the screen or page. A normal line is used for bonds in the plane of the screen or page.
Mechanistic arrows	2.2	These are used to show the movement of electrons in chemical processes. Single-barbed arrows show the movement of a single electron, while two-barbed arrows show the movement of electron pairs. The direction of electron movement is from the tail of the arrow to the head.
Naming nonmetallic binary compounds	2.3	These rules are used to name compounds containing only two nonmetallic elements. 1. The element closer to the left of the periodic table appears first. If both elements are from the same group of the periodic table, the lower one appears first. 2. The element that appears first retains its elemental name. 3. The second element begins with a root derived from its elemental name and ends with the suffix <i>-ide</i>. 4. When there is more than one atom of a given element in the formula, the name of the element usually contains a prefix that specifies the number of atoms present.

Naming oxoanions	2.3	These rules are used to name anions containing oxygen and at least one other element. 1. The name has a root taken from the name of the central atom. 2. When an element forms two different oxoanions, the one with fewer oxygen atoms ends in <i>-ite</i> and the other ends in <i>-ate</i> . 3. Chlorine, bromine and iodine each form four different oxoanions that are distinguished by prefixes and suffixes. 4. A polyatomic anion with a charge more negative than 1– may add H ⁺ to give another anion. These anions are named from the parent anion by adding the word <i>hydrogen</i> .
Functional groups	2.3	Functional groups are the basis for naming organic compounds. • Alcohols contain a hydroxyl group. • Aldehydes contain a terminal carbonyl group. • Ketones contain a non-terminal carbonyl group. • Carboxylic acids contain a carboxyl group.
Naming alkanes	2.3	There are two parts to the name of an alkane: a prefix, indicating the number of carbon atoms in the chain, and the suffix <i>-ane</i> .
Prefixes for carbon chain length	2.3	Knowledge of these prefixes is necessary for naming any organic compound: 1, meth-; 2, eth-; 3, prop-; 4, but-; 5, pent-; 6, hex-; 7, hept-; 8, oct-; 9, non-; 10, dec-.
General organic nomenclature	2.3	The prefix, infix and suffix of the name of an organic compound reflect the structure of that compound.

KEY TERMS

absolute uncertainty An uncertainty that has the same units as the quantity being measured.

accuracy A measurement is of high accuracy if it is close to the correct value.

acyclic alkanes Alkane molecules that consist solely of chains of carbon atoms.

alkane A molecule composed only of carbon and hydrogen atoms in which all carbon–carbon bonds are single.

alkyl group A group derived from an alkane by the removal of a hydrogen atom, commonly represented by the symbol R.

ampere (A) The SI unit of electric current; $A = C\ s^{-1}$.

anhydrous Describes a chemical substance that contains no water.

ball-and-stick model A three-dimensional representation of a molecule in which atoms are shown as balls, and bonds between atoms are shown as sticks.

binary compound A compound that contains only two elements.

candela (cd) The SI unit of luminous intensity.

catenation The linking of atoms of the same element (particularly carbon) to form chains.

chemical formula A formula written using chemical symbols and subscripts that describes the composition of a chemical compound or element.

condensed structural formula A shorthand method of representing molecules in which bonds between atoms are not drawn explicitly.

constitutional isomers Isomers with different sequences of atom connectivity.

cycloalkane An unsaturated hydrocarbon with carbon atoms joined together to form a ring that contains a carbon–carbon double bond.

dimensional analysis The use of units of a physical quantity to derive the equation used to determine its value.

functional group A group of atoms within an organic molecule that determines the molecule's chemical reactivity.

hashed wedge Denotes a bond going into the plane of the screen or page, away from the observer.

heterolytic Describes a bond-breaking process in which both electrons of a single bond end up on one of the atoms of the bond.

homolytic Describes a bond-breaking process in which each of the bonded atoms receives one electron.

hydrate A solid that contains a definite number of waters of crystallisation.

hydrocarbon A molecule composed only of carbon and hydrogen atoms.

isomers Molecules with the same molecular formula but different structures.

kelvin (K) The SI unit of temperature.

kilogram (kg) The SI unit of mass.

line structure A shorthand method of drawing structural formulae in which each vertex and line ending represents a carbon atom.

mechanistic arrows Arrows that show the movement of electrons in bond-breaking and bond-making processes.

metre (m) The SI unit of length.

mole (mol) The SI unit of amount of substance. One mole contains exactly $6.022\ 140\ 76 \times 10^{23}$ elementary entities.

molecular formula A formula that shows the actual numbers of different types of atoms present in a molecule.

nomenclature A system of naming.

oxoanion A negatively charged ion containing two or more elements, one of which is oxygen.

parent chain The longest straight carbon chain in an organic molecule.

percentage uncertainty An uncertainty expressed as a percentage.

precision A group of measurements is of high precision if all the values lie close together.

primary carbon atom A carbon atom attached to only one other carbon atom.

saturated hydrocarbon A compound composed solely of carbon and hydrogen atoms in which all C—C bonds are single; see also *alkane*.

scientific notation A method of expressing numbers in terms of powers of 10; for example, the number 3613 becomes 3.613×10^3 .

second (s) The SI unit of time.

secondary carbon atom A carbon atom attached to two other carbon atoms.

SI (Système International) units A system of units based on seven base units from which all others can be derived.

significant figures The figures in a physical measurement that are known to be certain plus the first figure that contains uncertainty.

solid wedge A solid wedge denotes a bond coming out of the screen or page, towards the observer.

space-filling model A three-dimensional representation of a molecule that attempts to show the actual relative sizes of atoms within a molecule.

structural formula A depiction of a molecule or polyatomic ion that shows how the constituent atoms are arranged, to which other atoms they are bonded, and the kinds of bonds (single, double or triple) present.

substituent A group attached to the longest carbon chain of an organic molecule.

terminal carbon A carbon atom at the end of a chain of carbon atoms.

tertiary carbon atom A carbon atom attached to three other carbon atoms.

unit A specific standard quantity of a particular property, against which all other quantities of that property can be measured.

REVIEW QUESTIONS

Measurement

LO1

- 2.1** Why must measurements always be written with a unit?
- 2.2** Why are units of length based on parts of the human body not a good idea?
- 2.3** Which SI base unit is defined in terms of the Boltzmann constant?
- 2.4** What is the only SI base unit that includes a decimal prefix?
- 2.5** Einstein's famous equation states that $E = mc^2$, where E is energy, m is the mass of an object in kg, and c is the speed of light in m s^{-1} . What is the SI derived unit of energy?
- 2.6** Give the prefixes that correspond to the following powers of 10.
- 10^{-1}
 - 10^{-3}
 - 10^3
 - 10^{-15}
 - 10^{-9}
 - 10^{-12}
 - 10^{21}
 - 10^{-18}
 - 10^2
- 2.7** What abbreviation is used for each of the powers of 10 given in question 2.6?
- 2.8** Chemists often use the non-SI unit litre (L) as the unit of volume in the laboratory. What is the derived SI unit of volume that is equal in volume to 1 L?
- 2.9** Why does dimensional analysis allow you to determine the correct form of an equation from knowledge of the units of the measurements involved?

- 2.10** A darts player, while aiming for three triple twenties, threw three bullseyes. Was the player accurate, precise, or both?
- 2.11** Analysis of a blood sample showed a concentration of $3.0 \mu\text{mol mL}^{-1}$ of a particular toxin. How high might the concentration actually have been? A more precise technique gave the concentration of the toxin as $3.027 \mu\text{mol mL}^{-1}$ of blood. How high might the concentration have been in this case?
- 2.12** There are 86 400 s in 1 day. By what conversion factor would you multiply 3600 s to convert it to days? By what conversion factor would you multiply 365 days to convert it to seconds?

Representations of molecules and reactions

LO2

- 2.13** Subscripts are often used in chemical formulae. How does a subscript that follows a group of atoms enclosed in parentheses differ from one that does not?
- 2.14** What must be true about two substances if they are to be called isomers of each other?
- 2.15** Write the chemical formula of each of the following substances.
- cholesterol, which contains 1 oxygen atom, 27 carbon atoms and 46 hydrogen atoms
 - ammonium sulfate, which contains two NH_4^+ ions and one SO_4^{2-} ion
 - human insulin, which contains 65 nitrogen atoms, 6 sulfur atoms, 257 carbon atoms, 77 oxygen atoms, and 383 hydrogen atoms

- 2.16** The line structures that follow are those of important drug molecules. Convert these line structures to structural formulae and give the chemical formula of each drug molecule.

2.17 Write line structures for compounds (a) to (f).

2.18 Write the chemical formula and the condensed structural formula for each of the following alkanes.

2.19 Provide a more abbreviated formula for each of the following condensed structural formulae, using parentheses and subscripts.

2.20 Describe the process represented by a two-barbed mechanistic arrow. How does this differ from that represented by a single-barbed mechanistic arrow?

Nomenclature

2.21 Write chemical formulae for the following compounds.

- selenium dioxide
- dinitrogen tetraoxide
- calcium fluoride
- dimercury dichloride
- sulfur hexachloride
- aluminium bromide

2.22 Name the following compounds.

- BrF_3
- H_2S

LO3

- OF_2
- SbF_5
- PCl_3
- N_2O_3
- SO_3
- BBr_3

2.23 Draw the structural formulae of the following molecules.

- butane
- 3-methylpentane
- 2,3-dimethylhexane

2.24 Why is there no such thing as a tertiary aldehyde?

REVIEW PROBLEMS

- 2.25** What number should replace the question mark in each of the following? **LO1**
- (a) 1 cm = ? m
 - (b) 1 km = ? m
 - (c) 1 m = ? pm
 - (d) 1 dm = ? m
 - (e) 1 g = ? kg
 - (f) 1 cg = ? g
 - (g) 1 nm = ? m
 - (h) 1 μ g = ? g
 - (i) 1 kg = ? g
 - (j) 1 Mg = ? g
 - (k) 1 mg = ? g
 - (l) 1 dg = ? g
- 2.26** Convert each of the following measurements to the given units. **LO1**
- (a) 100 °C to K (the boiling point of water)
 - (b) -78 °C to K (the temperature of a dry-ice/acetone bath)
 - (c) 273 K to °C (the freezing point of water)
 - (d) 298 K to °C (room temperature)
 - (e) 37 °C to K (body temperature)
- 2.27** Mercury is very unusual in that it is the only metal that exists as a liquid at room temperature and atmospheric pressure. It melts at 234 K. What is its melting point in °C? **LO1**
- 2.28** Sodium is a soft metal that can be easily cut with a knife. It melts at 98 °C. What is its melting point in K? **LO1**
- 2.29** How many significant figures do the following measured quantities have? **LO1**
- (a) 2.47 m
 - (b) 97.50 kg
 - (c) 3601 s
 - (d) 0.750 mg
 - (e) 0.0100 m³
 - (f) 2.40×10^0 g mL⁻¹
- 2.30** How many significant figures do the following measured quantities have? **LO1**
- (a) 0.5070 m
 - (b) 10.024 g
 - (c) 0.002 mol
 - (d) 2.00 km
 - (e) 10 kg
 - (f) 3.8005 s
- 2.31** How many significant figures do the following measured quantities have? **LO1**
- (a) 0.0001 kg
 - (b) 7.001 m
 - (c) 0.20×10^2 L
 - (d) 10.1010 g
 - (e) 0.100 mm
- 2.32** How many significant figures do the following measured quantities have? **LO1**
- (a) 2.777 μ mol
 - (b) 0.040 00 m³
 - (c) 21 740 m
 - (d) 8100 L
 - (e) 0.0206 V
- 2.33** Carry out the following calculations, rounding the answers to the correct number of significant figures. **LO1**
- (a) $0.0157 \text{ m} \times 43 \text{ m}$
 - (b) $2.00 \text{ g} - 0.012 \text{ g}$
 - (c) $(2.68 \text{ m}^3 - 1.26 \text{ m}^3)/(4057 \text{ kg} - 2904 \text{ kg})$
 - (d) $(4.08 \text{ m} + 100.2 \text{ m} + 2.5 \text{ m})/(154.9 \text{ s} - 15.44 \text{ s})$
 - (e) $(6.44 \text{ g} - 1.054 \text{ g})/3.721 \text{ mL}$
- 2.34** Carry out the following calculations and round the answers to the correct number of significant figures. **LO1**
- (a) $5.80 \text{ mol}/2.400 \text{ L}$
 - (b) $8.41 \text{ kg} + 0.004 \text{ kg}$
 - (c) $(12.8 \text{ g} - 4.3 \text{ g})/(2.407 \text{ L} - 0.003 \text{ L})$
 - (d) $(4.041 \text{ kJ} + 0.037 \text{ kJ})/(14.91 \text{ mol} - 7.5613 \text{ mol})$
 - (e) $(12.175 \text{ m} - 11.983 \text{ m})/(2.66 \text{ s} \times 1.411 \text{ s})$
- 2.35** Express the following numbers in scientific notation to three significant figures. **LO1**
- (a) 4340
 - (b) 32 000 000
 - (c) 0.003 287
 - (d) 42 000
 - (e) 0.000 008 00
 - (f) 324 300
- 2.36** Express the following numbers in scientific notation. **LO1**
- (a) 84 726
 - (b) 0.000 511 0
 - (c) 90 001
 - (d) 0.089 08
 - (e) 6.15
 - (f) 6 550 135
- 2.37** Write the following numbers in standard (non-scientific) form. **LO1**
- (a) 2.66×10^{-1}
 - (b) 8.9×10^{-4}
 - (c) 14.8×10^{-5}
 - (d) 7.21×10^3
 - (e) 6.1×10^0
 - (f) 543×10^2
- 2.38** Write the following numbers in standard (non-scientific) form. **LO1**
- (a) 5.13×10^{-3}
 - (b) 7.71×10^5
 - (c) 516×10^{-4}
 - (d) 8.43×10^{-7}
 - (e) 8.410×10^2
 - (f) 29.4×10^8
- 2.39** Carry out the following calculations and express the answers in scientific notation. **LO1**
- (a) $(4.0 \times 10^7) - (2.1 \times 10^5)$
 - (b) $(3.0 \times 10^{-2}) + (3.21 \times 10^{-5})$
 - (c) $(2.1 \times 10^7) \times (2.1 \times 10^5)$
 - (d) $(3.0 \times 10^4) \times (8.2 \times 10^{-5})$
 - (e) $(9.10 \times 10^{12})/(2.0 \times 10^{-3})^2$
- 2.40** Carry out the following calculations and express the answers in scientific notation. **LO1**
- (a) $(5.7 \times 10^3) \times (7.4 \times 10^3)$
 - (b) $(5.5 \times 10^{11})/(2.9 \times 10^1)^2$
 - (c) $(6.7 \times 10^{-4}) \times (1.8 \times 10^{-5})$
 - (d) $(4.1 \times 10^6) - (3.3 \times 10^5)$
 - (e) $(9.3 \times 10^{-4}) + (2.62 \times 10^{-2})$
- 2.41** Convert each of the following measurements to the given units. **LO1**
- (a) 32.0 dm to km
 - (b) 8.2 mg to μ g
 - (c) 75.3 mg to kg
 - (d) 137.5 mL to L
 - (e) 0.025 L to mL
 - (f) 342 pm to dm
- 2.42** Convert each of the following measurements to the given units. **LO1**
- (a) 26 L to m³

- (b) 2.98 kg to mg
 (c) 85 mmol to mol
 (d) 10.3 km to m
 (e) 5.79 mL to L
 (f) 7.31 KJ to J

2.43 Convert each of the following measurements to the given units and express your answers in scientific notation. **L01**

- (a) 75.0 kg to mg
 (b) 2.00 mmol to nmol
 (c) 5.207 km to dm
 (d) 233 μ s to ps
 (e) 5.00 mol L⁻¹ to mol m⁻³
 (f) 35.8 mm³ to m³

2.44 Convert each of the following measurements to the given units and express your answers in scientific notation. **L01**

- (a) 326 m to dm
 (b) 5.21 kg to g
 (c) 5.39 km to μ m
 (d) 51 nm to pm

- (e) 0.55 m³ to mm³
 (f) 47.1 g to mg

2.45 Which functional group does each of the following compounds contain? **L03**

- (a) CH₃CH=CH₂
 (b) CH₃CH₂OH
 (c) CH₃CH₂CH₂COOH
 (d) HOCH₂CH₂CH₃

2.46 Which functional group does each of the following compounds contain? **L03**

- (a) CH₃CH₂CHO
 (b) CH₃CH₂OH
 (c) CH₃CH₂C(=O)CH₃

2.47 Decide whether the members of each pair are identical, isomers or unrelated. **L02,3**

2.48 Examine each pair of molecules and decide whether they are identical, isomers or unrelated. **L02,3**

2.49 Write the IUPAC names of the following hydrocarbons. **L02,3**

2.50 There are only three saturated alcohols that contain three carbon atoms. Draw the structural formulae of these molecules. **L02**

2.51 Write structural formulae for all the possible aldehydes and ketones having the chemical formula C₄H₈O. **L02**

2.52 Write chemical formulae for the molecules represented by the following ball-and-stick models.

L02

2.53 Write chemical formulae for the molecules represented by the following ball-and-stick models.

L02

2.54 Write structural formulae for the molecules in problems 2.52 and 2.53.

2.55 Convert the following structural formulae to line structures.

L02

L02

2.56 Convert the following structural formulae to line structures.

L02

2.57 Convert the following line structures to structural formulae.

L02

2.58 Convert the following line structures into structural formulae.

L02

2.59 Which of the following statements are true about constitutional isomers?

L03

- They have the same chemical formula.
- They have the same atomic mass.
- They have the same order of attachment of atoms.
- They have the same physical properties.

2.60 Each member of the following set of compounds is an alcohol.

L02,3

- (a) Which line structures represent the same compound?
 (b) Which line structures represent compounds that are constitutional isomers?
 (c) Which line structures represent compounds that are not constitutional isomers?

2.61 Each member of the following set of compounds is either an aldehyde or a ketone.

L02,3

- (a) Which line structures represent the same compound?
 (b) Which line structures represent compounds that are constitutional isomers?
 (c) Which line structures represent compounds that are not constitutional isomers?

2.62 For each of the following pairs of compounds, determine whether the structural formulae shown represent:

L02,3

- (a) the same compound
 (b) different compounds that are constitutional isomers
 (c) different compounds that are not constitutional isomers.

- (a) $\text{CH}_3\text{CH}_2\text{OH}$ and CH_3OCH_3 (b) $\text{CH}_3\overset{\text{O}}{\parallel}\text{CCH}_3$ and $\text{CH}_3\text{CH}_2\overset{\text{O}}{\parallel}\text{CH}$
- (c) $\text{CH}_3\overset{\text{O}}{\parallel}\text{COCH}_3$ and $\text{CH}_3\text{CH}_2\overset{\text{O}}{\parallel}\text{COH}$ (d) $\text{CH}_3\overset{\text{OH}}{\mid}\text{CHCH}_2\text{CH}_3$ and $\text{CH}_3\overset{\text{O}}{\parallel}\text{CCH}_2\text{CH}_3$
- (e)  and $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3$ (f)  and $\text{CH}_2=\text{CHCH}_2\text{CH}_2\text{CH}_3$

2.64 Draw the product(s) that result(s) from the following mechanistic processes.

L02

2.65 Draw line structures for each of the following.

L02

- (a) four aldehydes with chemical formula $\text{C}_5\text{H}_{10}\text{O}$
 (b) one ketone with chemical formula $\text{C}_4\text{H}_8\text{O}$
 (c) three ketones with chemical formula $\text{C}_5\text{H}_{10}\text{O}$
 (d) four carboxylic acids with chemical formula $\text{C}_5\text{H}_{10}\text{O}_2$

2.66 Write chemical formulae for these compounds.

L03

- (a) barium chloride
 (b) magnesium nitrate
 (c) sulfur tetrachloride
 (d) propane
 (e) lithium phosphate
 (f) aluminium chloride
 (g) dinitrogen oxide

2.67 Write chemical formulae for these compounds.

L03

- (a) beryllium hydride
 (b) iodine trichloride
 (c) propanal
 (d) lithium oxide
 (e) rubidium sulfate
 (f) lead tetrachloride
 (g) calcium phosphate

2.68 Name the following compounds.

L03

- (a) S_2Cl_2
 (b) IF_7
 (c) HBr
 (d) N_2O_3
 (e) SiC
 (f) CH_3OH

2.69 Name the following compounds.

L03

- (a) SiCl_4
 (b) N_2O_5
 (c) CsH
 (d) PbO_2
 (e) $\text{CH}_3\text{CH}_2\text{COOH}$

2.70 Write the chemical formula of each compound.

L03

- (a) hydrogen sulfide
 (b) potassium chlorite
 (c) strontium sulfate
 (d) beryllium nitrite

2.71 Write the chemical formula of each compound.

L03

- (a) sodium chlorite
 (b) potassium permanganate
 (c) sodium carbonate

2.72 Name each of the following compounds.

L03

- (a) SrCO_3
 (b) SiCl_4
 (c) BF_3
 (d) NaBrO_3

2.73 Name each of the following compounds.

L03

- (a) Na_2SO_3
 (b) K_3PO_4
 (c) LiNO_2
 (d) $\text{K}_2\text{Cr}_2\text{O}_7$

2.74 Write chemical formulae for these compounds.

L03

- (a) calcium sulfite
 (b) sodium periodate
 (c) potassium hydrogencarbonate
 (d) lithium chloride
 (e) calcium hydride

2.75 Write chemical formulae for these compounds.

L03

- (a) potassium perchlorate
 (b) sodium hydrogensulfate
 (c) aluminium oxide
 (d) potassium oxalate

2.76 Name each of the following compounds.

L03

- (a) K_2SO_4
 (b) NaClO
 (c) BeCl_2
 (d) SrO
 (e) NaNO_3
 (f) CaSO_3
 (g) K_2CrO_4

2.77 Name each of the following compounds.

L03

- (a) NaHSO_3
 (b) $\text{Mg}(\text{OOCCH}_3)_2$
 (c) Rb_2CO_3
 (d) CsI
 (e) AlPO_4

2.78 Write IUPAC names for these alkanes.

L02,3

2.79 Draw line structures for these alkanes.

L02,3

2.81 Draw a structural formula for each of the following compounds.

L02,3

- (a) 2,2-dimethylpropane
- (b) 2,3-dimethylbutane
- (c) 2,3,4-trimethylnonane
- (d) 4-isopropylheptane
- (e) 3-ethyl-2,3,5-trimethylnonane
- (f) 2,3,4,5-tetramethylhexane

- (a) propanol
- (b) butanal
- (c) butanone
- (d) ethanoic acid
- (e) methanal
- (f) propanoic acid
- (g) methanoic acid

2.80 Explain why each of the following names is an incorrect IUPAC name, and write the correct IUPAC name for the intended compound.

L02,3

2.82 Write the IUPAC name for each compound.

- (a) 1,3-dimethylbutane
- (b) 4-methylpentane
- (c) 2,2-diethylbutane
- (d) 2-ethyl-3-methylpentane
- (e) 2-propylpentane
- (f) 2,2-diethylheptane

ADDITIONAL EXERCISES

2.83 As stated earlier in this chapter, chemists tend to use the litre (L), a non-SI unit, and its derivative, the millilitre (mL) as units of volume. A disadvantage of this is that there are no obvious conversion factors between these units and the derived SI unit of volume, the cubic metre (m^3). However, such conversion factors may be worked out using the following method. Consider a cube having edge lengths of 1 m. This has a volume of $1 \text{ m} \times 1 \text{ m} \times 1 \text{ m} = 1 \text{ m}^3$. We now take the same cube and, knowing there are 100 cm in 1 m, we express its edge lengths as 100 cm. Therefore, the volume of this same cube is now $100 \text{ cm} \times 100 \text{ cm} \times 100 \text{ cm} = 1\,000\,000 \text{ cm}^3$. Thus, there are $1\,000\,000 \text{ cm}^3$ in 1 m^3 .

L01

Use this method, and the fact that $1 \text{ cm}^3 = 1 \text{ mL}$, to calculate the following conversion factors.

- (a) How many dm^3 are there in 1 m^3 ?
- (b) How many cm^3 are there in 1 dm^3 ?
- (c) How many mm^3 are there in 1 m^3 ?
- (d) How many mm^3 are there in 1 dm^3 ?
- (e) How many L are there in 1 m^3 ?
- (f) How many cm^3 are there in 10 L?
- (g) How many mL are there in 100 dm^3 ?

2.84 The IUPAC system divides the name of an organic compound into a prefix (showing the number of carbon atoms), an infix (showing the presence of carbon-carbon single, double or triple bonds), and a suffix (showing the presence of an alcohol,

an aldehyde, a ketone or a carboxylic acid). Assume for the purposes of this problem that, to be an alcohol (-ol), the hydroxyl group must be bonded to a carbon atom which has only single bonds to other attached atoms.

L02,3

Given this information, write the structural formula of a compound with an unbranched chain of four carbon atoms that is an:

- alkane
- alkene
- alkyne
- alkanol
- alkenol
- alkynol
- alkanal
- alkenal
- alkynal
- alkanone
- alkenone
- alkynone
- alkanoic acid

(n) alkenoic acid

(o) alkynoic acid.

(Note: For some parts of this problem, only one structural formula is possible. For other parts, two or more structural formulae are possible. Where two or more are possible, we will deal with how the IUPAC system distinguishes between them when we come to the chapters on those particular functional groups.)

2.85 In everyday life, we encounter chemicals with unsystematic names. What is the name a chemist would use for each of the following substances? **L03**

- limestone, CaCO_3
- laughing gas, N_2O
- potash, K_2CO_3
- silica, SiO_2
- caustic soda, NaOH
- bleach, NaClO
- titanium white, TiO_2
- cadmium yellow, CdS

2.86 A mineral is a chemical compound found in the Earth's crust. What are the chemical names of the following minerals? **L03**

- $\text{Mg}(\text{OH})_2$ (brucite)
- CuS (covellite)
- CaF_2 (fluorite)
- TiO_2 (rutile)

2.87 The line structures of three different vitamins are given below. Write the chemical formula for each compound. **L02**

2.88 The following molecules are known for their characteristic fragrances. Convert each line structure into a complete structural formula. **L02**

2.89 The compounds in the following pairs of substances are quite different from each other despite having similar names. Write correct formulae for each pair. **L03**

- sodium nitrite and sodium nitrate
- potassium carbonate and potassium hydrogencarbonate
- iodine and iodide ion
- sodium chloride and sodium hypochlorite
- nitrogen oxide and nitrogen dioxide
- potassium chlorate and potassium perchlorate
- ammonia and ammonium ion

2.90 Provide IUPAC-approved names for each of the following compounds. **L03**

- NH_4Cl
- BrF_5
- SO_2

2.91 Provide the IUPAC names of each of the following compounds. **L03**

- Li_3PO_4
- Li_2HPO_4
- LiH_2PO_4
- NaIO_3
- NaIO_4

2.92 Express the results of the following logarithmic calculations to the correct number of significant figures. **L01**

- $\ln(7.00 \times 10^2)$
- $\log(2.968 \times 10^6)$
- $\text{antilog}(-2.66)$
- $e^{-1.91}$
- $\log(5.129 + 1.67)$
- $\log[\log(1000)]$

2.93 As we will see in the chapter on gases, the root mean square velocity $\bar{\mu}_{\text{rms}}$ of a gas molecule is given by the following equation, where the units of R are $\text{J mol}^{-1} \text{K}^{-1}$, T are K, and M are kg mol^{-1} . **L01**

$$\bar{\mu}_{\text{rms}} = \left(\frac{3RT}{M} \right)^{\frac{1}{2}}$$

Given that the units of $\bar{\mu}_{\text{rms}}$ are m s^{-1} , show that the units on both sides of the equation are the same.

2.94 In the chapter on reaction kinetics, we will learn about rates of chemical reactions and how they can be described by rate laws. Consider the following gas-phase reaction.

We can write this reaction's rate law as follows.

$$\text{rate of equation} = k [\text{NO}]^2 [\text{O}_2]$$

In this equation, the square brackets denote the concentrations of NO and O_2 in mol L^{-1} . Determine the units of the rate constant k , given that the rate of reaction has units of $\text{mol L}^{-1} \text{s}^{-1}$. **L01**

2.95 From knowledge of their given units, determine an equation relating each of the following groups of variables and constants. **L01**

- volume (V , L), concentration (c , mol L^{-1}) and amount (n , mol). Make amount the subject.
- speed of light (c , m s^{-1}), energy (E , J), Planck's constant (h , J s) and wavelength (λ , m). Make energy the subject.
- specific heat (c , $\text{J g}^{-1} \text{K}^{-1}$), temperature change (ΔT , K), mass (m , g) and heat (q , J). Make mass the subject.
- gas density (ρ , kg m^{-3}), pressure (p , Pa), molar mass (M , kg mol^{-1}), the gas constant (R , $\text{J mol}^{-1} \text{K}^{-1}$) and temperature (T , K). Make pressure the subject. (Hint: Recall that Pa is a derived unit.)

2.96 A student wished to use mechanistic arrows to depict the electron movements in the following process. **L02**

Explain why the student's use of arrows in each answer below is incorrect.

MATHS FOR CHEMISTRY

In chemistry, as in any science involving a significant amount of maths, it is imperative that you are confident in rearranging mathematical equations. Below are very brief guidelines on how to do this for two major classes of equations you will encounter.

THE EQUATION TO BE REARRANGED INVOLVES ADDITION OR SUBTRACTION

Consider the equation:

$$a + b = c$$

How do we rearrange this to make b the subject of the equation? In other words, how do we write the equation in the following form?

$$b = ?$$

We start by knowing that b is going to be the only term on the left-hand side of the equation, so both a and c must appear on the

right-hand side of the equation. As c is already on the right-hand side of the equation, we only have to move a . But how do we do this?

We make use of the fact that *we can make the same change to both sides of any equation without altering the overall equation*. For example, consider the equation below.

$$2 + 4 = 6$$

We can make any change to the equation that we want to, as long as we make the identical change on both sides of the equals sign. For example, if we added 5 to both sides of the equation, we would have the equation below.

$$2 + 4 + 5 = 6 + 5$$

Both sides of the equation are still equal.

We can now use this fact to rearrange the above equation $a + b = c$ to make b the subject. We want to remove a from the left-hand side of

the equation, so we need to subtract a from both sides of the equation. This will then give:

$$a + b - a = c - a$$

On the left-hand side, we know that $a + b - a$ leaves b , and therefore we rewrite the above equation as follows.

$$b = c - a$$

And there we have our rearranged equation.

THE EQUATION TO BE REARRANGED INVOLVES MULTIPLICATION OR DIVISION

Consider the following equation.

$$a \times b = c$$

How do we rearrange this to make b the subject of the equation? In other words, how do we write the equation in the form:

$$b = ?$$

In this case, we again want to move a to the right-hand side of the equation. We now do this by dividing both sides of the equation by a . This will then give:

$$\frac{a \times b}{a} = \frac{c}{a}$$

The a terms on the left-hand side of the equation can be cancelled and this then gives the following.

$$b = \frac{c}{a}$$

The examples above are the simplest possible, but the principles involved are identical to those used in rearranging much more complicated equations. As we outlined in the chapter, you can also use the units in an equation as a check that you have rearranged it correctly. There is no substitute for practice when it comes to becoming expert in carrying out these manipulations. Worked example 2.17 presents some rearrangements to assist you with this. You should try to work them out yourself before looking at the solutions.

WORKED EXAMPLE 2.17

Rearranging equations

- Rearrange the First Law of Thermodynamics, $\Delta U = q + w$, to make q the subject.
- Rearrange the ideal gas equation $pV = nRT$ to make T the subject.
- Rearrange Faraday's Law, amount of product $= \frac{It}{zF}$ to make F the subject.
- Rearrange the expression for enthalpy, $H = U + pV$, to make p the subject.
- Rearrange the expression for the energy of a photon, $E = \frac{hc}{\lambda}$, to make c the subject.
- Rearrange the expression for cell potential,

$$E^\circ = \frac{RT}{zF} \ln K_c$$

to make R the subject.

- Rearrange the van der Waals equation

$$\left(p + \frac{n^2a}{V^2}\right)(V - nb) = nRT$$

to make b the subject.

Analysis

These examples are progressively more complicated, but they all make use of the same two principles we described above. We can make any change we want to any equation as long as the change we make is identical on both sides of the equals sign.

Solution

- $\Delta U = q + w$

We want q as the subject, so subtract w from both sides of the equation. This then gives:

$$\Delta U - w = q + w - w$$

which can then be rewritten as:

$$\Delta U - w = q$$

or:

$$q = \Delta U - w$$

- $pV = nRT$

We want T as the subject, so divide both sides of the equation by nR . This then gives:

$$\frac{pV}{nR} = \frac{nRT}{nR}$$

The nR terms on the right-hand side of the equation will cancel out, to give:

$$\frac{pV}{nR} = T$$

or:

$$T = \frac{pV}{nR}$$

- Amount of product $= \frac{It}{zF}$

We want F as the subject. We do this in two steps. Firstly, we multiply both sides of the equation by F , to get F on the left-hand side of the equation. This will give:

$$(\text{amount of product}) \times F = \frac{ItF}{zF}$$

The F terms on the right-hand side of the equation will cancel out, to give:

$$(\text{amount of product}) \times F = \frac{It}{z}$$

Now we move (amount of product) to the right-hand side of the equation by dividing both sides of the equation by (amount of product). This then gives:

$$\frac{(\text{amount of product}) \times F}{(\text{amount of product})} = \frac{\left(\frac{It}{z}\right)}{(\text{amount of product})}$$

The (amount of product) terms on the left-hand side will cancel out, to give:

$$F = \frac{\left(\frac{It}{z}\right)}{(\text{amount of product})}$$

You can leave the equation in this form, or carry out one last simplification, which gives:

$$F = \left(\frac{It}{z \times (\text{amount of product})} \right)$$

(d) $H = U + pV$

We want p to be the subject. We do this in two steps. Firstly, subtract U from both sides of the equation, to give the following.

$$H - U = U + pV - U$$

This can then be rewritten as:

$$H - U = pV$$

We now divide both sides of the equation by V , which gives:

$$\frac{H - U}{V} = \frac{pV}{V}$$

The V terms on the right-hand side cancel out, to give:

$$\frac{H - U}{V} = p$$

or:

$$p = \frac{H - U}{V}$$

(e) $E = \frac{hc}{\lambda}$

We want c to be the subject. We could do this the way we have learned to above, in two steps, by firstly multiplying both sides of the equation by λ , then dividing both sides of the equation by h . However, there are two equivalent ways in which we can do this in a single step. We could divide both sides of the equation by $\frac{h}{\lambda}$, or multiply both sides of the equation by $\frac{\lambda}{h}$. These both lead to the same answer, namely:

$$\frac{E\lambda}{h} = c$$

or:

$$c = \frac{E\lambda}{h}$$

(f) $E^\circ = \frac{RT}{zF} \ln K_c$

We want R to be the subject. There are a number of equivalent ways we could do this. We will begin by dividing both sides of the equation by $\ln K_c$, which will give:

$$\frac{E^\circ}{\ln K_c} = \frac{RT}{zF} \frac{\ln K_c}{\ln K_c}$$

The $\ln K_c$ terms on the right-hand side of the equation will cancel out to give:

$$\frac{E^\circ}{\ln K_c} = \frac{RT}{zF}$$

We can then either divide both sides of the equation by $\frac{T}{zF}$ or multiply both sides of the equation by $\frac{zF}{T}$. Both approaches give the same answer:

$$\frac{E^\circ}{\ln K_c} \frac{zF}{T} = \frac{RT}{zF} \frac{zF}{T}$$

On the right-hand side of the equation, $\frac{T}{zF} \times \frac{zF}{T} = 1$ and therefore, the above equation becomes:

$$\frac{E^\circ}{\ln K_c} \frac{zF}{T} = R$$

or:

$$R = \frac{E^\circ}{\ln K_c} \frac{zF}{T}$$

(g) $\left(p + \frac{n^2 a}{V^2} \right) (V - nb) = nRT$

We want b to be the subject. Again, there are a number of equivalent ways of doing this. We will start by trying to isolate b on the left-hand side of the equation. Therefore, dividing both sides of the equation by $\left(p + \frac{n^2 a}{V^2} \right)$ will give:

$$\frac{\left(p + \frac{n^2 a}{V^2} \right) (V - nb)}{\left(p + \frac{n^2 a}{V^2} \right)} = \frac{nRT}{\left(p + \frac{n^2 a}{V^2} \right)}$$

The $\left(p + \frac{n^2 a}{V^2} \right)$ terms on the left-hand side of the equation will cancel out, leaving:

$$(V - nb) = \frac{nRT}{\left(p + \frac{n^2 a}{V^2} \right)}$$

Now we will subtract V from both sides of the equation:

$$(V - nb) - V = \left(\frac{nRT}{\left(p + \frac{n^2 a}{V^2} \right)} \right) - V$$

and simplifying this gives:

$$-nb = \left(\frac{nRT}{\left(p + \frac{n^2 a}{V^2} \right)} \right) - V$$

Finally, if we divide both sides of the equation by $-n$, we obtain:

$$\frac{-nb}{-n} = \frac{\left(\frac{nRT}{\left(p + \frac{n^2 a}{V^2} \right)} \right) - V}{-n}$$

which simplifies to:

$$b = \frac{\left(\frac{nRT}{\left(p + \frac{n^2 a}{V^2} \right)} \right) - V}{-n}$$

This is probably sufficient, but can be simplified further if you're feeling brave.

Chemical reactions and stoichiometry

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 3.1** explain how a chemical equation represents a chemical reaction
 - 3.2** balance chemical equations
 - 3.3** use the mole concept in stoichiometric calculations
 - 3.4** determine empirical formulae from quantitative analysis data
 - 3.5** calculate theoretical and actual yields based on balanced equations
 - 3.6** apply stoichiometric concepts to reactions in solutions.
-

Chemical plants produce large quantities of basic chemicals used in everyday consumer goods, industrial processes and research laboratories. However, if you manage an alumina refinery, like Rio Tinto's Yarwun refinery, pictured, and want to run it efficiently, you must know how much starting material is needed to obtain a product with the best possible yield.

The Yarwun Alumina Refinery

Some of the information comes from chemical equations. Chemical equations summarise information about chemical reactions. They show the substances you start with and the substances you end up with. They also show the relative proportions of the substances involved.

In this chapter, you will learn how to use balanced chemical equations and the rules of stoichiometry to work out the mass of the substances required to form a desired mass of a product. A good understanding of stoichiometry is essential for all areas of chemistry, including industrial-scale production, pharmaceutical

manufacture and controlling reactions in research laboratories. It is also essential for students wanting to understand basic chemistry.

3.1 Chemical equations

LEARNING OBJECTIVE 3.1 Explain how a chemical equation represents a chemical reaction.

The production of new substances from one or more chemical species is called a **chemical reaction**. A **chemical equation**, a concept we briefly introduced in the chapter on the atom, may be used to describe what happens when a chemical reaction occurs. It uses chemical formulae to provide a before-and-after picture of the chemical substances involved. Consider, for example, the reaction between hydrogen and oxygen to give water. The chemical equation that describes this reaction is as follows.

The two formulae that appear to the left of the arrow are those of the **reactants**, hydrogen and oxygen, that is, the substances that react to form the product. The formula of the product, water, is written to the right of the arrow. **Products** are the substances that are formed in the reaction. The arrow means ‘react to produce’. Thus, this equation tells us that *hydrogen and oxygen react to produce water*. The reverse process, the reaction of water to form hydrogen and oxygen, can also occur, but only to a very small extent. Reactions in which both the forward and reverse reactions occur are called **reversible reactions**. The majority of chemical reactions are reversible to some extent, but, for now, we are only concerned with the forward reaction. We will learn more about reversible reactions in the chapter on chemical equilibrium.

In this example, only one substance is formed in the reaction, so there is only one product. As we will see, however, in most chemical reactions there is more than one product. If we want to determine the identity of the products, we are engaged in **qualitative analysis**; we simply determine which substances are present in a sample without measuring their amounts. By contrast, in **quantitative analysis**, our goal is to measure the amounts of the various substances in a sample.

Stoichiometry (from the Greek *stoicheion* meaning ‘element’ and *metrein* meaning ‘measuring’) is concerned with the relative proportions of reactants and products in a chemical reaction. In the equation for the reaction of hydrogen and oxygen, the number 2 precedes the formulae of hydrogen and water. The numbers in front of the formulae are called **stoichiometric coefficients**, and they indicate the ratio of species of each kind among the reactants and products. Thus, 2H_2 means 2 molecules of H_2 , and $2\text{H}_2\text{O}$ means 2 molecules of H_2O . When no number is written, the stoichiometric coefficient is 1 (so the coefficient of O_2 equals 1). Stoichiometric coefficients can also refer to ions or atoms.

Stoichiometric coefficients are required to ensure the equation conforms to the law of conservation of mass (discussed in the chapter on the atom). Because atoms cannot be created or destroyed in a chemical reaction, we must have the same number of atoms of each kind present before and after the reaction (i.e. on both sides of the arrow), as shown in figure 3.1. This is an example of a **balanced chemical equation**. (Refer back to figure 2.16 to remind yourself of the colours we use in this text to represent atoms of the various elements in space-filling and ball-and-stick models.) Another example of a balanced chemical equation is shown in figure 3.2: the equation for the reaction of butane, C_4H_{10} , with oxygen, O_2 . Butane can be used as the fuel in camping stoves.

FIGURE 3.1

The reaction between 2 molecules of hydrogen and 1 molecule of oxygen gives 2 molecules of water, as represented by the space-filling models and chemical equation shown here.

FIGURE 3.2

The chemical equation for the combustion of butane, C_4H_{10} . The products are carbon dioxide and water.

In the equation in figure 3.2, the 2 before C_4H_{10} tells us that 2 molecules of butane are involved in the reaction. This involves a total of 8 carbon atoms and 20 hydrogen atoms (see figure 3.3). Notice that we have multiplied the numbers of atoms of C and H in 1 molecule of C_4H_{10} by the coefficient 2. The 13 in front of O_2 means that 13 molecules of O_2 are required for complete reaction of 2 molecules of C_4H_{10} . On the right, we find 8 molecules of CO_2 , which contain a total of 8 carbon atoms. Similarly, 10 water molecules contain 20 hydrogen atoms. Finally, we can count 26 oxygen atoms on both sides of the equation.

FIGURE 3.3

Understanding coefficients in an equation. The expression $2\text{C}_4\text{H}_{10}$ describes 2 molecules of butane (depicted here as ball-and-stick models), each of which contains 4 carbon and 10 hydrogen atoms. This gives a total of 8 carbon and 20 hydrogen atoms.

Specifying states of matter

In a chemical equation, it is useful to specify the physical states of the reactants and products; that is, whether they are solids, liquids or gases. This is done by writing (s) for solid, (l) for liquid or (g) for gas after the chemical formula. For example, the equation for the combustion of carbon in a charcoal briquette can be written as follows.

At times, we will also find it useful to indicate that a particular substance is dissolved in water. We do this by writing (aq), meaning ‘aqueous solution’, after the formula. For instance, the reaction between stomach acid (an aqueous solution of HCl) and CaCO_3 , the active ingredient in some antacids, is shown below.

This type of chemical equation is called a molecular equation. It shows all reactants and products, with molecular substances written as discrete molecules (e.g. H_2O) and ionic compounds written in terms of their empirical formulae (e.g. CaCO_3 ; see section 3.4). If ionic compounds are involved, we can also write net ionic equations that only show the ions involved in the actual reaction (see section 3.6).

PRACTICE EXERCISE 3.1

How many atoms of each element appear on each side of the arrow in the following equation?

PRACTICE EXERCISE 3.2

Rewrite the equation in practice exercise 3.1 to show that $\text{Mg}(\text{OH})_2$ is a solid, HCl and MgCl_2 are dissolved in water, and H_2O is a liquid.

3.2 Balancing chemical equations

LEARNING OBJECTIVE 3.2 Balance chemical equations.

We have learned that a chemical equation is a shorthand, quantitative description of a chemical reaction. An equation is *balanced* when the atoms present among the reactants are also present in the same number among the products. As we learned, stoichiometric coefficients (the numbers in front of formulae) are multiplier numbers for their respective formulae, and the values of the coefficients determine whether an equation is balanced.

Always approach the balancing of an equation as a two-step process.

Step 1: Write the unbalanced 'equation'. Organise the formulae in the pattern of an equation with plus signs and an arrow.

Step 2: Adjust the coefficients so that there are equal numbers of each kind of atom on each side of the arrow. Apply the following guidelines in sequence.

- Balance elements other than H and O.
- Balance as a group those polyatomic ions (ions consisting of two or more covalently bonded atoms; see the chapter on the language of chemistry) that appear unchanged on both sides of the arrow.
- Balance ions so that the overall charge is the same on both sides of the arrow.
- Balance those species that appear on their own (as elements or ions).
- Balance the number of H and O atoms on both sides (e.g. by using H_2O or OH^-).

The guidelines are derived from experience, but are not hard and fast rules. The sequence of rules is chosen so that the species that are most difficult to balance are handled first and the easiest ones last (H and O are easily balanced in aqueous solutions).

In step 2, make no changes in the formulae, either in the atomic symbols or their subscripts. If you do, the equation will involve different substances from those intended. It may still balance, but the equation will not be for the reaction you want.

Let's begin with simple equations that can be balanced by inspection. An example is the reaction of aluminium metal with hydrochloric acid (see figure 3.4). First, we need the correct formulae and physical states. In this example, we use the molecular equation (see above) even though both HCl and AlCl_3 exist as ions in aqueous solution. The reactants are aluminium, $\text{Al}(\text{s})$, and hydrochloric acid, $\text{HCl}(\text{aq})$. We also need formulae for the products. The reaction results in the formation of aqueous aluminium chloride, which we write as $\text{AlCl}_3(\text{aq})$, and hydrogen gas, $\text{H}_2(\text{g})$. Recall that hydrogen normally exists as diatomic molecules and not as individual atoms.

Step 1: Write an unbalanced equation.

Step 2: Adjust the coefficients to get equal numbers of each kind of atom on both sides of the arrow by applying the guidelines in the order given above. Using the guidelines, we will look at Cl first in our example. Because there are 3 Cl atoms to the right of the arrow but only 1 to the left, we put a 3 in front of the HCl on the left side.

FIGURE 3.4

Aluminium and hydrochloric acid react to form aluminium chloride and hydrogen gas.

Since there are no polyatomic ions in this example, we look next at species that appear on their own (Al and H₂, in this example). You can see that Al looks balanced, but there are 3 H atoms on the left and only 2 on the right. We can balance these by putting a coefficient of 3 in front of H₂ and then doubling the coefficient for HCl.

However, Cl is now not balanced; there are 6 Cl atoms on the left and only 3 on the right. Therefore, we need a coefficient of 2 in front of AlCl₃.

Everything is now balanced except for Al; there is 1 Al atom on the left but 2 on the right. We put a coefficient of 2 in front of Al.

Now there are 2 Al, 6 H and 6 Cl atoms on each side of the equation and everything is balanced. Note that the equation $4\text{Al(s)} + 12\text{HCl(aq)} \rightarrow 4\text{AlCl}_3\text{(aq)} + 6\text{H}_2\text{(g)}$ is also balanced, but it is usual to write balanced equations using the *smallest* whole-number coefficients.

WORKED EXAMPLE 3.1

Writing a balanced equation

Aqueous solutions of calcium hydroxide, Ca(OH)₂, and phosphoric acid, H₃PO₄, react to give calcium phosphate, Ca₃(PO₄)₂, and water. The calcium phosphate precipitates from solution. Write the balanced equation for this reaction.

Analysis

First, write an unbalanced equation that includes the reactant formulae on the left-hand side and the product formulae on the right. Include the designation (aq) for all substances dissolved in water and (l) for H₂O itself when it is in its liquid state. Then adjust stoichiometric coefficients (*never subscripts!*) until there is the same number of each type of atom on the left and right sides of the equation.

Solution

There are several things not in balance, but our guidelines suggest that we work with Ca first, rather than with O and H atoms, or the PO₄³⁻ polyatomic ions, which remain unchanged on both sides of the equation. There are 3 Ca atoms on the right side, so we put a 3 in front of Ca(OH)₂ on the left, as a trial.

Now the Ca atoms are in balance. The PO₄³⁻ anions are not balanced; there are 2 on the right side and only 1 on the left side. We put a 2 in front of H₃PO₄ as the next step.

Not counting the PO₄³⁻ anions, we have on the left 6 O and 6 H atoms in 3Ca(OH)₂ plus 6 H atoms in H₃PO₄, for a net total of 6 O and 12 H atoms on the left. On the right, in H₂O, we have 1 O and 2 H atoms. The ratio of 6 O to 12 H atoms on the left is equivalent to the ratio of 1 O to 2 H atoms on the right, so we write the multiplier (coefficient) 6 in front of H₂O.

We now have a balanced equation.

Is our answer reasonable?

A count of the total number of atoms on each side of the equation shows that they are the same. On each side we have 3 Ca, 12 H, 2 P and 14 O atoms. The coefficients used cannot be reduced to smaller whole numbers and so we have an equation balanced with the smallest whole-number coefficients.

PRACTICE EXERCISE 3.3

When aqueous solutions of barium chloride, BaCl₂, and aluminium sulfate, Al₂(SO₄)₃, are mixed, a reaction occurs in which solid barium sulfate, BaSO₄, precipitates from the

solution. The other product is AlCl₃(aq). Write the balanced equation for this reaction.

3.3 The mole

LEARNING OBJECTIVE 3.3 Use the mole concept in stoichiometric calculations.

In the preceding sections, you have seen that chemical formulae tell us about the relative numerical proportions of atoms in molecules or ionic compounds, and that chemical equations are a convenient way to summarise what happens in chemical reactions. In this and the following sections, you will investigate the quantitative relationships further and find that these are governed by the rules of stoichiometry.

In a chemical reaction, the relative ratios of reactants resulting in a given ratio of products are given by the chemical equations that we looked at in earlier sections of this chapter. That, however, is on an atomic or molecular level. For example, the following equation tells you that 1 molecule of A reacts with 2 molecules of B to form 1 molecule of AB_2 .

Suppose that we wanted to carry out this reaction in the laboratory. Given the size and mass of individual atoms, which we described in the chapter on the atom, we cannot see, count or weigh individual atoms, ions or molecules. Instead, we need to weigh out and work with larger numbers. What numbers can we use?

For guidance, we look to the SI unit for **amount of substance**, symbol n , which is the **mole** (unit symbol: mol). By definition (see table 2.1), one mole contains exactly $6.022\,140\,76 \times 10^{23}$ elementary entities. When this value is expressed in the unit mol^{-1} , it is called the **Avogadro constant** (N_A). We will generally quote the Avogadro constant to four significant figures.

$$N_A = 6.022 \times 10^{23} \text{ mol}^{-1}$$

The numerical value of the Avogadro constant is almost beyond comprehension. Consider, for example, that 6.022×10^{23} grains of sand would cover Australia and New Zealand to a depth of about 1.3 metres. However, because atoms are so incredibly small, a mole of atoms, molecules or ions takes up comparatively little space (see figures 3.5 and 3.6).

FIGURE 3.5

One mole of different elements (clockwise from top left: sulfur, aluminium, mercury and copper). Each of these element samples contains 6.022×10^{23} atoms.

FIGURE 3.6

One mole of different compounds (clockwise from top left: copper sulfate pentahydrate, water, sodium chromate and sodium chloride).

The definition of a mole does not restrict the nature of an elementary entity. For example, 1 mol of eggs would contain 6.022×10^{23} eggs. We can in fact think of the mole as being the ‘chemist’s dozen’ — just as 12 eggs constitute a dozen, 6.022×10^{23} eggs constitute a mole. In chemistry terms, the elementary entities of interest are usually atoms, ions or molecules. Most importantly, the mole can be used to link atomic mass and macroscopic amounts. If we multiply an atomic mass unit, u , (described in the chapter on the atom) by N_A , we obtain almost exactly 1 g.

$$1.660\,539\,066\,60 \times 10^{-27} \text{ kg} \times 6.022\,140\,76 \times 10^{23} \text{ mol}^{-1} = 0.999\,999\,999\,65 \times 10^{-3} \text{ kg mol}^{-1}$$

For the purposes of this text, where we generally quote numbers to 4 significant figures, and for almost all practical purposes in the chemistry laboratory, we can say that whatever anything weighs in atomic mass units, a mole of it will weigh in grams. The mole, therefore, simplifies our lives as chemists, as we generally work on gram scales in the laboratory.

When we talk about an amount, we mean an amount of substance in moles. While the number of specified entities in a mole is constant, the mass of 1 mol of those entities depends on the mass of the individual entities. It is important, therefore, that we specify exactly which particular species we are discussing when we use amounts. We must also be careful to avoid ambiguities. For example, the phrase ‘1 mol of oxygen’ is ambiguous, because we have not specified whether we are talking about 1 mol of oxygen atoms, O, or oxygen molecules, O₂. It is important, therefore, to include a chemical formula whenever amounts are used.

We call the mass of 1 mol of any specified entity the **molar mass (*M*)**. This serves as the link between mass (*m*) and amount of substance (*n*) through the following equation.

$$M = \frac{m}{n}$$

The SI unit of molar mass is actually kg mol⁻¹, but this is rarely used in practice. Molar mass values are almost always quoted in units of g mol⁻¹, that is, the number of grams per mole of substance.

Values of molar mass for the elements are tabulated in appendix J, and it is informative to look at some of these. Note that these values refer to 1 mol of atoms of the elements, regardless of whether the elements themselves exist in atomic form. For example, the tabulated molar mass of I is 126.904 47 g mol⁻¹ even though elemental iodine exists as I₂ molecules, not I atoms.

We need to appreciate that the molar mass of an element is determined by the isotopic make-up of that element. The molar masses of all elements with more than one naturally occurring isotope reflect the relative mass and abundance of each isotope, as discussed in the chapter on the atom.

Because no element has a molar mass exactly equal to an integer, for simplicity of calculations in this text we will usually use molar masses to four significant figures. There is no need to learn the values of molar mass (they will always be available), but it is important to learn how to use them. The definition of molar mass, expressed in the equation above, and one other equation, which we will encounter later in this chapter, enables you to solve *any* stoichiometry problem. The approach to doing stoichiometry problems is deciding how to apply these two equations.

WORKED EXAMPLE 3.2

Calculating an amount from a mass

The largest diamond found in Australia came from the Mer-
lin mine in the Northern Territory. It has a mass of 20.95 g. If
the stone consists of pure carbon, what amount of C does
it contain, given that the molar mass of C is 12.01 g mol⁻¹?

Analysis

A good method to follow when beginning any stoichiometry
problem is to ask two questions: ‘What value does the
question want me to determine?’, and ‘What data have I
been given?’. Write down the answers to these questions
and then look for an equation that contains as many as
possible of these. In this case, we are asked to determine
an amount (*n*), and we have been given a molar mass (*M*)
and a mass (*m*). The equation that contains all of these is
 $M = \frac{m}{n}$.

Solution

We rearrange $M = \frac{m}{n}$ to solve for *n*:

$$n = \frac{m}{M}$$

Hence:

$$\begin{aligned} n &= \frac{20.95 \text{ g}}{12.01 \text{ g mol}^{-1}} \\ &= 1.744 \text{ mol} \end{aligned}$$

Therefore, this diamond contains 1.744 mol of carbon.

Is our answer reasonable?

We have 20.95 g of carbon in the diamond. Given that 1 mol
of C has a mass of 12.01 g, we should expect an answer
of slightly less than 2 mol, which we have. Our answer
therefore is reasonable.

PRACTICE EXERCISE 3.4

What amount of sulfur molecules, S₈, is present in 35.6 g of sulfur? The molar mass of atomic sulfur, S, is 32.06 g mol⁻¹.

When solving this type of problem, always check the units of the answer. This is especially important if it is necessary to rearrange the equation to solve the problem. The units will *always* be correct if you have rearranged the equation correctly. In worked example 3.2, we are dividing mass by molar mass. Grams in the numerator (the top line) will cancel grams in the denominator (the bottom line), leaving $\frac{1}{\text{mol}^{-1}}$ as our final unit. This is the same as $\frac{1}{\frac{1}{\text{mol}}}$, which is mol, meaning that our units are correct. As we saw in the chapter on the language of chemistry, units are also very powerful in helping you to remember equations. The equation $M = \frac{m}{n}$ is easy to remember if you know that the units of molar mass are g mol^{-1} : in other words, grams (the unit of mass) divided by moles (the unit of amount). This then gives the correct form of the equation.

WORKED EXAMPLE 3.3

Calculating a mass from an amount

Calcium phosphate, $\text{Ca}_3(\text{PO}_4)_2$, is often used to coat some of the surfaces of bone or dental implants to permit bone to bond with the implant surface. A schematic is shown in figure 3.7.

FIGURE 3.7 Some surfaces on bone implants are coated with calcium phosphate to permit bone to bond to the surface.

If a coating procedure can deposit 0.115 mol of pure $\text{Ca}_3(\text{PO}_4)_2$ on an implant, what is the mass of the coating? The molar mass of Ca is 40.08 g mol^{-1} , of P is 30.97 g mol^{-1} and of O is 16.00 g mol^{-1} .

Analysis

We are asked to calculate a mass (m) and we are given an amount (n) and the molar masses (M) of Ca, P and O. We will therefore use $M = \frac{m}{n}$ again, but we will have to calculate the molar mass of $\text{Ca}_3(\text{PO}_4)_2$ from the individual molar masses of the elements before we can substitute the data into the equation.

Solution

$$\begin{aligned} M_{\text{Ca}_3(\text{PO}_4)_2} &= (3 \times 40.08 \text{ g mol}^{-1}) + (2 \times 30.97 \text{ g mol}^{-1}) + (8 \times 16.00 \text{ g mol}^{-1}) \\ &= 310.2 \text{ g mol}^{-1} \end{aligned}$$

We now rearrange $M = \frac{m}{n}$ to make m the subject: $m = Mn$. Substitution of the data gives:

$$\begin{aligned} m &= 310.2 \text{ g mol}^{-1} \times 0.115 \text{ mol} \\ &= 35.7 \text{ g} \end{aligned}$$

Therefore, the coating of $\text{Ca}_3(\text{PO}_4)_2$ weighs 35.7 g.

Is our answer reasonable?

The coating contains a little over 0.1 mol of $\text{Ca}_3(\text{PO}_4)_2$. Since 0.1 of 310 g is 31 g, and our answer of 35.7 g is slightly more than 31 g, it makes sense.

PRACTICE EXERCISE 3.5

What mass of sodium carbonate, Na_2CO_3 , corresponds to 0.125 mol of Na_2CO_3 ?

PRACTICE EXERCISE 3.6

Determine the amount of BaSO_4 in a 45.8 g sample of BaSO_4 .

3.4 Empirical formulae

LEARNING OBJECTIVE 3.4 Determine empirical formulae from quantitative analysis data

Whenever a new compound is prepared, it is usually analysed to determine the mass percentages of the elements it contains. From these mass percentages, it is possible to obtain an empirical formula of the compound. The **empirical formula** is the simplest whole-number ratio of atoms within that compound. For example, the empirical formula of butane (chemical formula C_4H_{10}) is C_2H_5 . If we know the ratio by mass of each element within a compound, we can then determine its empirical formula by using the relationship $M = \frac{m}{n}$.

Mole ratios from chemical formulae

Consider the chemical formula for water, H_2O .

- 1 water molecule contains 2 H atoms and 1 O atom.
- 2 water molecules contain 4 H atoms and 2 O atoms.
- 1 dozen water molecules contain 2 dozen H atoms and 1 dozen O atoms.
- 1 mol of water molecules contains 2 mol of H atoms and 1 mol of O atoms.

Whether we are dealing with atoms, dozens of atoms or moles of atoms, the chemical formula tells us that the ratio of H atoms to O atoms in H_2O is always 2 to 1. *For chemical compounds, mole ratios are the same as the ratios of the individual atoms.*

This fact lets us prepare mole-to-mole conversion factors involving elements in compounds as we need them. For example, in the formula P_4O_{10} , the subscripts mean that there are 4 mol of P for every 10 mol of O in this compound. We also know that 1 mol of P_4O_{10} contains 4 mol of P and 10 mol of O.

In the laboratory, stoichiometry is commonly used to relate the masses of two starting materials that are needed to synthesise a compound and to determine reaction yields, as we will see later in this chapter.

WORKED EXAMPLE 3.4

Calculating amounts of elements within a compound

Leaves have a characteristic green colour due to the presence of the green pigment chlorophyll, which has the formula $\text{C}_{55}\text{H}_{72}\text{MgN}_4\text{O}_5$. A particular sample of chlorophyll was found to contain 0.0011 g of Mg. What mass of carbon was present in the sample? ($M_{\text{C}} = 12.01 \text{ g mol}^{-1}$; $M_{\text{Mg}} = 24.31 \text{ g mol}^{-1}$)

Analysis

We are asked to calculate a mass of carbon (m_{C}) and are given a mass of magnesium (m_{Mg}) and molar masses of both carbon and magnesium. The data given allow us to calculate the amount of magnesium (n) in the sample using $M = \frac{m}{n}$; we then use the mole ratio between Mg and C, which is implicit in the formula of chlorophyll, to determine the amount of C present. Once we have this amount, we then use $M = \frac{m}{n}$ again to convert it to mass.

Solution

First, we calculate the amount of Mg corresponding to 0.0011 g of Mg.

$$M = \frac{m}{n}$$

$$n = \frac{m}{M} = \frac{0.0011 \text{ g}}{24.31 \text{ g mol}^{-1}} = 4.5 \times 10^{-5} \text{ mol}$$

We now look at the formula of chlorophyll, $\text{C}_{55}\text{H}_{72}\text{MgN}_4\text{O}_5$, to obtain the mole ratio between Mg and C. In 1 molecule of chlorophyll, we have 1 atom of Mg and 55 atoms of C. Therefore, in 1 mol of chlorophyll, we have 1 mol of Mg and 55 mol of C, meaning that there is 55 times the amount of C as there is Mg in chlorophyll. In this problem, we have $4.5 \times 10^{-5} \text{ mol}$ Mg, so we obtain the amount of C from:

$$\begin{aligned} n_{\text{C}} &= n_{\text{Mg}} \times 55 \\ &= 4.5 \times 10^{-5} \text{ mol} \times 55 \\ &= 2.5 \times 10^{-3} \text{ mol} \end{aligned}$$

Now we know the amount of carbon, we can convert this to mass.

$$\begin{aligned} m &= Mn \\ &= 12.01 \text{ g mol}^{-1} \times (2.5 \times 10^{-3} \text{ mol}) \\ &= 3.0 \times 10^{-2} \text{ g} \end{aligned}$$

Therefore, 0.030 g C was present in the sample.

Is our answer reasonable?

The molar mass of Mg is about twice that of C. Since we need 55 mol C for every 1 mol Mg, the mass of C we require

should be about 30 times that of Mg. Our answer was 0.030 g C for 0.0011 g Mg, so the mass of C we got is about 30 times the mass of the Mg we started with. This seems reasonable.

PRACTICE EXERCISE 3.7

What mass of iron is in a 15.0 g sample of Fe_3O_4 ?

PRACTICE EXERCISE 3.8

What mass of iron is required to react with 25.6 g of O_2 to form Fe_2O_3 ? Assume that all of the oxygen is consumed in the reaction.

Determination of chemical formulae

In research laboratories, chemists often synthesise entirely new compounds or isolate previously unknown compounds from plant and animal tissues. They must then determine the formula and structure of the compound. This usually involves mass spectrometry (see the chapter on structure determination), which gives an experimental value for the molar mass. The compound can also be decomposed chemically to find the masses of elements within a given amount of compound, a process called **elemental analysis** (see the Chemical Connections feature on the Mark Wainwright Analytical Centre, UNSW Sydney).

CHEMICAL CONNECTIONS

Elemental analysis at the Mark Wainwright Analytical Centre, UNSW Sydney

Arguably, the most important aspect of chemistry is the synthesis of new compounds. Chemists around the world prepare at least one million never-before-made compounds every year, and every one of these must be characterised in some way. One of the fundamental techniques used is elemental analysis, in which the mass percentages of elements in the new compound are determined. As we will see in this chapter, mass percentage data allow us to obtain an empirical formula for the compound; we can use this in combination with a variety of other methods, which we will meet in later chapters, to determine its structure.

The Mark Wainwright Analytical Centre at UNSW Sydney is one of the very few microanalytical services available in Australasia. It has many years of expertise in elemental analysis and carries out analyses for many universities in Australia and New Zealand.

Routine elemental analyses involve determination of the mass percentages of C, H, N and S in a compound, and are often carried out using an automated elemental analyser such as the one shown in the schematic diagram in figure 3.8. The samples are combusted with oxygen at high temperature (oxidation) in the presence of a catalyst. The resulting gases are then passed over a catalyst layer and through copper to remove excess O_2 and to reduce nitrogen oxides to nitrogen (reduction). The gases, CO_2 , H_2O , SO_2 and N_2 , are then separated by injection onto a chromatography column, and the amount of each is measured using a very sensitive thermal conductivity detector. These data are then converted to mass percentages of C, H, N and S, respectively.

Elements other than C, H, N or S in a sample must be analysed manually, and standard methods are available for these. Note that O is not usually analysed directly, and its mass percentage in an organic compound is generally obtained by subtracting the total mass percentages of all the other elements from 100.

FIGURE 3.8

Diagram of an automated elemental analysis system for carbon, hydrogen, nitrogen and sulfur. The diagram illustrates the combustion chamber, the chromatography column, a thermal conductivity detector, and a sample of a chromatogram with peaks for N_2 , CO_2 , H_2O and SO_2 .

Let us see how experimental mass measurements can be used to determine a compound's formula. The usual form for describing the relative masses of the elements in a compound is a list of percentages by mass called the compound's **mass percentage composition**. In general, a **percentage by mass** is found by using the following equation.

$$\% \text{ by mass of element} = \frac{\text{mass of element present in the sample}}{\text{mass of whole sample}} \times 100 \%$$

WORKED EXAMPLE 3.5

Calculating a percentage composition from chemical analysis

A sample of a liquid with a mass of 8.657 g was found to contain 5.217 g of carbon, 0.9620 g of hydrogen and 2.478 g of oxygen. What is the percentage composition of this compound?

Analysis

We must apply the percentage composition equation for each element. The 'mass of whole sample' here is 8.657 g, so we take each element in turn and do the calculations.

Solution

$$\text{mass \% (C)} = \frac{5.217 \text{ g}}{8.657 \text{ g}} \times 100\% = 60.26\%$$

$$\text{mass \% (H)} = \frac{0.9620 \text{ g}}{8.657 \text{ g}} \times 100\% = 11.11\%$$

$$\text{mass \% (O)} = \frac{2.478 \text{ g}}{8.657 \text{ g}} \times 100\% = 28.62\%$$

$$\text{Sum of percentages} = 99.99\%$$

One of the useful things about a percentage composition is that it allows us to work out the mass of each of the elements in 100 g of the substance without further calculation. For example, the results in this problem tell us that in 100.00 g of the liquid there is 60.26 g of carbon, 11.11 g of hydrogen and 28.62 g of oxygen.

Is our answer reasonable?

The 'check' is that the percentages must add up to 100% if the individual masses add up to the total mass, allowing for small differences caused by rounding and experimental error.

PRACTICE EXERCISE 3.9

From 0.5462 g of a compound, 0.1417 g of nitrogen and 0.4045 g of oxygen was isolated. What is the percentage composition of this compound? Are any other elements present in the compound?

Elements can combine in many different ways. Nitrogen and oxygen, for example, form all of the following compounds: N_2O , NO , NO_2 , N_2O_3 , N_2O_4 and N_2O_5 . To identify an unknown sample of a compound of nitrogen and oxygen, we compare the percentage composition found by experiment with the calculated percentages for each possible formula.

WORKED EXAMPLE 3.6

Calculating a theoretical percentage composition from a chemical formula

Are the mass percentages of 25.92% N and 74.09% O consistent with the chemical formula N_2O_5 ? ($M_{\text{N}} = 14.01 \text{ g mol}^{-1}$; $M_{\text{O}} = 16.00 \text{ g mol}^{-1}$)

Analysis

Essentially, we are asked to calculate the mass percentages of N and O in the compound N_2O_5 . The data we are given are the molar masses (M) of N and O. The only equation we know that contains molar mass is $M = \frac{m}{n}$ so we will have to use this at some stage. To calculate the theoretical percentages by mass of N and O in N_2O_5 , we need the masses of N and O in a specific sample of N_2O_5 . If we choose 1 mol of the given compound as the sample, calculating the rest of the data will be easier.

Solution

We know that 1 mol of N_2O_5 contains 2 mol of N and 5 mol of O. The corresponding masses of N and O are found using $M = \frac{m}{n}$ as follows.

$$\begin{aligned}m_{\text{N}} &= Mn = 14.01 \text{ g mol}^{-1} \times 2 \text{ mol} = 28.02 \text{ g} \\m_{\text{O}} &= Mn = 16.00 \text{ g mol}^{-1} \times 5 \text{ mol} = 80.00 \text{ g}\end{aligned}$$

The mass of 1 mol of N_2O_5 will, therefore, be the sum of the mass of N and the mass of O in 1 mol of the molecule; that is, $28.02 \text{ g} + 80.00 \text{ g} = 108.02 \text{ g}$.

We can now calculate the percentages by mass as we did in worked example 3.5.

$$\text{mass \% (N)} = \frac{28.02 \text{ g}}{108.02 \text{ g}} \times 100 = 25.94\%$$

$$\text{mass \% (O)} = \frac{80.00 \text{ g}}{108.02 \text{ g}} \times 100 = 74.06\%$$

Therefore, the experimental data are consistent with the formula N_2O_5 .

Is our answer reasonable?

We get a good match between the calculated and experimental values, which is always encouraging! In problems like this, you should double-check your calculations and make sure that the percentages of all the elements present add up to 100% if the individual masses add up to the total mass, within rounding and experimental error.

PRACTICE EXERCISE 3.10

Calculate the percentage composition of NO_2 .

Determination of empirical formulae

The compound that forms when phosphorus burns in oxygen consists of molecules with the formula P_4O_{10} . When a formula gives the composition of one *molecule*, it is called the **molecular formula**. Notice, however, that both the subscripts 4 and 10 are divisible by 2, so the *smallest* numbers that tell us the *ratio* of P to O is 2 to 5. A simpler (but less informative) formula that expresses this ratio is P_2O_5 . This is called the *empirical formula* because it can be obtained from an elemental analysis of the compound.

To obtain an empirical formula, we need to determine the mass of each element in a sample of the compound. From mass, we then calculate amount, from which we obtain the mole ratios of the elements. Because the ratio by moles is the same as the ratio by atoms, we can construct the empirical formula.

Only rarely is it possible to obtain the masses of every element in a compound by the use of just one weighed sample; two or more analyses on different samples may be required. For example, suppose an analyst is given a compound known to consist exclusively of calcium, chlorine and oxygen. The mass of calcium in one weighed sample and the mass of chlorine in another sample would be determined in

separate experiments. Then the mass data for calcium and chlorine would be converted to percentages by mass (equivalent to the mass of each of these elements in a sample of 100 g). This allows the data from different samples to be compared directly. The mass percentage of oxygen would then be calculated by difference because $\%Ca + \%Cl + \%O = 100\%$. Each mass percentage can be related to the corresponding amount of the element. The mole proportions are converted to whole numbers, giving us the subscripts for the empirical formula.

Therefore, the three steps necessary to determine an empirical formula are as follows.

1. Assume we are studying 100 g of the compound. Therefore, the individual mass percentages correspond to the actual masses of the elements in 100 g of the compound.
2. Convert the ratio of elements by mass to a ratio by amount, by dividing the mass of each element by its molar mass.
3. Divide the resulting numbers by the smallest one, which will give the smallest ratio of the elements in the compound. If this gives any numbers that are not integers, multiply all numbers in the ratio by the smallest factor that will result in all numbers being integers.

WORKED EXAMPLE 3.7

Calculating an empirical formula from percentage composition

A white powder used in paints, enamels and ceramics has the following mass percentage composition.

Ba, 69.6%; C, 6.09%; O, 24.3%

What is its empirical formula? ($M_{Ba} = 137.3 \text{ g mol}^{-1}$; $M_C = 12.01 \text{ g mol}^{-1}$; $M_O = 16.00 \text{ g mol}^{-1}$)

Analysis

We are asked to calculate an empirical formula, and we are given mass percentage compositions and molar mass (M) values. We can convert mass percentage to mass (m) simply by choosing 100 g of compound to study. We can then calculate amounts of Ba, C and O by using $M = \frac{m}{n}$, and use these to obtain the necessary mole ratios for the empirical formula.

Solution

A 100 g sample of the compound will contain 69.6 g Ba, 6.09 g C and 24.3 g O. We first relate these masses to amounts.

$$n_{Ba} = \frac{m}{M} = \frac{69.6 \text{ g}}{137.3 \text{ g mol}^{-1}} = 0.507 \text{ mol}$$

$$n_C = \frac{m}{M} = \frac{6.09 \text{ g}}{12.01 \text{ g mol}^{-1}} = 0.507 \text{ mol}$$

$$n_O = \frac{m}{M} = \frac{24.3 \text{ g}}{16.00 \text{ g mol}^{-1}} = 1.52 \text{ mol}$$

Our ratio of Ba:C:O is therefore 0.507:0.507:1.52. However, chemical formulae contain whole numbers, so we divide each amount by the smallest amount. The ratio then becomes:

$$\frac{0.507 \text{ mol}}{0.507 \text{ mol}} : \frac{0.507 \text{ mol}}{0.507 \text{ mol}} : \frac{1.52 \text{ mol}}{0.507 \text{ mol}} = 1 : 1 : 3$$

Therefore, our mole ratio is 1 Ba:1 C:3 O, and the empirical formula is BaCO_3 .

Is our answer reasonable?

If the formula is correct, there are 3 mol of oxygen for every 1 mol of carbon in the compound. So, for every 1 mol (12 g) of carbon in the compound, there should be 3 mol (48 g) of oxygen. The carbon-to-oxygen mass ratio is 12:48, or 1:4. This is consistent with the ratio of carbon and oxygen percentages ($6.09:24.3 \approx 1:4$).

PRACTICE EXERCISE 3.11

A white solid that is used to whiten paper has the following mass percentage composition: Na, 32.4%; S, 22.6%. The rest of the mass is oxygen. What is the empirical formula of the compound?

In practice, a compound is seldom broken down completely to its elements in a quantitative analysis. Instead, the compound is changed into other compounds. The reactions separate the elements by capturing each one entirely (quantitatively) in a separate compound with a known formula.

In the following example, we illustrate an indirect analysis of a compound made entirely of carbon, hydrogen and oxygen. Such compounds burn completely in pure oxygen — the reaction is called **combustion** — and the sole products are carbon dioxide and water vapour. The complete combustion of ethanol, $\text{CH}_3\text{CH}_2\text{OH}$, for example, occurs according to the following equation.

The carbon dioxide and water can be separated and then their masses determined. Notice that all of the carbon atoms in the original compound end up among the CO_2 molecules and all of the hydrogen atoms are in H_2O molecules. In this way at least two of the original elements, C and H, are entirely separated.

Modern microanalytical techniques allow the simultaneous determination of C, H, N and S, as described in the chemical connections feature on the Mark Wainwright Analytical Centre. Initial combustion of the sample and subsequent passage of the resulting gas mixture over a catalyst results in the conversion of all C in the sample to CO_2 , all the H to H_2O , all the N to N_2 and all the S to SO_2 . The mass of each gas, and hence the mass of each element (C, H, N and S), is then determined. We convert the masses of the elements into percentages of the element by mass in the compound. We then add up the percentages and subtract from 100 to get the percentage of O. We then calculate the empirical formula from the percentage composition as described earlier.

The empirical formula is all that we need for ionic compounds. For molecular compounds, however, chemists prefer *molecular* formulae because they give the number of atoms of each type in a molecule, rather than just the ratio of the elements in a compound, as the empirical formula does.

Sometimes an empirical formula and a molecular formula are the same. Two examples are H_2O and NH_3 . More often, however, the subscripts of a molecular formula are whole-number multiples of those in the empirical formula. The subscripts of the molecular formula P_4O_{10} , for example, are each two times those in the empirical formula, P_2O_5 , as we saw earlier. The molar mass of P_4O_{10} is likewise two times the molar mass of P_2O_5 . This observation helps us find the molecular formula for a compound, provided we have a way of experimentally determining the molar mass of the compound. If the experimental molar mass *equals* the calculated mass of an empirical formula, the empirical formula itself is also a molecular formula. Otherwise, the experimental molar mass will be some whole-number multiple of the value calculated from the empirical formula. Whatever the whole number is, it is a common multiplier for the subscripts of the empirical formula.

3.5 Stoichiometry, limiting reagents and percentage yield

LEARNING OBJECTIVE 3.5 Calculate theoretical and actual yields based on balanced equations.

So far, we have focused on relationships between elements within a single compound. In this section, we focus on the relationships between amounts of substances involved in a chemical reaction. The critical link between amounts of substances involved in a reaction is the mole-to-mole ratio obtained from the balanced chemical equation that describes the reaction. Consider the equation that describes the burning of octane, C_8H_{18} , in oxygen, O_2 , to give carbon dioxide and water vapour.

This equation can be interpreted on a molecular scale as follows: for every 2 molecules of liquid octane that react with 25 molecules of oxygen gas, 16 molecules of carbon dioxide gas and 18 molecules of water vapour are produced.

We can also interpret the equation on a molar scale as follows: 2 mol of liquid octane react with 25 mol of oxygen gas to produce 16 mol of carbon dioxide gas and 18 mol of water vapour.

Let us see how mole-to-mole relationships obtained from a balanced chemical equation can be used to relate the amount of one substance to the amount of another when both substances are involved in a chemical reaction.

WORKED EXAMPLE 3.8

Stoichiometry of chemical reactions

What amount of sodium phosphate, Na_3PO_4 , can be made from 0.240 mol of NaOH by the following reaction?

Analysis

We use a similar approach to that used in worked example 3.4 but, in this case, we require the mole ratio between different compounds. We obtain this mole ratio directly from the stoichiometry of the balanced chemical equation.

Solution

We can see from the stoichiometric coefficients that 3 mol of NaOH will react to give 1 mol of Na_3PO_4 . Therefore, if we start with 0.240 mol NaOH, we will obtain the following.

$$\frac{0.240 \text{ mol}}{3} = 0.0800 \text{ mol Na}_3\text{PO}_4$$

Is our answer reasonable?

There are really only two possible answers we could get to this problem — the correct one (0.0800 mol) and the incorrect one (0.720 mol), which would be obtained by multiplying rather than dividing by 3. Looking at the balanced chemical equation, we can see that the amount of Na_3PO_4 produced is less than the original amount of NaOH. In this case, our answer should be less than 0.240 mol, and it is.

PRACTICE EXERCISE 3.12

What amount of sulfuric acid, H_2SO_4 , is needed to react completely with 0.366 mol of NaOH according to the following reaction?

PRACTICE EXERCISE 3.13

If 0.575 mol of CO_2 is produced by the combustion of butane, C_4H_{10} , what amount of oxygen is consumed? The balanced chemical equation is as follows.

Mole ratios in chemical reactions

We often need to relate mass of one substance to mass of another in a chemical reaction. Consider, for example, the reaction of glucose, $\text{C}_6\text{H}_{12}\text{O}_6$, one of the body's primary energy sources, with oxygen.

The body combines glucose and oxygen to give carbon dioxide and water. The balanced equation for the overall reaction is as follows.

What mass of oxygen must the body take in to completely process 1.00 g of glucose?

The first thing we should notice about this problem is that we are relating amounts of *two different substances* in a reaction. The link between the amounts of substances is the mole-to-mole relationship between glucose and O_2 given by the chemical equation. In this case, the equation tells us that 1 mol of $\text{C}_6\text{H}_{12}\text{O}_6$ will react completely with 6 mol of O_2 .

If we insert the mole-to-mole conversion between our starting point (1.00 g $\text{C}_6\text{H}_{12}\text{O}_6$) and the desired quantity (g O_2), we cut the problem into three simple steps.

We obtain the amount of $\text{C}_6\text{H}_{12}\text{O}_6$ from the mass of $\text{C}_6\text{H}_{12}\text{O}_6$ using the molar mass of $\text{C}_6\text{H}_{12}\text{O}_6$. We then obtain the amount of O_2 from the amount of $\text{C}_6\text{H}_{12}\text{O}_6$, using the stoichiometry of the balanced equation. Finally, we obtain the mass of O_2 from the amount of O_2 using the molar mass of O_2 . If we have carried out these manipulations correctly, the answer should be 1.07 g O_2 .

One of the most common mistakes made in stoichiometry problems like this is the incorrect determination and use of the mole ratios for substances in the reaction. This often arises from an error in working out the amounts of substance needed for complete reaction. The three-step procedure above tells us that the amounts of the two substances that react with each other must have the same ratio as given in the chemical equation. For the reaction above, we need 6 times the amount of O_2 compared to the amount of $\text{C}_6\text{H}_{12}\text{O}_6$, that is, $n_{\text{O}_2} = 6n_{\text{C}_6\text{H}_{12}\text{O}_6}$.

WORKED EXAMPLE 3.9**Stoichiometric mass calculations**

Metallic iron can be made by the thermite reaction, the spectacular reaction of aluminium with iron oxide, Fe_2O_3 . So much heat is generated that the iron forms in the liquid state. The balanced chemical equation is as follows.

Assume that you need to produce 86.0 g of Fe in a welding operation. What mass of Fe_2O_3 and what mass of aluminium must be used for this operation, assuming all the Fe_2O_3 is converted to Fe? ($M_{\text{Fe}} = 55.85 \text{ g mol}^{-1}$; $M_{\text{O}} = 16.00 \text{ g mol}^{-1}$; $M_{\text{Al}} = 26.98 \text{ g mol}^{-1}$)

Analysis

We are asked to find the masses of Al and Fe_2O_3 required to prepare 86.0 g of Fe. We are given a mass of Fe (m) and the molar mass of Fe (M) so we can calculate the amount of Fe (n) using $M = \frac{m}{n}$. We then use the mole ratios in the balanced chemical equation to calculate the amounts of Al and Fe_2O_3 . The final step is to use $M = \frac{m}{n}$ to obtain the masses from these amounts.

In summary:

**Solution**

Firstly, we calculate the amount of Fe in 86.0 g.

$$n = \frac{m}{M} = \frac{86.0 \text{ g}}{55.85 \text{ g mol}^{-1}} = 1.54 \text{ mol}$$

Using the stoichiometric coefficients from the balanced chemical equation, we can see that the formation of 2 mol of Fe requires 2 mol of Al and 1 mol of Fe_2O_3 . In other words, we will require the same amount of Al, but half the amount of Fe_2O_3 .

Therefore:

$$n_{\text{Al}} = n_{\text{Fe}} = 1.54 \text{ mol}$$

$$n_{\text{Fe}_2\text{O}_3} = \frac{n_{\text{Fe}}}{2} = 0.770 \text{ mol}$$

We then use $M = \frac{m}{n}$ to obtain the masses from these amounts.

$$m_{\text{Al}} = Mn = 26.98 \text{ g mol}^{-1} \times 1.54 \text{ mol} = 41.5 \text{ g}$$

$$m_{\text{Fe}_2\text{O}_3} = Mn = 159.70 \text{ g mol}^{-1} \times 0.770 \text{ mol} = 123 \text{ g}$$

Is our answer reasonable?

As the formation of Fe from Fe_2O_3 involves loss of oxygen from Fe_2O_3 , we would expect the mass of Fe_2O_3 required to be greater than the mass of Fe produced. Given that 2 mol of Al give 2 mol of Fe, we would expect the mass of Al required to be about half the mass of Fe produced (86.0 g), as the molar mass of Al is about half that of Fe. Hence, our answers appear reasonable.

PRACTICE EXERCISE 3.14

What mass of aluminium oxide is also produced when 86.0 g of Fe is formed by the reaction described in worked example 3.9?

Limiting reagents

We have seen that balanced chemical equations can tell us how to mix reactants together in just the right proportions to get a certain amount of product. For example, ethanol, $\text{CH}_3\text{CH}_2\text{OH}$, is prepared industrially as follows.

The equation tells us that 1 mol of ethene will react with 1 mol of water to give 1 mol of ethanol. We can also interpret the equation on a molecular level; every molecule of ethene that reacts requires 1 molecule of water to produce 1 molecule of ethanol.

If we have 3 molecules of ethene reacting with 3 molecules of water, 3 ethanol molecules are produced.

What happens if we mix 3 molecules of ethene with 5 molecules of water? The ethene will be completely used up before all the water, and the product mixture will contain 2 unreacted water molecules, as shown below.

This situation can be exploited in the manufacture of chemicals to ensure that the more expensive reactant (ethene, in this case) is completely used up.

In the reaction mixture above, ethene is called a **limiting reagent** because it limits the amount of product (ethanol) that can form. Water is called an **excess reagent** because we have more of it than is needed to completely consume all the ethene. It is important to realise that in any reaction one or more reactants will be limiting. If all reactants are present in the exact amounts required by the stoichiometry of the reaction, then in essence *all* are limiting the amount of product that can be formed. They are not usually referred to as limiting reagents in this case.

To predict the amount of product we may theoretically obtain in a reaction, we need to identify the limiting reagent(s). In the previous example, we saw that we needed only three H₂O molecules to react with three C₂H₄ molecules; we had five H₂O molecules, so H₂O was present in excess and C₂H₄ was the limiting reagent.

Once we have identified the limiting reagent(s), it is possible to calculate the amount of product that might form and the amount of excess reagent(s), if any, that would be left over.

WORKED EXAMPLE 3.10

Limiting reagent

Gold(III) hydroxide, Au(OH)₃, is used for electroplating gold onto other metals. It can be made by the following reaction.

To prepare a fresh supply of Au(OH)₃, a chemist at an electroplating plant mixed 20.00 g of KAuCl₄ with 25.00 g of Na₂CO₃ (both dissolved in a large excess of water). What is the maximum mass of Au(OH)₃ that can form?

($M_{\text{Na}_2\text{CO}_3} = 105.99 \text{ g mol}^{-1}$; $M_{\text{KAuCl}_4} = 377.88 \text{ g mol}^{-1}$; $M_{\text{Au}(\text{OH})_3} = 247.99 \text{ g mol}^{-1}$)

Analysis

We are asked to determine the maximum mass of $\text{Au}(\text{OH})_3$ that can be formed. We are given masses (m) of both KAuCl_4 and Na_2CO_3 and their molar masses (M). This allows us to calculate the amounts of both KAuCl_4 and Na_2CO_3 using $M = \frac{m}{n}$. We then use the ratios of amounts to stoichiometric coefficients in the balanced chemical equation to determine if either KAuCl_4 or Na_2CO_3 is present in excess. The other substance would then be the limiting reagent.

Solution

Begin by calculating the amounts of KAuCl_4 and Na_2CO_3 using $M = \frac{m}{n}$.

$$\begin{aligned}M &= \frac{m}{n} \\n &= \frac{m}{M} \\n_{\text{Na}_2\text{CO}_3} &= \frac{m}{M} = \frac{25.00 \text{ g}}{105.99 \text{ g mol}^{-1}} = 2.359 \times 10^{-1} \text{ mol} \\n_{\text{KAuCl}_4} &= \frac{m}{M} = \frac{20.00 \text{ g}}{377.88 \text{ g mol}^{-1}} = 5.293 \times 10^{-2} \text{ mol}\end{aligned}$$

We know, from the stoichiometry of the reaction, that 2 mol of KAuCl_4 require 3 mol of Na_2CO_3 for complete reaction. So, the amount of KAuCl_4 divided by 2 should equal the amount of Na_2CO_3 divided by 3 for the reactants to be present in the quantities required by the stoichiometry of the reaction. This can be represented as follows.

$$\frac{n_{\text{Na}_2\text{CO}_3}}{3} = \frac{n_{\text{KAuCl}_4}}{2}$$

If the ratios are unequal, the *smaller* number indicates the limiting reagent. In the experiment, we use:

$$\begin{aligned}\frac{n_{\text{Na}_2\text{CO}_3}}{3} &= \frac{2.359 \times 10^{-1} \text{ mol}}{3} = 0.07863 \text{ mol} \\ \frac{n_{\text{KAuCl}_4}}{2} &= \frac{5.293 \times 10^{-2} \text{ mol}}{2} = 0.02647 \text{ mol}\end{aligned}$$

This means that we have too much Na_2CO_3 , so KAuCl_4 is the limiting reagent. The amount of KAuCl_4 now determines the amount of $\text{Au}(\text{OH})_3$ that can be formed. To calculate how much $\text{Au}(\text{OH})_3$ will be formed, we again use the stoichiometric coefficients from the balanced chemical equation. We see that 2 mol of KAuCl_4 will form 2 mol of $\text{Au}(\text{OH})_3$ so:

$$n_{\text{Au}(\text{OH})_3} = n_{\text{KAuCl}_4} = 5.293 \times 10^{-2} \text{ mol}$$

Converting this amount of $\text{Au}(\text{OH})_3$ to mass gives the following.

$$m = Mn = 247.99 \text{ g mol}^{-1} \times (5.293 \times 10^{-2} \text{ mol}) = 13.13 \text{ g}$$

Therefore, using the reaction conditions given, we obtain a maximum of 13.13 g of $\text{Au}(\text{OH})_3$.

Is our answer reasonable?

The main thing in calculations of this type is to get the mole ratios correct and, indeed, to interpret them correctly. We can see that the molar mass of KAuCl_4 is more than three times that of Na_2CO_3 . Since we are using a larger mass of Na_2CO_3 in the reaction, we will have a significantly larger amount of Na_2CO_3 than KAuCl_4 , and our calculations bear this out. The molar mass of $\text{Au}(\text{OH})_3$ is about two-thirds that of KAuCl_4 and, given that their mole ratio in the balanced chemical equation is 1 : 1, we would expect the mass of $\text{Au}(\text{OH})_3$ to be about two-thirds the initial mass of KAuCl_4 , which it is. The answer is reasonable.

PRACTICE EXERCISE 3.15

In an industrial process for producing nitric acid, the first step is the reaction of ammonia with oxygen at high temperature in the presence of a platinum gauze to form nitrogen monoxide as follows.

What is the maximum mass of nitrogen monoxide that can form from an initial mixture of 30.00 g of NH_3 and 40.00 g of O_2 ?

Percentage yield

The balanced chemical equation for a reaction allows you to calculate the theoretical maximum amount of product that can be synthesised from a given amount of starting material. In most chemical syntheses, the amount of a product actually isolated falls short of the calculated maximum amount. Losses occur for

several reasons. Some are mechanical, such as materials sticking to glassware. In some reactions, losses occur by the evaporation of a volatile product. In others, a solid product separates from the solution as it forms because it is largely insoluble. The solid is removed by filtration. What stays in solution, although relatively small, contributes to some loss of product.

One of the common causes of obtaining less than the stoichiometric amount of a product is the occurrence of a reaction or reactions that compete with the desired reaction. A competing reaction produces a **by-product** — a substance other than the product that we want to obtain. A second product of the desired reaction is also called a by-product; however, it does not reduce the yield. The synthesis of phosphorus trichloride from P and Cl₂, for example, gives some phosphorus pentachloride as well, because PCl₃ can react further with Cl₂.

The competition is between newly formed PCl₃ and unreacted phosphorus for chlorine. The production of TiO₂ is an example of the formation of a by-product that does not reduce the yield.

Here HCl is the by-product, but it does not reduce the yield of TiO₂.

Another cause of lower than theoretical yields is a reversible reaction, where the forward and backward reactions occur concurrently. This is further discussed in the chapter on chemical equilibrium.

The **theoretical yield** of a product is what would be obtained if the maximum amount of product was formed and no losses occurred. It is calculated based on the balanced chemical equation and the amounts of the reactants available. The **actual yield** of the product is simply how much has been isolated in practice. You can calculate the **percentage yield** of product to describe how successful the preparation was. The percentage yield is the actual yield calculated as a percentage of the theoretical yield.

$$\text{percentage yield} = \frac{\text{actual yield}}{\text{theoretical yield}} \times 100\%$$

It is important to realise that the actual yield is an experimentally determined quantity. The theoretical yield is always a calculated quantity based on a chemical equation and the amounts of the reactants available.

WORKED EXAMPLE 3.11

Calculating a percentage yield

A chemist set up a synthesis of phosphorus trichloride, PCl₃, by mixing 12.0 g of P with 35.0 g of Cl₂ and obtained 42.4 g of PCl₃. The equation for the reaction is as follows.

Calculate the percentage yield of this compound.

($M_{\text{P}} = 30.97 \text{ g mol}^{-1}$; $M_{\text{Cl}_2} = 70.90 \text{ g mol}^{-1}$; and $M_{\text{PCl}_3} = 137.32 \text{ g mol}^{-1}$)

Analysis

We are asked to calculate a percentage yield. We are given masses of all three components in the reaction and their molar masses (M). This means we can calculate the amounts of all three using $M = \frac{m}{n}$. To calculate the percentage yield, we must first decide on which reactant to base our calculations. We must calculate the amounts of each before we can make that decision. If we find that a reactant is a limiting reagent, the percentage yield is

based on that reactant. To calculate the percentage yield, we must first calculate the theoretical yield: in other words, the maximum amount of product that can theoretically be formed according to the balanced chemical equation. In addition to the chemical equation, we only need $M = \frac{m}{n}$.

Solution

We begin by calculating the amounts of both P and Cl₂ used.

$$n_{\text{P}} = \frac{m}{M} = \frac{12.0 \text{ g}}{30.97 \text{ g mol}^{-1}} = 3.87 \times 10^{-1} \text{ mol}$$

$$n_{\text{Cl}_2} = \frac{m}{M} = \frac{35.0 \text{ g}}{70.90 \text{ g mol}^{-1}} = 4.94 \times 10^{-1} \text{ mol}$$

From the balanced chemical equation, we know that P reacts with Cl₂ in the mole ratio 2:3. Therefore, for complete reaction, theoretically:

$$\frac{n_{\text{Cl}_2}}{3} = \frac{n_{\text{P}}}{2}$$

The experimental ratios are $\frac{0.494 \text{ mol}}{3} = 0.165$ for Cl_2 and $\frac{0.387 \text{ mol}}{2} = 0.194$ for P. This means that we do not have sufficient Cl_2 to react with all the P present, so Cl_2 is the limiting reagent. We now base our subsequent calculations on this. From the balanced chemical equation, we know that:

$$\frac{n_{\text{Cl}_2}}{3} = \frac{n_{\text{PCl}_3}}{2}$$

Therefore:

$$0.165 \text{ mol Cl}_2 = \frac{n_{\text{PCl}_3}}{2}$$

Thus:

$$n_{\text{PCl}_3} = 2(0.165 \text{ mol}) = 0.330 \text{ mol}$$

Converting this to mass, we obtain the following.

$$m = Mn = 137.32 \text{ g mol}^{-1} \times 0.330 \text{ mol} = 45.3 \text{ g}$$

The actual mass obtained was 42.4 g, so the percentage yield is given by the following calculation.

$$\begin{aligned} \text{percentage yield} &= \frac{\text{actual yield}}{\text{theoretical yield}} \times 100\% \\ &= \frac{42.4 \text{ g}}{45.3 \text{ g}} \times 100\% = 93.6\% \end{aligned}$$

Is our answer reasonable?

The obvious check is that the actual yield can never be more than the theoretical yield. So, on this score, our answer is reasonable. Again, the most common place where errors are made is in the use of the mole ratios. In this example, we must end up with *fewer* moles of PCl_3 than Cl_2 , so we must multiply n_{Cl_2} by $\frac{2}{3}$, not $\frac{3}{2}$.

PRACTICE EXERCISE 3.16

Ethanol, $\text{CH}_3\text{CH}_2\text{OH}$, can be converted to acetic acid (the acid in vinegar), CH_3COOH , by the action of sodium dichromate, $\text{Na}_2\text{Cr}_2\text{O}_7$, in aqueous sulfuric acid according to the equation below.

In one experiment, 24.0 g of $\text{CH}_3\text{CH}_2\text{OH}$, 90.0 g of $\text{Na}_2\text{Cr}_2\text{O}_7$ and a known excess of sulfuric acid were mixed, and 26.6 g of acetic acid was isolated. Calculate the percentage yield of CH_3COOH .

Another way to look at the yield of a reaction is to consider the so-called **atom efficiency**. Atom efficiency takes into account all atoms in the starting materials and compares them to the number of atoms in the desired product. There is a difference between a reaction where most of the atoms of the starting material(s) end up forming the desired product and a reaction where a large fraction of the atoms in the starting material(s) end up as unwanted by-products. There may be a trade-off between the percentage yield of a reaction and the atom efficiency on occasion. Concerns about pollution and cost certainly favour reactions (at least on the industrial scale) that produce the least amount of waste material.

3.6 Solution stoichiometry

LEARNING OBJECTIVE 3.6 Apply stoichiometric concepts to reactions in solutions.

Chemical reactions are most often carried out in solution because this allows intimate mixing of the reactants, which leads to more rapid reaction. A **solution** is a homogeneous mixture in which the atoms, molecules or ions of the components freely intermingle (see figure 3.9). When a solution forms, at least two substances are involved. One is called the solvent and all of the others are called solutes. The **solvent** is usually taken to be the component present in largest amount and is the medium into which the solutes are mixed or dissolved. Liquid water is a typical and very common solvent, but the solvent can actually be in any physical state — solid, liquid or gas. Unless stated otherwise, we will assume that any solutions we mention are aqueous solutions, so that liquid water is understood to be the solvent.

A **solute** is any substance dissolved in the solvent. It might be a gas, like the carbon dioxide dissolved in carbonated drinks. Some solutes are liquids, like the ethylene glycol dissolved in water to stop it from freezing in a car's radiator. Solids, of course, can be solutes, like the sugar dissolved in lemonade or the salt dissolved in sea water.

FIGURE 3.9

In the photo on the left, a crystal of iodine, I_2 , that was added to a beaker containing ethanol started dissolving on its way to the bottom of the beaker, the purplish iodine crystal forming a reddish-brown solution. The photo on the right shows how after stirring the mixture with a spatula the solution takes on a homogeneous reddish-brown colour, due to the iodine molecules dissolved in the solvent as indicated in the schematic below the picture. Called 'tincture of iodine', such solutions were once widely used as antiseptics.

The concentration of solutions

We use the concentration of a solution to describe its composition. The **concentration** is defined as the amount of solute dissolved in a particular volume of solution. The concentration of substance X is often represented as $[X]$. When the amount is given in moles and the volume in litres, it is called the **molarity** or molar concentration and has the units mol L^{-1} (often abbreviated M , not to be confused with the abbreviation for molar mass, M). The equation that defines concentration (c) is as follows.

$$c = \frac{n}{V}$$

We stated earlier that there were only two equations needed to solve any stoichiometric problem. $M = \frac{m}{n}$ was the first, and this is the second. Again, we must commit this equation to memory, but it is easy to remember when we consider the units of concentration; mol L^{-1} implies amount divided by volume (in L).

Thus, a 1.00 L solution that contains 0.100 mol of NaCl has a molarity of 0.100 mol L^{-1} , and we would refer to this solution as 0.100 *molar* NaCl or as 0.100 mol L^{-1} NaCl. A 0.100 L solution containing 0.0100 mol of NaCl would have the same concentration because the *ratio* of amount of solute to volume of solution is the same.

$$\frac{0.100 \text{ mol NaCl}}{1.00 \text{ L NaCl}} = \frac{0.0100 \text{ mol NaCl}}{0.100 \text{ L NaCl}} = 0.100 \text{ mol L}^{-1} \text{ NaCl}$$

Concentration is particularly useful because it lets us obtain a given amount of a substance simply by measuring a volume of a previously prepared solution, and this measurement is quick and easy to do in the

laboratory. If we had a stock supply of 0.100 mol L NaCl solution, for example, and we needed 0.100 mol of NaCl for a reaction, we would simply measure out 1.00 L of the solution because there is 0.100 mol of NaCl in this volume.

We do not have to work with whole litres of solutions. It is the *ratio* of the amount of solute to the volume of solution, not the total volume, that matters. Suppose, for example, that we dissolved 0.0200 mol of sodium chromate, Na₂CrO₄, in sufficient solvent to give a final volume of 0.250 L. The concentration of the solution would be found by:

$$c = \frac{n}{V} = \frac{0.0200 \text{ mol}}{0.250 \text{ L}} = 0.0800 \text{ mol L}^{-1}$$

Such a solution can be accurately prepared in a *volumetric flask*, which is a narrow-necked container with an etched mark high on its neck. When filled ‘up to the mark’, the flask contains the volume given by its label. Figure 3.10 shows how to use a 250 mL volumetric flask to prepare a solution of known concentration.

FIGURE 3.10

The preparation of a solution of known molarity. (a) A 250 mL volumetric flask, one of a number of sizes available for preparing solutions. When filled to the line etched around its neck, this flask contains exactly 250 mL of solution. The flask here already contains a weighed amount of solute. (b) Water is being added. (c) The solute is brought completely into solution before the level is brought up to the narrow neck of the flask. (d) More water is added to bring the level of the solution to the etched line or ‘up to the mark’. (e) The flask is stoppered and then inverted many times to mix its contents thoroughly.

WORKED EXAMPLE 3.12

Calculating the concentration of a solution

A student prepared a solution of NaCl by dissolving 1.461 g of NaCl in water and making up to the final volume of 250.0 mL in a volumetric flask to study the effect of dissolved salt on the rusting of an iron sample. What is the concentration of this solution in mol L⁻¹?

Solution

Firstly, we convert the mass of NaCl to amount using the following.

$$M = \frac{m}{n} \quad n = \frac{m}{M} = \frac{1.461 \text{ g}}{58.44 \text{ g mol}^{-1}} = 2.500 \times 10^{-2} \text{ mol}$$

We then substitute the data into $c = \frac{n}{V}$ and solve for c .

$$c = \frac{n}{V} = \frac{2.500 \times 10^{-2} \text{ mol}}{0.2500 \text{ L}} = 1.000 \times 10^{-1} \text{ mol L}^{-1}$$

Therefore, the concentration of the NaCl solution is 1.000 × 10⁻¹ mol L⁻¹.

Is our answer reasonable?

A 1 mol L⁻¹ solution of NaCl would contain 58.44 g of NaCl in 1 litre, so a 0.1 mol L⁻¹ solution would contain about 6 g in 1 L. We have 0.25 L, so we would expect about (0.25 × 6 g) = 1.5 g in 0.25 L, which is roughly what we have. The answer is certainly reasonable. An easy mistake to make in problems of this type is to forget to convert mL to L. As the concentration was required in mol L⁻¹ and the solution volume is given in mL, we must *divide* by 1000 to convert to L.

Notice that worked example 3.12 uses both $M = \frac{m}{n}$ and $c = \frac{n}{V}$. As we have stressed, with these two equations, there is no stoichiometric problem we cannot solve!

PRACTICE EXERCISE 3.17

As part of a study to determine if just the chloride ion in NaCl accelerates the rusting of iron, a student decided to see if iron rusted as rapidly when exposed to a solution of Na_2SO_4 . This solution was made by dissolving 3.550 g of Na_2SO_4 in water and making up the final volume to 100.0 mL in a volumetric flask. What is the concentration of this solution?

In the laboratory, we must often prepare a solution with a specific concentration. Usually, we select the volume of solution that we need, then calculate how much solute must be used. Depending on the accuracy that you require, you will need to use a balance that allows you to weigh your sample to the required number of significant figures. Figure 3.11 shows a range of balances and glassware used to prepare solutions of known concentration. As is discussed in the Chemical Connections feature on inclusive chemistry education, laboratory work is inclusive and with technological support can be carried out independently by students with blindness or vision impairment independently.

FIGURE 3.11

(a) Glassware that can be used for measuring volumes to different accuracies. (b) Standard analytical balance, which can be read to 1×10^{-4} g.

Worked example 3.13 illustrates the kind of calculation required and also demonstrates the following useful relationship: *whenever we know both the volume and the concentration of a solution, we can calculate the amount of solute from $c = \frac{n}{V}$.*

WORKED EXAMPLE 3.13

Preparing a solution of known concentration

Strontium nitrate, $\text{Sr}(\text{NO}_3)_2$, is used in fireworks to produce brilliant red colours. What mass of strontium nitrate would a chemist need to prepare 250.0 mL of a 0.100 mol L^{-1} $\text{Sr}(\text{NO}_3)_2$ solution? ($M_{\text{Sr}(\text{NO}_3)_2} = 211.64 \text{ g mol}^{-1}$)

Analysis

We are asked to calculate a mass (m) of strontium nitrate and we are given the volume (V) and concentration (c) of a strontium nitrate solution, as well as the molar mass (M) of strontium nitrate. The concentration and volume will allow us to calculate the amount (n) of strontium nitrate using $c = \frac{n}{V}$, and we can then use this amount in the equation $M = \frac{m}{n}$ to calculate the mass of strontium nitrate.

Solution

We rearrange $c = \frac{n}{V}$ to solve for n .

$$n = cV = 0.100 \text{ mol L}^{-1} \times 0.2500 \text{ L} = 0.0250 \text{ mol} \\ = 2.50 \times 10^{-2} \text{ mol}$$

We can now use $M = \frac{m}{n}$ to obtain the mass.

$$m = Mn = 211.64 \text{ g mol}^{-1} \times (2.50 \times 10^{-2} \text{ mol}) = 5.29 \text{ g}$$

Therefore, the chemist would require 5.29 g of $\text{Sr}(\text{NO}_3)_2$ to prepare the solution.

Is our answer reasonable?

In 1 Litre of 0.100 mol L^{-1} $\text{Sr}(\text{NO}_3)_2$, there would be 0.1 mol of $\text{Sr}(\text{NO}_3)_2$, about 20 g. Therefore, in 0.25 L of this solution, we would have roughly $(0.25 \times 20 \text{ g}) = 5 \text{ g}$. The answer, 5.29 g, is close to this, so it makes sense.

PRACTICE EXERCISE 3.18

What mass of AgNO_3 is needed to prepare 0.250 L of $0.0125 \text{ mol l}^{-1}$ AgNO_3 solution?

CHEMICAL CONNECTIONS

Inclusive chemistry education

The ‘Salamanca Statement on Principles, Policy and Practice in Special Needs Education’ was adopted in 1994 by representatives of 92 governments and 25 international organisations. This rights-based focus on inclusive learning furthered the goals of UNESCO’s *Education for All* initiative — bringing the benefits of a quality basic education to ‘every citizen in every society’. The importance of inclusion of people with disabilities within education continues to be recognised and is explicitly mentioned in the indicators and targets of the United Nations’ Sustainable Development Goals.

First-year general chemistry courses serve as a gateway to a range of advanced science, technology, engineering and mathematics (STEM) fields of study and hence represent an important target for inclusive educational experiences. In first-year chemistry in Australia and New Zealand, approximately half of all contact hours are spent in the chemistry laboratory. In the current set-up, laboratory work is challenging for students who are blind or vision impaired. Generally, these students complete laboratory practicals with help from sighted laboratory assistants. An assistant performs the experiments under the direction of the blind or vision-impaired student, who describes the process to them. In turn, the assistant informs a blind or vision-impaired student of their results and observations when requested to do so. This unique relationship is known in the chemical education literature as the director–assistant approach, where the blind or vision-impaired student is directing their sighted assistant through the tasks to be performed in the laboratory. While this enables students to adequately meet the requirements of their degree, it falls well short of enabling full participation in laboratory learning. As a consequence, this approach restricts the learning potential in the laboratory of blind or vision-impaired students.

In recent years, technological advances such as the Sci-Voice™ Talking LabQuest (see figure 3.12) have provided opportunities for independent laboratory work for blind or vision-impaired students. Researchers at the University of Sydney have partnered with Independence Science in developing a completely inclusive first-year laboratory curriculum for students who are blind or vision impaired. This will be achieved through text-to-speech talking laboratory equipment supplemented by multi-sensory methodologies embedded

FIGURE 3.12

Ms Ashley Neybert of Independence Science demonstrating the use of the Sci-Voice™ Talking LabQuest at a workshop for students who are blind or vision impaired

directly into the chemistry laboratory curriculum. Multi-sensory methodologies include having raised prints of chromatography plates; vibration of a mobile phone coupled with pitch of sound to encode colour intensity for titrations; changing sound frequency to indicate slope of line; and encoding of infrared wavenumbers in musical notes.

The aim is for blind and vision-impaired students to be engaged in their own learning, with the wide-ranging beneficial effects of improving student self-efficacy, self-confidence and laboratory skills, and to build a more inclusive learning culture. The inclusive design principles underlying this project will also benefit the general student cohort, both in their understanding of chemical principles and their awareness of the importance of accessibility.

Diluting a solution

It is not always necessary to begin with a solute in pure form to prepare a solution with a known concentration. The solute can already be dissolved in a solution of relatively high concentration, often called the stock solution, and this can be *diluted* with the same pure solvent to make a solution of the desired lower concentration. Dilution is accomplished by adding more solvent to the solution, which causes the

concentration (the amount per unit volume) to decrease (figure 3.13). The choice of apparatus used depends on the precision required. If high precision is necessary, pipettes and volumetric flasks are used (see figure 3.11a). If we can do with less precision, we might use graduated cylinders instead. Worked example 3.14 shows how we can use $c = \frac{n}{V}$ to calculate the final concentration of a diluted solution.

FIGURE 3.13

Diluting a solution. When solvent is added to a solution, the solute particles become more spread out and the solution becomes more dilute. The concentration of the solute in the solution becomes lower, while the total amount of solute remains constant.

WORKED EXAMPLE 3.14

Preparing a solution of known concentration by dilution

How could we prepare 100.0 mL of 0.0400 mol L⁻¹ K₂Cr₂O₇ from a solution of 0.200 mol L⁻¹ K₂Cr₂O₇?

Analysis

We are asked how to dilute a concentrated solution to give a solution of a particular concentration. We know both the volume (V) and the concentration (c) of the final solution, so use of $c = \frac{n}{V}$ will allow us to calculate n from these data. As we know the concentration of the initial solution, and we have calculated the required n , $c = \frac{n}{V}$ will allow us to calculate V , the volume of the initial solution required.

Solution

We are going to use $c = \frac{n}{V}$ twice, to calculate two different things. Firstly, we calculate $n_{\text{K}_2\text{Cr}_2\text{O}_7}$ in our final solution.

$$n = cV = 0.0400 \text{ mol L}^{-1} \times 0.1000 \text{ L} = 4.00 \times 10^{-3} \text{ mol}$$

This is the amount of K₂Cr₂O₇ that, when dissolved in 100.0 mL, will give a concentration of 0.0400 mol L⁻¹. We

now turn our attention to the initial solution and use this calculated amount, in conjunction with the concentration, to calculate V , the volume of the initial solution required.

$$V = \frac{n}{c} = \frac{4.00 \times 10^{-3} \text{ mol}}{0.200 \text{ mol L}^{-1}} = 0.0200 \text{ L}$$

Therefore, we take 20.0 mL of the original solution, pour it into a 100 mL volumetric flask and make it up to the mark with water to get a 0.0400 mol L⁻¹ solution of K₂Cr₂O₇. The technique is broadly similar to that shown in figure 3.10, but starting with a concentrated solution rather than a solute.

Is our answer reasonable?

Think about the magnitude of the dilution, from 0.2 mol L⁻¹ to 0.04 mol L⁻¹. Notice that the concentrated solution is five times as concentrated as the dilute solution ($5 \times 0.04 = 0.2$). To reduce the concentration by a factor of five requires that we increase the volume by a factor of five, and we see that 100 mL is 5×20 mL. The answer appears to be correct.

In a dilution, the amount of solute in the concentrated solution is the same as in the diluted solution. This allows us to use a shortcut for the calculation that we carried out in worked example 3.14.

If we define c_1 and V_1 as the concentration and volume of the initial solution and c_2 and V_2 as those of the final solution, because n is the same in both solutions we can write $n = c_1 V_1$ and $n = c_2 V_2$. As the amount, n , is the same for both solutions, we can then cancel out n , to give the equation $c_1 V_1 = c_2 V_2$. If we know the initial concentration and the final volume and concentration we can solve for the initial volume.

$$V_1 = \frac{c_2}{c_1} \times V_2$$

That is, if we multiply the final volume by the ratio of final to initial concentration, we obtain the required volume of the initial solution. For worked example 3.14, we could write the following.

$$\begin{aligned} V_1 &= \frac{c_2}{c_1} \times V_2 \\ &= \frac{0.0400 \text{ mol L}^{-1}}{0.200 \text{ mol L}^{-1}} \times 0.1000 \text{ L} = 0.0200 \text{ L} \end{aligned}$$

PRACTICE EXERCISE 3.19

How could 0.100 L of 0.125 mol L⁻¹ H₂SO₄ solution be made from a 0.500 mol L⁻¹ H₂SO₄ solution?

Applications of solution stoichiometry

When we deal quantitatively with reactions in solution, we often work with volumes of solutions and concentrations.

WORKED EXAMPLE 3.15

Stoichiometry involving reactions in solution

Before the advent of digital cameras, silver bromide, AgBr, was used extensively in photographic film. This compound is essentially insoluble in water, and one way to prepare it is to mix solutions of the water-soluble compounds, silver nitrate and calcium bromide (see figure 3.14).

Suppose we wished to prepare AgBr by the following precipitation reaction.

What volume of 0.125 mol L⁻¹ CaBr₂ solution would be required to react completely with 50.0 mL of 0.115 mol L⁻¹ AgNO₃?

Analysis

We are asked to calculate a volume of CaBr₂ solution, and we are given the volume (*V*) and concentration (*c*) of a AgNO₃ solution. We can calculate the amount (*n*) of AgNO₃ using $c = \frac{n}{V}$. We are also given a balanced chemical equation, and we will need to use this to obtain the mole ratio between AgNO₃ and CaBr₂. We then use the stoichiometric coefficients from the balanced chemical equation to calculate *n*_{CaBr₂}. Finally, we will use $c = \frac{n}{V}$ along with the concentration of the CaBr₂ solution to calculate the volume of the initial solution required.

Solution

We start by calculating *n*_{AgNO₃}.

$$c = \frac{n}{V}$$

$$n = cV = 0.115 \text{ mol L}^{-1} \times (50.0 \times 10^{-3} \text{ L}) = 5.75 \times 10^{-3} \text{ mol}$$

From the balanced chemical equation, we know that 2 mol of AgNO₃ will react with 1 mol of CaBr₂. Therefore:

$$n_{\text{CaBr}_2} = \frac{n_{\text{AgNO}_3}}{2} = \frac{5.75 \times 10^{-3} \text{ mol}}{2} = 2.88 \times 10^{-3} \text{ mol}$$

We now know *n*_{CaBr₂} and the concentration of the CaBr₂ solution, so we can substitute these values into $c = \frac{n}{V}$ to

calculate *V*, the volume of the CaBr₂ solution required.

$$V = \frac{n}{c} = \frac{2.88 \times 10^{-3} \text{ mol}}{0.125 \text{ mol L}^{-1}} = 0.0230 \text{ L} = 2.30 \times 10^{-2} \text{ L}$$

Therefore, 23.0 mL of the CaBr₂ solution will react completely with 50.0 mL of the 0.115 mol L⁻¹ AgNO₃ solution.

Is our answer reasonable?

The molarities of the two solutions are about the same, but only 1 mol of CaBr₂ is needed for every 2 mol of AgNO₃. Therefore, the volume of CaBr₂ solution needed (23.0 mL) should be about half the volume of AgNO₃ solution taken (50.0 mL), which it is.

FIGURE 3.14

Addition of CaBr₂(aq) to AgNO₃(aq) results in precipitation of creamy white AgBr(s).

PRACTICE EXERCISE 3.20

What volume of 0.124 mol L^{-1} NaOH is required to react completely with 15.4 mL of 0.108 mol L^{-1} H_2SO_4 according to the following equation?

Stoichiometry of solutions containing ions

In worked example 3.15, we used an equation involving ionic compounds to solve a stoichiometry problem. Ionic compounds dissociate into their constituent ions if they dissolve in water and this can have important consequences in stoichiometric calculations involving such solutions. For example, in worked example 3.15, we used calcium bromide, CaBr_2 , as a reactant. Suppose we are working with an aqueous solution labelled ' $0.10 \text{ mol L}^{-1} \text{CaBr}_2$ '. This means there is 0.10 mol of CaBr_2 dissolved in each litre of this solution **dissociated** into Ca^{2+} and Br^- ions.

From the stoichiometry of the dissociation, we see that 1 mol of $\text{Ca}^{2+}(\text{aq})$ and 2 mol of $\text{Br}^-(\text{aq})$ are formed from each mole of $\text{CaBr}_2(\text{s})$. Therefore, 0.10 mol of $\text{CaBr}_2(\text{s})$ will yield 0.10 mol of $\text{Ca}^{2+}(\text{aq})$ and 0.20 mol of $\text{Br}^-(\text{aq})$. In $0.10 \text{ mol L}^{-1} \text{CaBr}_2$, then, the concentration of $\text{Ca}^{2+}(\text{aq})$ is 0.10 mol L^{-1} and the concentration of $\text{Br}^-(\text{aq})$ is 0.20 mol L^{-1} . Notice that the concentration of a particular ion equals the concentration of the salt multiplied by the number of ions of that kind in the formula of the salt.

We use the term 'dissolution' to describe the process of a solute dissolving in a solvent, and it is important that you understand the difference between the terms 'dissolution' and 'dissociation'. When an ionic compound undergoes dissolution (dissolves) in a solvent, it undergoes dissociation into its constituent ions. We showed the equation for this process with reference to $\text{CaBr}_2(\text{s})$ above, and assumed that the salt dissociates fully. However, dissociation reactions do not necessarily do that, and the extent of such reactions depends on the nature of the ionic compound. We will assume 100% dissociation of all ionic compounds in the remaining examples in this chapter. We will investigate partial dissociation in the chapter on solutions and solubility.

Initially you may find it difficult to know exactly which ionic species dissolve in water and which ones do not, but with experience you will be able to make reasonable assessments. In the first instance a table of solubility rules can be a great help. Table 3.1 summarises the rules for the solubilities of many common ionic compounds and you may find it helpful to be familiar with these.

TABLE 3.1 Solubility of common binary ionic compounds in water

If the anion is	the compound is usually	except for ^(a)
F^-	soluble	Mg^{2+} , Ca^{2+} , Sr^{2+} , Ba^{2+} and Pb^{2+} (Al^{3+})
Cl^-	soluble	Ag^+ and Hg_2^{2+} (Pb^{2+})
Br^-	soluble	Ag^+ and Hg_2^{2+} (Hg^{2+} and Pb^{2+})
I^-	soluble	Ag^+ , Hg_2^{2+} , Hg^{2+} and Pb^{2+}
NO_3^-	soluble	none
SO_4^{2-}	soluble	Sr^{2+} , Ba^{2+} , Hg_2^{2+} and Pb^{2+} (Ag^+ and Ca^{2+})
CH_3COO^-	soluble	none (Ag^+ and Hg_2^{2+})
OH^-	insoluble	Li^+ , Na^+ , K^+ and Ba^{2+} (Ca^{2+} and Sr^{2+})
SO_3^{2-}	insoluble	Li^+ , Na^+ , K^+ , NH_4^+ and Mg^{2+}
PO_4^{3-}	insoluble	Na^+ , K^+ and NH_4^+

CO_3^{2-}	insoluble	$\text{Li}^+, \text{Na}^+, \text{K}^+$ and NH_4^+
$\text{C}_2\text{O}_4^{2-}$	insoluble	$\text{Li}^+, \text{Na}^+, \text{K}^+$ and NH_4^+

(a) For the purposes of this table, insoluble compounds are deemed to have molar solubilities of less than $1 \times 10^{-2} \text{ mol L}^{-1}$ in water, slightly soluble compounds have molar solubilities in water between $1 \times 10^{-1} \text{ mol L}^{-1}$ and $1 \times 10^{-2} \text{ mol L}^{-1}$, while soluble compounds have molar solubilities greater than $1 \times 10^{-1} \text{ mol L}^{-1}$ in water. Cations in parentheses form slightly soluble compounds with the specified anion. Most oxides and sulfides are insoluble in water; apparent exceptions to this rule (e.g. Li_2O and MgS) are generally complicated by hydrolysis reactions and are therefore not listed.

In worked example 3.15, we wrote the balanced chemical equation as the molecular equation.

We can also write this in terms of the ions present as the ionic equation.

The net reaction that occurred was as follows.

The NO_3^- and Ca^{2+} took no part in the reaction, remaining simply as aqueous ions throughout. We call such ions **spectator ions**. Balanced ionic equations written without the inclusion of spectator ions are called **net ionic equations**. That is, net ionic equations show only those ions that participate in the reaction.

WORKED EXAMPLE 3.16

Calculating the concentrations of ions in a solution

What are the concentrations of the ions in a 0.20 mol L^{-1} solution of $\text{Al}_2(\text{SO}_4)_3(\text{aq})$?

Analysis

The concentrations of the ions are determined by the concentration of the salt and its stoichiometry. We need to write a balanced chemical equation for the dissolution of the salt in water; from this, we can determine the concentration of each ion in the solution using the given concentration of the salt.

Solution

When $\text{Al}_2(\text{SO}_4)_3$ dissolves, it dissociates as follows.

Each mole of $\text{Al}_2(\text{SO}_4)_3$ yields 2 mol of Al^{3+} ions and 3 mol of SO_4^{2-} ions on dissolution, assuming complete dissociation. In other words, the concentration of Al^{3+} will be double the original concentration and the concentration of SO_4^{2-} will be treble the original concentration. The concentrations of the ions in the solution will therefore be $0.40 \text{ mol L}^{-1} \text{ Al}^{3+}$ and $0.60 \text{ mol L}^{-1} \text{ SO}_4^{2-}$.

PRACTICE EXERCISE 3.21

What are the molar concentrations of the ions in $0.25 \text{ mol L}^{-1} \text{ FeCl}_3(\text{aq})$?

PRACTICE EXERCISE 3.22

In an aqueous solution of Na_3PO_4 , the PO_4^{3-} concentration was determined to be 0.250 mol L^{-1} . What was the sodium ion concentration in the same solution?

We have seen that a net ionic equation is convenient for focusing on the net chemical change in reactions involving ions. Let us study some examples that illustrate how such equations can be used in stoichiometric calculations.

WORKED EXAMPLE 3.17

Stoichiometry calculations using net ionic equations

When aqueous solutions of AgNO_3 and CaCl_2 are mixed, a white precipitate of AgCl(s) is formed (see figure 3.15). The net ionic equation for the formation of this precipitate is as follows.

FIGURE 3.15

Addition of a solution of $\text{AgNO}_3(\text{aq})$ is added to a solution of $\text{CaCl}_2(\text{aq})$ results in precipitation of AgCl(s) .

What volume of $0.100 \text{ mol L}^{-1} \text{ AgNO}_3$ solution is needed to react completely with 25.0 mL of $0.400 \text{ mol L}^{-1} \text{ CaCl}_2$ solution to form AgCl(s) ?

Analysis

We are asked to calculate a volume of AgNO_3 solution. The volume (V) and concentration (c) of the CaCl_2 solution given

in the question allow us to calculate n_{CaCl_2} and hence n_{Cl^-} using $c = \frac{n}{V}$. From the stoichiometry of the reaction, we can then determine the required n_{Ag^+} . We can then calculate the required volume using the given concentration of the AgNO_3 solution.

Solution

We are given a volume and a concentration of the CaCl_2 solution, so we substitute these values into $c = \frac{n}{V}$.

$$\begin{aligned} n_{\text{CaCl}_2} &= cV = 0.400 \text{ mol L}^{-1} \times (25.0 \times 10^{-3} \text{ L}) \\ &= 1.00 \times 10^{-2} \text{ mol} \end{aligned}$$

We know that 1 mol of CaCl_2 will give 2 mol of Cl^- on dissolution in water (assuming complete dissociation), so:

$$n_{\text{Cl}^-} = 2 \times (1.00 \times 10^{-2} \text{ mol}) = 2.00 \times 10^{-2} \text{ mol}$$

The stoichiometry of the balanced chemical equation for the reaction of Ag^+ and Cl^- shows that 1 mol of Cl^- will react with 1 mol of Ag^+ . Therefore, we can say that:

$$n_{\text{Ag}^+} = n_{\text{Cl}^-} = 2.00 \times 10^{-2} \text{ mol}$$

Before we calculate the required volume, we need to look at the stoichiometry of AgNO_3 . Because 1 mol of AgNO_3 will give us 1 mol of Ag^+ when dissolved in solution:

$$n_{\text{Ag}^+} = n_{\text{AgNO}_3}$$

Now we obtain:

$$V = \frac{n}{c} = \frac{2.00 \times 10^{-2} \text{ mol}}{0.100 \text{ mol L}^{-1}} = 0.200 \text{ L}$$

Thus, we require 0.200 L of $0.100 \text{ mol L}^{-1} \text{ AgNO}_3$ solution.

Is our answer reasonable?

Silver ions react with chloride ions in a $1:1$ ratio. CaCl_2 solution is four times the concentration of the AgNO_3 solution and, as 1 mol of CaCl_2 dissolves to give 2 mol of Cl^- , the Cl^- concentration in this solution is eight times the concentration of the AgNO_3 solution. Therefore, we would expect a volume of AgNO_3 solution eight times the volume of the CaCl_2 solution. As $8 \times 25 = 200$, our answer appears correct.

PRACTICE EXERCISE 3.23

What volume of $0.500 \text{ mol L}^{-1} \text{ KOH}$ is needed to react completely with 60.0 mL of a $0.250 \text{ mol L}^{-1} \text{ FeCl}_2$ solution to precipitate Fe(OH)_2 ?

In section 3.5, we learned how to recognise and solve problems in which the reactants are not present in the exact ratios required by the stoichiometry of the reaction. Similar problems can be encountered when working with solutions.

Calculation involving the stoichiometry of an ionic reaction

A suspension of $\text{Mg}(\text{OH})_2$ in water is sometimes used as an antacid. It can be made by adding NaOH to a solution containing Mg^{2+} . Suppose that 40.0 mL of a 0.200 mol L^{-1} NaOH solution is added to 25.0 mL of a 0.300 mol L^{-1} MgCl_2 solution. The net ionic equation for the reaction is:

What mass of $\text{Mg}(\text{OH})_2$ will be formed, and what will the concentrations of the ions in the solution be after the reaction is complete? ($M_{\text{Mg}(\text{OH})_2} = 58.33 \text{ g mol}^{-1}$)

Analysis

We are asked to calculate the mass of $\text{Mg}(\text{OH})_2$ and the concentrations of ions in solution at the end of the reaction. We are given concentrations (c) and volumes (V) of both the NaOH and MgCl_2 solutions, which allow us to calculate amounts (n) of these using $c = \frac{n}{V}$. We are also given the molar mass (M) of $\text{Mg}(\text{OH})_2$, which allows us to use $M = \frac{m}{n}$ to calculate the mass (m) of $\text{Mg}(\text{OH})_2$. This problem is similar to worked example 3.17, but slightly more complex. Here we must calculate the amounts of Mg^{2+} and OH^{-} present initially, and work out whether they are present in the required stoichiometric ratio or, if not, which one of them will be limiting. We then proceed in the same way as we have done in other problems, using $M = \frac{m}{n}$ to calculate the mass of $\text{Mg}(\text{OH})_2$ formed. We obtain the concentrations of the ions left in solution by difference.

Solution

We begin by calculating the amounts of both NaOH(aq) and MgCl_2 (aq), and then calculating $n_{\text{Mg}^{2+}}$ and $n_{\text{OH}^{-}}$ from these.

$$\begin{aligned} n_{\text{NaOH}} &= cV = 0.200 \text{ mol L}^{-1} \times (40.0 \times 10^{-3} \text{ L}) \\ &= 8.00 \times 10^{-3} \text{ mol} \end{aligned}$$

As 1 mol of NaOH gives 1 mol of OH^{-} on dissolution in water:

$$n_{\text{OH}^{-}} = n_{\text{NaOH}} = 8.00 \times 10^{-3} \text{ mol}$$

Similarly:

$$\begin{aligned} n_{\text{MgCl}_2} &= cV = 0.300 \text{ mol L}^{-1} \times (25.0 \times 10^{-3} \text{ L}) \\ &= 7.50 \times 10^{-3} \text{ mol} \end{aligned}$$

Since 1 mol of MgCl_2 gives 1 mol of Mg^{2+} on dissolution in water:

$$n_{\text{Mg}^{2+}} = n_{\text{MgCl}_2} = 7.50 \times 10^{-3} \text{ mol}$$

Looking at the balanced chemical equation, we see that 1 mol of Mg^{2+} will react with 2 mol of OH^{-} . Therefore, we would require $1.50 \times 10^{-2} \text{ mol}$ of OH^{-} , but we have only $8.00 \times 10^{-3} \text{ mol}$, meaning that OH^{-} is the limiting reagent. Therefore, from the balanced chemical equation, $8.00 \times 10^{-3} \text{ mol OH}^{-}$ will react with $4.00 \times 10^{-3} \text{ mol Mg}^{2+}$ to give $4.00 \times 10^{-3} \text{ mol Mg}(\text{OH})_2$. We can obtain the mass of

this amount using $M = \frac{m}{n}$ and the given molar mass of $\text{Mg}(\text{OH})_2$.

$$m = Mn = 58.33 \text{ g mol}^{-1} \times (4.00 \times 10^{-3} \text{ mol}) = 0.233 \text{ g}$$

Therefore, the reaction forms $0.233 \text{ g Mg}(\text{OH})_2(\text{s})$.

We still have to calculate the concentrations of the ions in solution at the end of the reaction. The ions present will be Mg^{2+} , Cl^{-} and Na^{+} . We have already calculated the amount of NaOH as $8.00 \times 10^{-3} \text{ mol}$, so $n_{\text{Na}^{+}} = 8.00 \times 10^{-3} \text{ mol}$. The final volume of the solution is 65.0 mL (40.0 mL of NaOH solution plus 25.0 mL of MgCl_2 solution), so:

$$c_{\text{Na}^{+}} = \frac{n}{V} = \frac{8.00 \times 10^{-3} \text{ mol}}{65.0 \times 10^{-3} \text{ L}} = 0.123 \text{ mol L}^{-1}$$

We have also calculated the amount of MgCl_2 as $7.50 \times 10^{-3} \text{ mol}$, and, as 1 mol of MgCl_2 gives 2 mol of Cl^{-} on dissolution in water, $n_{\text{Cl}^{-}} = 2n_{\text{MgCl}_2} = 1.50 \times 10^{-2} \text{ mol}$. We can then obtain the concentration from the following.

$$c_{\text{Cl}^{-}} = \frac{n}{V} = \frac{1.50 \times 10^{-2} \text{ mol}}{65.0 \times 10^{-3} \text{ L}} = 0.231 \text{ mol L}^{-1}$$

We will assume that all of the OH^{-} in solution has precipitated as $\text{Mg}(\text{OH})_2$ so the final concentration of OH^{-} will be 0.00 mol L^{-1} (in fact, in the chapter on solutions and solubility, we will see that a very small amount of OH^{-} will remain in solution, but not enough to make a significant difference to our calculation here). The final concentration we need to calculate is that of Mg^{2+} . This is slightly more involved than the others, as we need to remember that some of the Mg^{2+} has been precipitated as $\text{Mg}(\text{OH})_2$. Earlier, we calculated the initial amount of Mg^{2+} as $7.50 \times 10^{-3} \text{ mol}$. We also calculated that $4.00 \times 10^{-3} \text{ mol}$ of Mg^{2+} has precipitated as $\text{Mg}(\text{OH})_2$, so we can obtain the amount of Mg^{2+} in solution by difference.

$$\begin{aligned} n_{\text{Mg}^{2+} \text{ in solution}} &= (7.50 \times 10^{-3} \text{ mol}) - (4.00 \times 10^{-3} \text{ mol}) \\ &= 3.50 \times 10^{-3} \text{ mol} \end{aligned}$$

Therefore, the concentration of Mg^{2+} in solution is as follows.

$$c_{\text{Mg}^{2+}} = \frac{n}{V} = \frac{3.50 \times 10^{-3} \text{ mol}}{65.0 \times 10^{-3} \text{ L}} = 5.38 \times 10^{-2} \text{ mol L}^{-1}$$

Is our answer reasonable?

This was a fairly complex problem and there are no simple calculations we can make to verify our answers. However, there are a couple of key steps we might double-check. First, we can check that we have identified the limiting reagent correctly. In the previous calculation, we selected Mg^{2+} and determined if there was enough OH^{-} to react with it. As a check, let us look at OH^{-} to see if there is enough Mg^{2+} . We began with $8 \times 10^{-3} \text{ mol}$ of OH^{-} , which requires half that amount of Mg^{2+} ($4 \times 10^{-3} \text{ mol Mg}^{2+}$) to react completely. The amount of Mg^{2+} available ($7.5 \times 10^{-3} \text{ mol}$) is more than enough, so Mg^{2+} will be left over and OH^{-} is limiting. Our analysis confirms that we have selected the correct limiting reagent.

Another place to be careful is in the calculation of the final concentrations of the ions in the reaction mixture. Whenever we add one aqueous solution to another, the mixture will have a final volume that is the sum of the volumes of the two solutions combined. When calculating

the concentrations of anything in the final mixture, we have to use the final combined volume of the mixture. We see that we have taken this into account, so we can feel confident that we have done this part of the calculation correctly.

PRACTICE EXERCISE 3.24

What amount of BaSO_4 will form if 20.0 mL of 0.600 mol L^{-1} BaCl_2 is mixed with 30.0 mL of 0.500 mol L^{-1} MgSO_4 ? Determine the concentration of each ion in the final reaction mixture.

The worked examples in this chapter so far have specified the reactants and products involved. There will be occasions when we do not know the composition of one of these, but stoichiometry can still help to determine the amount of a particular element in an unknown compound. The calculations required for these kinds of problems are not new; they are simply applications of the stoichiometric calculations we have already learned.

WORKED EXAMPLE 3.19

Calculation involving an unknown compound

A compound used as an insecticide contains carbon, hydrogen and chlorine. Reactions were carried out on a 1.340 g sample of the compound that converted all of its chlorine to chloride ions dissolved in water. This aqueous solution was treated with an excess of AgNO_3 solution, and the AgCl precipitate was collected and then weighed. Its mass was 2.709 g. What was the percentage by mass of Cl in the original insecticide sample? ($M_{\text{Cl}} = 35.45 \text{ g mol}^{-1}$; $M_{\text{AgCl}} = 143.32 \text{ g mol}^{-1}$)

Analysis

We are asked to calculate a percentage by mass. We are given the mass (m) and molar mass (M) of AgCl so we can calculate the amount of AgCl using $M = \frac{m}{n}$. We can obtain the rest of the necessary data using mole ratios. The important point to understand in this problem is that all the chlorine in the AgCl that was collected originated from the insecticide sample. The strategy, therefore, is to determine the mass of Cl in 2.709 g of AgCl . We then assume that this is the mass of chlorine in the original 1.340 g sample of insecticide and calculate the percentage Cl as follows.

$$\% \text{ Cl by mass} = \frac{\text{mass of Cl in sample}}{\text{mass of sample}} \times 100\%$$

Solution

We begin by calculating the amount of AgCl using $M = \frac{m}{n}$.

$$n_{\text{AgCl}} = \frac{m}{M} = \frac{2.709 \text{ g}}{143.32 \text{ g mol}^{-1}} = 1.890 \times 10^{-2} \text{ mol}$$

As 1 mol of AgCl contains 1 mol of Cl, the amount of Cl in the original insecticide sample must be $1.890 \times 10^{-2} \text{ mol}$. We calculate the mass of this amount using $M = \frac{m}{n}$.

$$m = Mn = 35.45 \text{ g mol}^{-1} \times 1.890 \times 10^{-2} \text{ mol} = 0.6700 \text{ g}$$

We can now calculate the % Cl by mass.

$$\begin{aligned} \% \text{ Cl by mass} &= \frac{\text{mass of Cl in sample}}{\text{mass of sample}} = \frac{0.6700 \text{ g}}{1.340 \text{ g}} \times 100\% \\ &= 50.00\% \end{aligned}$$

Is our answer reasonable?

Let us consider the molar masses of AgCl and Cl ($143.32 \text{ g mol}^{-1}$ and 35.45 g mol^{-1} , respectively). If we round these to 140 and 35, we can say that Cl is approximately 25% of AgCl by mass ($35/140 = 0.25$). Approximately 3 g of AgCl was obtained; 25% of 3 g equals 0.75 g of Cl, which is close to the value we obtained. The original sample weighed 1.34 g, which is nearly twice 0.75 g (the mass of Cl), so an answer of 50% Cl by mass seems reasonable.

PRACTICE EXERCISE 3.25

A sample of a mixture containing CaCl_2 and MgCl_2 weighed 2.000 g. The sample was dissolved in water, and H_2SO_4 was added until the precipitation of CaSO_4 was complete. The CaSO_4 was filtered, dried completely and weighed. A total of 0.736 g of CaSO_4 was obtained. What amount of Ca^{2+} was in the original 2.000 g sample?

SUMMARY

3.1 Explain how a chemical equation represents a chemical reaction.

A chemical reaction is the formation of one or more substances (products) from one or more starting materials (reactants). A chemical equation is a symbolic before-and-after description of a chemical reaction. A qualitative analysis is concerned only with which substances are present. A quantitative analysis is concerned with the amounts of all the various substances. Stoichiometry is concerned with the relative proportions of products and reactants in a reaction. Stoichiometric coefficients are written in front of formulae in chemical equations to indicate the number of specified entities of each kind among the reactants and products. A balanced chemical equation has the same number of atoms of each kind in the products and reactants, thus conforming to the law of conservation of mass. The physical states of reactants and products can be shown in chemical equations using (s) for solid, (l) for liquid and (g) for gas. We use (aq) to indicate an aqueous solution (i.e. when a substance is dissolved in water).

3.2 Balance chemical equations.

A chemical equation is balanced when all atoms present among the reactants are also somewhere among the products. To balance an equation, we first write the unbalanced equation and then adjust the stoichiometric coefficients to get equal numbers of each kind of atom on each side of the arrow.

3.3 Use the mole concept in stoichiometric calculations.

The mole (mol) is the SI base unit for amount of substance. One mole contains exactly $6.022\,140\,76 \times 10^{23}$ elementary entities. When expressed in units of mol^{-1} , this numerical value is called the Avogadro constant (N_A).

For almost all practical applications in the laboratory, whatever an elementary entity weighs in atomic mass units, 1 mol of those entities weighs in g. The molar mass, M , is the mass of 1 mol of a substance.

3.4 Determine empirical formulae from quantitative analysis data.

The actual composition of a molecule is given by its molecular formula. An empirical formula gives the ratio of atoms, but in the smallest whole numbers, and it is generally the only formula we write for ionic compounds. The molar mass of a molecular compound is equal to that calculated from the compound's empirical formula or to a simple multiple of it. When the two calculated masses are the same, the molecular formula is the same as the empirical formula.

An empirical formula can be found from the masses of the elements obtained by the quantitative analysis of a known sample of the compound, or it can be calculated from the percentage composition (the percentage of an element in a compound is

the same as the number of grams of the element in 100 g of the compound). If there is $J\%$ of X in X_xZ_z , then 100 g of X_xZ_z contains J g of X . The amounts of X and Z can be calculated from the masses of X and Z . The subscripts in the empirical formula are obtained by adjusting these amounts to their corresponding whole-number ratios.

3.5 Calculate theoretical and actual yields based on balanced equations.

A chemical formula is a tool for stoichiometric calculations, because its subscripts tell us the mole ratios in which the various elements are combined. In 1 mol of X_xZ_z , x mol of X are combined with z mol of Z .

A balanced equation is a tool for reaction stoichiometry because its coefficients disclose the stoichiometric relationships. All problems of reaction stoichiometry must be solved at the mole level of the substances involved. If masses are given, they must first be changed to amounts.

The stoichiometric coefficients in a balanced chemical equation give the relative amounts of each reactant required for complete reaction. A reactant present in a smaller amount is called a limiting reagent. The theoretical yield of a product can be no more than that permitted by the limiting reagent. Sometimes, competing reactions (side reactions) that produce by-products reduce the actual yield. The ratio of the actual yield to the theoretical yield, expressed as a percentage, is the percentage yield.

3.6 Apply stoichiometric concepts to reactions in solutions.

A solution is a homogeneous mixture in which one or more solutes are dissolved in a solvent. Concentration is the ratio of the amount of solute to the volume of solution. Solutions of known concentration can be prepared by weighing accurate masses of compounds using an analytical balance and then making them up to a particular volume with solvent in a volumetric flask. Concentrated solutions of known concentration can be diluted quantitatively using volumetric glassware such as pipettes and volumetric flasks. Molarity is a useful concentration unit for any calculation involving the stoichiometry of reactions in solution. In ionic reactions, the concentrations of the ions in a solution of a salt can be derived from the molar concentration of the salt, taking into account the number of ions formed on dissolution of the salt. For reactions involving ions there are three possible ways to write reaction equations. A molecular equation uses the empirical formula for each compound to aid stoichiometric calculations. The ionic equation shows all the ions that are formed in solution, while the net ionic equation shows only those ions that are actually involved in the net reaction (i.e. excluding spectator ions).

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation
Chemical formula	3.1	We use subscripts in a formula to establish atom ratios and mole ratios between the elements in the substance.
Balanced chemical equation	3.2	We use coefficients to establish stoichiometric equivalencies that relate the amount of one substance to the amount of another in a chemical reaction. The coefficients also establish the ratios of reactants and products involved in the reaction.
The mole	3.3	The mole is the SI unit for amount of substance. 1 mol contains exactly $6.022\,140\,76 \times 10^{23}$ elementary entities.
Avogadro constant (N_A)	3.3	The Avogadro constant, to four significant figures, is $6.022 \times 10^{23} \text{ mol}^{-1}$.
Molar mass (M)	3.3	Molar mass is the mass of 1 mol of any substance.
$M = \frac{m}{n}$	3.3	This equation represents the relationship between mass (m), amount (n) and molar mass (M).
Percentage composition	3.4	We use percentage composition to represent the composition of a compound and as the basis for calculating the empirical formula. Comparing experimental and theoretical percentage compositions can help to establish the identity of a compound.
Theoretical, actual and percentage yields	3.5	We use these values to estimate the efficiency of a reaction. Remember that theoretical yield is calculated from the limiting reagent(s) using the balanced chemical equation. The percentage yield is given by the following equation. $\text{percentage yield} = \frac{\text{actual yield}}{\text{theoretical yield}} \times 100\%$
$c = \frac{n}{V}$	3.6	This equation represents the relationship between concentration (c), amount (n) and volume (V).

KEY TERMS

actual yield The mass of a product obtained from a reaction.

amount of substance A base quantity in the SI system, with the unit of mole (unit symbol: mol).

atom efficiency A measure of the number of atoms in the product compared to those in the starting materials. The more atoms are transferred to the product, the higher the atom efficiency and the lower the waste or side products for the reaction.

Avogadro constant (N_A) $6.022\,140\,76 \times 10^{23} \text{ mol}^{-1}$; the number of specified entities in 1 mol.

balanced chemical equation A chemical equation that has the same number of each type of atom and the same net charge on opposite sides of the arrow.

by-product A substance or substances formed in a reaction other than the desired product(s).

chemical equation A form of notation used to describe chemical reactions, in which the reactants and products of the reaction are separated by a directional arrow, with the reactants appearing on the left-hand side.

chemical reaction A process involving transformation of chemical species into different chemical species, usually involving the making and/or breaking of chemical bonds.

combustion A rapid reaction with oxygen accompanied by a flame and the evolution of heat and light.

concentration The ratio of the quantity of solute to the quantity of solution.

dissociate A general process in which molecules or ionic compounds separate into constituent particles (e.g. atoms or ions).

elemental analysis A method of chemical analysis by which a given amount of a compound is decomposed chemically to find the masses of elements within it.

empirical formula A chemical formula that uses the smallest whole-number subscripts to give the proportions of atoms of the different elements present.

excess reagent A reagent present in a larger amount than that required by the stoichiometry of the reaction.

limiting reagent A reagent present in a smaller amount than that required by the stoichiometry of the reaction.

mass percentage composition A list of the percentages by mass of the elements in a compound.

molar mass (M) The mass of 1 mol of the specified substance.

molarity Concentration in mol L^{-1} (M).

mole The SI unit of amount of substance. The definition of the mole is that 1 mol contains exactly $6.022\,140\,76 \times 10^{23}$ elementary entities.

molecular formula A formula that shows the actual numbers of different types of atoms present in a molecule.

net ionic equation An ionic equation from which spectator ions have been omitted. It is balanced when both atoms and electrical charges balance.

percentage by mass The number of grams of an element present in 100 g of a compound.

percentage yield The ratio, given as a percentage, between the quantity of product actually obtained in a reaction and the theoretical yield.

product The chemical species obtained as the result of a chemical reaction.

qualitative analysis The use of experimental procedures to determine what elements are present in a substance.

quantitative analysis The use of experimental procedures to determine the percentage composition of a compound or the percentage of a component of a mixture.

reactant A chemical species that is transformed in a chemical reaction.

reversible reaction A reaction capable of proceeding in either the forward or reverse direction.

solute A dissolved substance contained in a solution.

solution A homogeneous mixture of solvent(s) and solute(s).

solvent A substance that dissolves a solute or solutes to form a solution.

spectator ion An ion that does not participate in the reaction and that is excluded from the net ionic equation.

stoichiometric coefficients Numbers in front of formulae in chemical equations.

stoichiometry A description of the relative proportions of the reactants and products in a reaction as given by the stoichiometric coefficients in the balanced equation.

theoretical yield The maximum amount of a product determined by the stoichiometry of the reaction.

REVIEW QUESTIONS

Chemical equations

LO1

- 3.1** What do we mean when we say that a chemical equation is 'balanced'? Why do we balance chemical equations?
- 3.2** In a chemical reaction, what do we mean by the term 'reactants'? What do we mean by the term 'products'?
- 3.3** What do we call the numbers that are written in front of the formulae in a balanced chemical equation?
- 3.4** Magnesium metal, Mg, burns under water and produces a brilliant light. The reaction produces magnesium oxide and hydrogen gas. The chemical reaction that occurs can be represented by the following equation.

- (a) State in words how this equation is read.
- (b) Give the formula(e) of the reactant(s).
- (c) Give the formula(e) of the product(s).
- (d) Rewrite the equation to show that Mg and MgO are solids, H₂O is a liquid and H₂ is a gas.

Balancing chemical equations

LO2

- 3.5** When given the *unbalanced* equation:

and asked to balance it, student A wrote:

and student B wrote:

- (a) Both equations are balanced, but which student is correct?
- (b) Explain why the other student's answer is incorrect.

The mole

LO3

- 3.6** Define the term 'mole'.
- 3.7** Why are stoichiometry problems solved using amounts (in mol) rather than masses of reagents?
- 3.8** What information is required to calculate the amount of a substance from a given mass of that same substance?
- 3.9** Give the equation that relates molar mass, amount and mass.
- 3.10** How would you estimate the number of atoms in a gram of iron, using atomic mass units?
- 3.11** Which of the following contains more molecules: 1.5 mol of O₂ or 1.5 mol of H₂O?
- 3.12** (a) How many iron atoms are in 1 mol of Fe₃O₄?

- (b) What amount of iron atoms is in 1 mol of Fe₂O₃?

- 3.13** Why is the expression '2.0 mol of oxygen' ambiguous?

Empirical formulae

LO4

- 3.14** In general, what fundamental information, obtained from experimental measurements, is required to calculate the empirical formula of a compound?
- 3.15** Why is the changing of subscripts not allowed when balancing a chemical equation?
- 3.16** Give a step-by-step procedure for estimating the mass of A required to completely react with 400.0 g of B, given the following information.
- (a) A and B react to form A₅B₂.
- (b) A has a molar mass of 100.0 g mol⁻¹.
- (c) B has a molar mass of 200.0 g mol⁻¹.
- (d) There are 6.022 × 10²³ molecules of A in 1 mol of A.
- Which of these pieces of information was not needed?

Stoichiometry, limiting reagents and percentage yield

LO5

- 3.17** What information is required to determine the mass of oxygen that would react with 1 g of nitrogen?
- 3.18** A mixture of 0.020 mol of Ca and 0.020 mol of Cl₂ reacted completely to form CaCl₂ according to the following equation.

- (a) What information describes the *stoichiometry* of this chemical reaction?
- (b) What information gives the *scale* of the reaction?
- 3.19** In a report to a supervisor, a chemist described an experiment in the following way: '0.0800 mol of H₂O₂ decomposed into 0.0800 mol of H₂O and 0.0400 mol of O₂'. Express the chemistry and stoichiometry of this reaction by a balanced chemical equation.

Solution stoichiometry

LO6

- 3.20** Give the equation that relates concentration, volume and amount.
- 3.21** What is the definition of 'molarity'? Show that the ratio of millimoles (mmol) to millilitres (mL) is equivalent to the ratio of moles (mol) to litres (L).
- 3.22** What are spectator ions?
- 3.23** When a solution labelled 1.00 mol L⁻¹ HNO₃ is diluted with water to give 0.25 mol L⁻¹ HNO₃, what happens to the amount of HNO₃ in the solution?

- 3.24** Solutions A and B are labelled '0.15 mol L⁻¹ CaCl₂' and '0.2 mol L⁻¹ CaCl₂', respectively. Both solutions contain the same amount of CaCl₂. If solution A has a volume of 75 mL, what is the volume of solution B?
- 3.25** What is the difference between a qualitative analysis and a quantitative analysis?
- 3.26** The following equation represents the formation of cobalt(II) hydroxide.

- 3.27** Identify the spectator ions and write the net ionic equation. Consider the following reaction equation. Find any errors and correct them.

REVIEW PROBLEMS

- 3.28** Consider the following balanced equation.

L01

- (a) How many atoms of Na are on each side of the equation?
 (b) How many atoms of C are on each side of the equation?
 (c) How many atoms of O are on each side of the equation?
- 3.29** When sulfur impurities in fuels burn, they produce pollutants such as sulfur dioxide, a major contributor to acid rain. The following is a ball-and-stick model representing a possible reaction.

L01

On the left are reactant molecules and on the right are product molecules for a chemical reaction of this type.

Write the balanced chemical equation for this reaction, using the stoichiometric coefficients that give the smallest whole number of product molecules.

- 3.30** Write the balanced chemical equation that expresses the following statement: 'Iron can be made to react with molecular oxygen, O₂, to give iron oxide with the formula Fe₂O₃.'

L01

- 3.31** Racing car drivers can get extra power by burning methanol with nitrous oxide. Below on the left are the reactant molecules and on the right are product molecules of the chemical reaction. Write the balanced chemical equation for this reaction, using the stoichiometric coefficients that give the smallest whole number of product molecules.

L01,2

- 3.32** Is the following chemical equation balanced? The reaction it represents is used for the production of nitric acid, HNO₃, and is one of the reactions responsible for acid rain.

L01,2

If the equation is not balanced, find coefficients that would make it balanced.

3.33 Write the balanced chemical equation for the chemical reaction represented by the space-filling models below.

L01,2

3.34 Balance the following equations.

L02

- $\text{Ca}(\text{OH})_2 + \text{HCl} \rightarrow \text{CaCl}_2 + \text{H}_2\text{O}$
- $\text{NaHCO}_3 + \text{H}_2\text{SO}_4 \rightarrow \text{Na}_2\text{SO}_4 + \text{H}_2\text{O} + \text{CO}_2$
- $\text{AgNO}_3 + \text{CaCl}_2 \rightarrow \text{Ca}(\text{NO}_3)_2 + \text{AgCl}$
- $\text{C}_4\text{H}_{10} + \text{O}_2 \rightarrow \text{CO}_2 + \text{H}_2\text{O}$
- $\text{Fe}_2\text{O}_3 + \text{C} \rightarrow \text{Fe} + \text{CO}_2$

3.35 In what smallest whole-number ratio must N and O atoms combine to make dinitrogen pentoxide, N_2O_5 ? What is the mole ratio of the elements in this compound?

L03,4

3.36 What amount of silver atoms corresponds to 3.011×10^{22} atoms of silver?

L03

3.37 What amount of O is needed to combine with 3.00 mol of Al to produce the maximum amount of aluminium oxide, Al_2O_3 ?

L04,5

3.38 Determine the amounts of H_2 and N_2 that can be formed by the decomposition of 0.145 mol of ammonia, NH_3 .

L02,4

3.39 What amount of SF_6 would have to be decomposed to provide enough fluorine to prepare 1.50 mol of CF_4 through reaction with C?

L02,4

3.40 Determine the mass in grams of each of the following.

L03

- 1.85 mol Fe
- 1.85 mol O
- 1.85 mol Ca

3.41 What is the mass, in grams, of 1.50×10^{12} atoms of selenium?

L03

3.42 What amount of nickel is in 17.7 g of Ni?

L03

3.43 Calculate the molar mass of each of the following.

L03

- NaHCO_3
- $\text{K}_2\text{Cr}_2\text{O}_7$
- $(\text{NH}_4)_2\text{CO}_3$
- $\text{Al}_2(\text{SO}_4)_3$
- $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$

3.44 Calculate the mass in grams of each of the following.

L03

- 1.25 mol $\text{Ca}_3(\text{PO}_4)_2$
- 0.625 mol $\text{Fe}(\text{NO}_3)_3$
- 0.600 mol C_4H_{10}
- 1.45 mol $(\text{NH}_4)_2\text{CO}_3$

3.45 Calculate the amount of the compound in each of the following samples.

L03

- 21.5 g CaCO_3
- 1.56 g NH_3
- 16.8 g $\text{Sr}(\text{NO}_3)_2$
- 6.98 μg Na_2CrO_4

3.46 What mass of $(\text{NH}_4)_2\text{CO}_3$ fertiliser would be required in order to supply 333 g of atomic nitrogen to the soil?

L03

3.47 What mass of O is combined with 6.35×10^{21} atoms of N in the compound N_2O_3 ?

L03

3.48 The incandescent white of a fireworks display is caused by the reaction of phosphorus with O_2 to give P_4O_{10} .

L02,3

- Write the balanced chemical equation for the reaction.
- What mass of O_2 is needed to combine with 6.85 g of P?
- What mass of P_4O_{10} can be made from 8.00 g of O_2 ?
- What mass of P is needed to make 7.46 g of P_4O_{10} ?

3.49 Radioactive sodium pertechnetate is used to detect brain tumours. Quantitative analysis of a 0.896 g sample of sodium pertechnetate found 0.111 g of sodium and 0.477 g of technetium. The remainder was oxygen. Calculate the empirical formula of sodium pertechnetate.

L04

3.50 The composition of a dry-cleaning fluid, composed of only carbon and chlorine, was found to be 14.5% C and 85.5% Cl (by mass). What is the empirical formula of this compound?

L04

3.51 When 0.684 g of an organic compound containing only carbon, hydrogen and oxygen was burned in oxygen, 1.312 g CO_2 and 0.805 g H_2O was obtained. What is the empirical formula of the compound?

L04

3.52 A sample of a compound of mercury and bromine with a mass of 0.389 g was found to contain 0.111 g bromine. Its molar mass was found to be 561 g mol^{-1} . What are its empirical and molecular formulae? **L04**

3.53 Calculate the percentage composition by mass of all elements in each of the following. **L04**

- (a) Na_2HPO_4
- (b) $\text{NH}_4\text{H}_2\text{PO}_4$
- (c) CH_3COOH
- (d) CaSO_4
- (e) $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$

3.54 Chlorine is used by textile manufacturers to bleach cloth. Excess chlorine is destroyed by its reaction with sodium thiosulfate, $\text{Na}_2\text{S}_2\text{O}_3$, as follows. **L05**

- (a) What amount of $\text{Na}_2\text{S}_2\text{O}_3$ is needed to react with 0.20 mol of Cl_2 ?
- (b) What amount of HCl can form from 0.20 mol of Cl_2 ?
- (c) What amount of H_2O is required for the reaction of 0.20 mol of Cl_2 ?
- (d) What amount of H_2O reacts if 0.24 mol HCl is formed?

3.55 The following reaction is used to extract gold from pretreated gold ore. **L05**

- (a) What mass of Zn is needed to react with 0.17 mol of $\text{Au}(\text{CN})_2^-$?
- (b) What mass of Au can form from 0.17 mol of $\text{Au}(\text{CN})_2^-$?
- (c) What mass of $\text{Au}(\text{CN})_2^-$ is required for the reaction of 0.17 mol of Zn ?

3.56 Oxygen gas can be produced in the laboratory by decomposition of hydrogen peroxide, H_2O_2 . **L05**

What mass of O_2 can be produced from 221 g of H_2O_2 ?

3.57 Given the balanced chemical equation, determine the number of molecules of SO_2 that would be formed starting from the actual number of molecules of $\text{C}_2\text{H}_5\text{SH}$ and O_2 shown. **L05**

3.58 Using the balanced chemical equation from problem 3.57, which of $\text{C}_2\text{H}_5\text{SH}$ or O_2 was the limiting reagent if the product distribution for the reaction was that shown below? **L05**

3.59 The thermite reaction of powdered aluminium and iron(III) oxide produces so much heat that the iron that forms is molten. Because of this, the reaction is used when laying railway tracks to provide molten steel to weld steel rails together. **L05**

- Suppose that, in one batch of reactants, 3.00 mol of Al was mixed with 1.50 mol of Fe_2O_3 .
- Which reactant, if either, was the limiting reagent?
 - Calculate the mass of iron that can be formed from this mixture of reactants.
- 3.60** Silver nitrate, AgNO_3 , reacts with calcium chloride, CaCl_2 , to give silver chloride, AgCl , and calcium nitrate, $\text{Ca}(\text{NO}_3)_2$. A solution containing 18.0 g of AgNO_3 was mixed with a solution containing 32.4 g of CaCl_2 . What mass of which reactant remains after the reaction is complete? **L05**
- 3.61** Barium sulfate, BaSO_4 , is made by the following reaction. **L05**
- $$\text{Ba}(\text{NO}_3)_2(\text{aq}) + \text{Na}_2\text{SO}_4(\text{aq}) \rightarrow \text{BaSO}_4(\text{s}) + 2\text{NaNO}_3(\text{aq})$$
- An experiment began with 75.00 g of $\text{Ba}(\text{NO}_3)_2$ and an excess of Na_2SO_4 . After collecting and drying the product, 64.45 g of BaSO_4 was obtained. Calculate the theoretical yield and percentage yield of BaSO_4 .
- 3.62** The potassium salt of benzoic acid (potassium benzoate, $\text{C}_6\text{H}_5\text{COOK}$), can be made by the action of potassium permanganate, KMnO_4 , on toluene, $\text{C}_6\text{H}_5\text{CH}_3$, as follows. **L05**
- $$\text{C}_6\text{H}_5\text{CH}_3 + 2\text{KMnO}_4 \rightarrow \text{KC}_6\text{H}_5\text{COO} + 2\text{MnO}_2 + \text{KOH} + \text{H}_2\text{O}$$
- The maximum practical yield for this reaction is 71%. Given that, what is the minimum mass of toluene required to produce 14.5 g of potassium benzoate?
- 3.63** Calculate the concentration of a solution prepared by dissolving: **L06**
- 4.00 g of NaOH in 100.0 mL of solution
 - 16.0 g of CaCl_2 in 250.0 mL of solution
 - 14.0 g of KOH in 75.0 mL of solution
 - 6.75 g of $\text{HO}_2\text{CCO}_2\text{H}$ in 500 mL of solution.
- 3.64** Calculate the mass of each solute needed to make each of the following solutions. **L06**
- 125 mL of 0.200 mol L^{-1} $\text{NaCl}(\text{aq})$
 - 245 mL of 0.360 mol L^{-1} $\text{C}_6\text{H}_{12}\text{O}_6(\text{aq})$
 - 452 mL of 0.250 mol L^{-1} $\text{H}_2\text{SO}_4(\text{aq})$
- 3.65** If 25.0 mL of 0.50 mol L^{-1} H_2SO_4 is diluted to a volume of 125 mL, what is the concentration of the resulting solution? **L06**
- 3.66** To what volume must 25.0 mL of 18.0 mol L^{-1} H_2SO_4 be diluted to produce 1.50 mol L^{-1} $\text{H}_2\text{SO}_4(\text{aq})$? **L06**
- 3.67** Calculate the amounts of each of the ions in the following solutions. **L06**
- 35.0 mL of 1.25 mol L^{-1} $\text{KOH}(\text{aq})$
 - 32.3 mL of 0.45 mol L^{-1}
 - 50.0 mL of 0.40 mol L^{-1} $\text{AlCl}_3(\text{aq})$
- 3.68** Calculate the concentrations of each of the ions in the following solutions. **L06**
- 0.25 mol L^{-1} $\text{Cr}(\text{NO}_3)_3(\text{aq})$
 - 0.10 mol L^{-1} $\text{CuSO}_4(\text{aq})$
 - 0.16 mol L^{-1} $\text{Na}_3\text{PO}_4(\text{aq})$
 - 0.075 mol L^{-1} $\text{Al}_2(\text{SO}_4)_3(\text{aq})$
- 3.69** In a solution of $\text{Al}_2(\text{SO}_4)_3(\text{aq})$, the Al^{3+} concentration is 0.12 mol L^{-1} . What mass of $\text{Al}_2(\text{SO}_4)_3$ is in 50.0 mL of this solution? **L06**
- 3.70** What volume of 0.25 mol L^{-1} $\text{NiCl}_2(\text{aq})$ solution is needed to react completely with 20.0 mL of 0.15M $\text{Na}_2\text{CO}_3(\text{aq})$ solution? What mass of NiCO_3 will be formed? The reaction can be represented by the following equation. **L06**
- $$\text{Na}_2\text{CO}_3(\text{aq}) + \text{NiCl}_2(\text{aq}) \rightarrow \text{NiCO}_3(\text{s}) + 2\text{NaCl}(\text{aq})$$
- 3.71** What volume of 0.200 mol L^{-1} $\text{FeCl}_3(\text{aq})$ solution is needed to react completely with 25.0 mL of 0.0450 mol L^{-1} $\text{AgNO}_3(\text{aq})$ solution? What mass of AgCl will be formed? The net ionic equation for the reaction is as follows. **L06**
- $$\text{Ag}^+(\text{aq}) + \text{Cl}^-(\text{aq}) \rightarrow \text{AgCl}(\text{s})$$
- 3.72** Consider the reaction of aluminium chloride with silver acetate. What volume of 0.200 mol L^{-1} $\text{AlCl}_3(\text{aq})$ would be needed to react completely with 40.0 mL of 0.500 mol L^{-1} $\text{AgOOCCH}_3(\text{aq})$ solution? The net ionic equation for the reaction is as follows. **L06**
- $$\text{Ag}^+(\text{aq}) + \text{Cl}^-(\text{aq}) \rightarrow \text{AgCl}(\text{s})$$
- 3.73** Suppose that 25.0 mL of 0.440 mol L^{-1} $\text{NaCl}(\text{aq})$ is added to 25.0 mL of 0.320 mol L^{-1} $\text{AgNO}_3(\text{aq})$. **L06**
- What amount of AgCl would precipitate?
 - Determine the concentration of each of the ions in the reaction mixture after the reaction.
- 3.74** A mixture is prepared by adding 25.0 mL of 0.185 mol L^{-1} $\text{Na}_3\text{PO}_4(\text{aq})$ to 34.0 mL of 0.140 mol L^{-1} $\text{Ca}(\text{NO}_3)_2(\text{aq})$. **L06**
- What mass of $\text{Ca}_3(\text{PO}_4)_2$ will be formed?
 - Determine the concentration of each of the ions in the mixture after reaction.

ADDITIONAL EXERCISES

- 3.75** Write the net ionic equations for the following reactions. Include the designations for the states — solid, liquid, gas and aqueous solution. For any substance soluble in water, assume that it is used as an aqueous solution. **L06**

- $\text{CaCO}_3 + 2\text{HNO}_3 \rightarrow \text{Ca}(\text{NO}_3)_2 + \text{CO}_2 + \text{H}_2\text{O}$
- $\text{CaCO}_3 + \text{H}_2\text{SO}_4 \rightarrow \text{CaSO}_4 + \text{CO}_2 + \text{H}_2\text{O}$

- $\text{FeS} + 2\text{HBr} \rightarrow \text{H}_2\text{S} + \text{FeBr}_2$
- $2\text{KOH} + \text{SnCl}_2 \rightarrow 2\text{KCl} + \text{Sn}(\text{OH})_2$

- 3.76** Answer the following questions about an insecticide with the chemical formula $\text{C}_9\text{H}_{10}\text{ClN}_5\text{O}_2$. **L03,6**

- What amount of carbon atoms is there in 10.0 g of the compound?

- (b) What mass of oxygen is there in 10.0 g of the compound?
- (c) The label on a 75 mL bottle of garden insecticide states that the solution contains 0.010% insecticide and 99.99% inert ingredients. What amount, and how many molecules, of the insecticide are in the bottle? (Assume that the density of the solution is 1.00 g mL^{-1} .)
- (d) The instructions on the bottle of insecticide in (c) are to dilute the insecticide by adding 1.0 mL of the solution to 4.0 L of water. If you spray 60 L of the diluted insecticide mixture on your rose garden, what amount of the active ingredient is dispersed?

3.77 The mineral turquoise has the following formula. **L03**

3.79 The thyroid gland produces hormones that help regulate body temperature, metabolic rate, reproduction, synthesis of red blood cells and more. Iodine must be present in the diet to produce these thyroid hormones. Iodine deficiency leads to sluggishness and weight gain, and can cause severe problems in the development of a foetus. One thyroid hormone is thyroxine, with the chemical formula $\text{C}_{15}\text{H}_{11}\text{I}_4\text{NO}_4$. What mass of thyroxine can be produced from 150 μg of iodine, the recommended daily intake for an Australian adult? How many molecules is this? **L03,5**

- 3.80** Police officers confiscate a packet of white powder that they believe contains heroin. Purification by a forensic chemist yields a 38.70 Mg sample for combustion analysis. This sample produces 97.46 mg CO_2 and 20.81 mg H_2O on complete combustion. A second sample is analysed for its nitrogen content, which is 3.8%. Show by calculations whether these data are consistent with the formula for heroin, $\text{C}_{21}\text{H}_{22}\text{NO}_5$. **L04,5**
- 3.81** When an unknown compound containing only carbon and hydrogen is burned completely in O_2 , 1.45 g of CO_2 and 0.47 g of H_2O is recovered. What additional information, if any, is needed before the molecular formula of the unknown compound can be determined? **L04,5**
- 3.82** A sulfur-containing ore of copper releases sulfur dioxide when heated in air. A 5.26 g sample of the ore releases 2.12 g of SO_2 on heating. Assuming that the ore contains only copper and sulfur, what is the empirical formula? **L04**
- 3.83** Vitamin B_{12} is a large molecule called cobalamin. There is 1 atom of cobalt in each molecule of vitamin B_{12} , and the mass percentage of cobalt is 4.34%. Calculate the molar mass of cobalamin.
- 3.84** Element *E* forms a compound with the formula ECl_5 . Elemental analysis shows that the compound is 58.28% chlorine by mass. Identify element *E*. **L04**
- 3.85** A sample of a component of petroleum was subjected to combustion analysis. An empty vial of mass 2.7534 g was filled with the sample, after which the vial plus sample had a mass of 2.8954 g. The sample was burned and the resulting CO_2 and H_2O were collected in separate traps. Before combustion, the CO_2 trap had a mass of 54.4375 g and the H_2O trap had a mass of 47.8845 g. At the end of the analysis, the CO_2 trap had a

- (a) What mass of aluminium is in a 6.75 g sample of turquoise?
- (b) How many phosphate ions are in a sample of turquoise that contains $5.00 \times 10^{-3} \text{ g}$ of oxygen?
- 3.78** Adenosine triphosphate (ATP) is used to generate chemical energy in plant and animal cells. The molecular formula of ATP is $\text{C}_{10}\text{H}_{16}\text{N}_5\text{O}_{13}\text{P}_3$. Answer the following questions about ATP. **L03,5**
- (a) What is the percentage composition by mass of each element in ATP?
- (b) How many P atoms are in 1.75 μg of ATP?
- (c) If a cell consumes 3.0 pmol of ATP, what mass has it consumed?
- (d) What mass of ATP contains the same number of H atoms as the number of N atoms in 37.5 Mg of ATP?

new mass of 54.9140 g and the H_2O trap had a new mass of 47.9961 g. Determine the empirical formula of this component of petroleum. **L04**

- 3.86** In the Haber-Bosch synthesis of ammonia, N_2 and H_2 react at high temperature, but they never react completely. In a typical reaction, 11.0 kg of H_2 and 39.0 kg of N_2 react to produce 31.0 kg of NH_3 . Find the theoretical yield, the percentage yield and the masses of H_2 and N_2 that remain unreacted, assuming that no other products form. **L05**
- 3.87** Silicon tetrachloride is used in the electronics industry to make elemental silicon for computer chips. Silicon tetrachloride is prepared from silicon dioxide, graphite and chlorine gas according to the following equation. **L05**

If the reaction achieves 87.3% yield, how much silicon tetrachloride can be prepared from 85.0 g of each starting material, and how much of each reactant remains unreacted?

- 3.88** A 0.113 g sample of a mixture of sodium chloride and sodium nitrate was dissolved in water, and enough silver nitrate solution was added to precipitate all of the chloride ions. The mass of silver chloride obtained was 0.250 g. What mass percentage of the sample was sodium chloride? **L06**
- 3.89** In an experiment, 40.0 mL of $0.270 \text{ mol L}^{-1} \text{ Ba}(\text{OH})_2(\text{aq})$ was mixed with 25.0 mL of $0.330 \text{ mol L}^{-1} \text{ Al}_2(\text{SO}_4)_3(\text{aq})$. **L06**
- (a) Write the net ionic equation for the reaction that takes place.
- (b) What is the total mass of precipitate that forms?
- (c) What are the molar concentrations of the ions that remain in the solution after the reaction is complete?

- 3.90** What volume of $0.10 \text{ mol L}^{-1} \text{ HCl(aq)}$ must be added to 50.0 mL of $0.40 \text{ mol L}^{-1} \text{ HCl(aq)}$ to give a final solution that has a molarity of 0.25 mol L^{-1} ? **L06**
- 3.91** Solution A is prepared by dissolving 90.0 g of Na_3PO_4 in enough water to make 1.5 L of solution. Solution B is 2.5 L of $0.705 \text{ mol L}^{-1} \text{ Na}_2\text{SO}_4(\text{aq})$. **L06**
- (a) What is the molar concentration of Na_3PO_4 in solution A?
- (b) What volume of solution A contains 2.50 g of Na_3PO_4 ?
- (c) A 50.0 mL sample of solution B is mixed with a 75.00 mL sample of solution A. Calculate the concentration of Na^+ ions in the final solution.
- 3.92** A chemist needs a solution that contains aluminium ions, sodium ions and sulfate ions. In the laboratory she finds a large volume of 0.355 mol L^{-1} sodium sulfate solution and a bottle of solid $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$. The chemist puts 255 mL of the sodium sulfate solution and 5.74 g of aluminium sulfate 18-hydrate in a 500 mL volumetric flask. The flask is made up to the mark with water. Determine the molar concentration of aluminium ions, sodium ions and sulfate ions in the solution. **L06**
- 3.93** The waters of our oceans contain many elements in trace amounts. Rubidium, for example, is present at the level of 2.2 nM (nanomolar). How many ions of rubidium are present in 1.00 L of sea water? How many litres would have to be processed to recover 1.00 kg of rubidium, assuming the recovery process was 100% efficient? **L06**
- 3.94** Pure acetic acid, CH_3COOH , has a concentration of 17.4 mol L^{-1} . A research student measured out 100.0 mL of pure acetic acid and added enough water to make 500.0 mL of solution. A 75.0 mL portion of the acetic acid solution was then mixed with enough water to make 1.50 L of dilute solution. What was the final molarity of acetic acid in the dilute solution? **L06**
- 3.95** A student in a biological laboratory needed a solution that was 0.30 mol L^{-1} in sodium acetate, NaOOCCH_3 , and 0.15 mol L^{-1} in acetic acid, CH_3COOH . On hand were stock solutions of 2.5 mol L^{-1} sodium acetate and 2.5 mol L^{-1} acetic acid. Describe how the student prepared 1.5 L of the desired solution. **L06**
- 3.96** Silver jewellery is usually made from silver and copper alloys. The amount of copper in an alloy can vary considerably. The finest quality alloy is sterling silver, which is 92.5% silver by mass. To determine the composition of a silver–copper alloy, a jeweller dissolved 0.141 g of metal shavings in 50 mL of concentrated nitric acid and then added 1.00 mol L^{-1} solution until no more precipitate formed. Filtration and drying yielded 0.164 g of AgCl precipitate. What was the mass composition of the silver alloy? **L06**
- 3.97** Aluminium sulfate is used in the manufacture of paper and in the water purification industry. In the solid state, aluminium sulfate is a hydrate with the formula $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$. **L03,6**
- (a) What mass of sulfur is there in 0.500 mol of solid aluminium sulfate?
- (b) How many water molecules are there in a 4.81 g sample of solid aluminium sulfate?
- (c) What amount of sulfate ions is there in a sample of solid aluminium sulfate that contains 12.5 mol of oxygen atoms?
- (d) An aqueous solution of aluminium sulfate has a density of 1.05 g mL^{-1} . What is the molar concentration of aluminium ions in the solution?

Atomic energy levels

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 4.1** list some basic properties of atoms
 - 4.2** explain the wave-like and particle-like properties of light, and how light interacts with atoms
 - 4.3** describe the properties of electrons
 - 4.4** explain the properties of bound electrons
 - 4.5** describe atomic orbitals in terms of electron distributions and energies
 - 4.6** explain the structure of the periodic table in terms of electrons
 - 4.7** write electron configurations
 - 4.8** describe periodic trends in chemical and physical properties
 - 4.9** describe periodic trends in relation to ions.
-

In the right combination, atoms and light combine to create one of the most remarkable tools of modern technology, the laser. Laser light is more highly organised than normal light. Laser light is monochromatic (has a single wavelength) and is highly directional, whereas conventional light sources typically produce light of many wavelengths. Figures 4.1a and 4.1b demonstrate these differences. In figure 4.1a, we see red laser light with wavelength of 650 nm pass through a prism. Although the light is refracted, there is no splitting into different colours, as we see for white light that forms a rainbow when refracted by water droplets in the air (see figure 4.1b). This confirms that laser light consists of only one wavelength while normal white light comprises many wavelengths. Many of the applications of lasers take advantage of the high degree of organisation.

FIGURE 4.1

(a) Laser light consists of a single wavelength and therefore does not split into different colours when passed through a glass prism, whereas (b) white light consists of many wavelengths, and thus splits into its component colours when forming a rainbow.

(a)

(b)

Lasers are used in, for example, Blu-ray players, barcode scanners, eye surgery and fibre-optic communications. Lasers have also become versatile tools for scientific research. For example, finely tuned lasers have been used to deposit vapour-phase atoms on solid surfaces in regular patterns. The ability to manipulate individual atoms is likely to have important applications in nanotechnology.

Every laser is based on the interactions between light and atoms or molecules. In this chapter, we describe the properties of atoms and light and the energy changes that accompany the interactions between them. Then we describe the properties of electrons bound to atoms and how these contribute to atomic structure. We explore the details of atomic orbital energies and relate them to the familiar form and structure of the periodic table. Orbital energy levels have consequences that are far reaching, for example, they determine the stability and reactivity of atoms. The periodic table is based on orbital energy levels and provides the foundation for interpreting patterns of chemical behaviour related to an element's position in the table.

4.1 Characteristics of atoms

LEARNING OBJECTIVE 4.1 List some basic properties of atoms.

The atom is the fundamental building block of all matter. In this chapter, we will investigate the properties of atoms in some detail. We will start by outlining the basic characteristics of atoms; we read about many of these characteristics in the introductory chapter on the atom.

Atoms possess mass, most of which is concentrated in the nucleus. The nucleus of an atom is small and positively charged, and all nuclei, except that of the hydrogen atom ^1H , consist of both positively charged protons and neutral neutrons. For neutral atoms, the positive charge of the nucleus is exactly balanced by negatively charged electrons; that is, a neutral atom contains equal numbers of protons and electrons. Atoms occupy volume, the majority of which is taken up by the electron cloud in the region of space around the nucleus. The chemical properties of elements are determined to a large extent by both their atomic size and their number of accessible (valence) electrons. Finally, atoms can attract one another and, as a result, can combine to form, for example, molecules.

This chapter examines in detail how both the number of electrons and their specific arrangement influence chemical properties. Light is an essential tool for probing the properties of electrons and since there are similarities between the properties of light and electrons, we will begin our discussion by describing the properties of light and its interaction with atoms.

4.2 Characteristics of light

LEARNING OBJECTIVE 4.2 Explain the wave-like and particle-like properties of light, and how light interacts with atoms.

The most useful tool for studying the structure of atoms is **electromagnetic radiation**. What we call **light** is one form of this radiation, with other forms including radio waves, microwaves and X-rays (see figure 4.5 later in the chapter). We need to know about the fundamental properties of light to understand what electromagnetic radiation reveals about atomic structure.

Wave-like properties of light

Light has wave-like properties. A wave is a regular oscillation in some particular property, such as the up-and-down variation in position of water waves. Water waves vary with time. A surfer waiting for a 'big one' bobs up and down as 'small ones' pass by. Light waves vary with time too, in a more regular manner than water waves. This variation is characterised by the wave's **frequency** (ν), which is the number of wave crests passing a point in space in 1 second (so the unit is s^{-1} , also designated hertz or Hz). Water waves also vary in height as you move away from the beach; that is, the height of the wave varies with position. Light waves vary in space in a manner illustrated in figure 4.2. This variation in space is characterised by the **wavelength** (λ), which is the distance between successive wave crests. Wavelengths are measured in units of length, such as metres or nanometres. As we will see below, frequency and wavelength are not independent variables, but are inversely proportional to each other.

Amplitude is the maximum displacement of a wave from its centre. The amplitude of a light wave determines the **intensity** of the light. As figure 4.3 illustrates, a bright light is more intense than a dim one

as its waves have higher amplitudes. It is important to note that the intensity of light is proportional to the square of its amplitude. The amplitude itself has no physical meaning because at any moment in time the amplitude of the wave can be negative or positive, while the square is always positive and equivalent to photon density.

Waves can also be described in terms of their phase. **Phase** refers to the starting position of a wave with respect to one wavelength. We can see that waves in figures 4.4a and 4.4b have the same amplitude and wavelengths, but different starting points. We say that the two waves have different phases. We can see this more clearly in figure 4.4c, which shows the two waves superimposed. If they had the same phase (and the same amplitude and wavelength), they would line up perfectly. When two waves interact, the outcome is influenced, among other things, by their relative phases. The amplitudes of both waves will be added, which in the example in figure 4.4 would lead to exact cancellation.

Light waves, and all other types of electromagnetic radiation, always move through a vacuum at the same speed. The speed of light is a fundamental constant $c = 2.997\,924\,58 \times 10^8 \text{ m s}^{-1}$ (we will round it to $2.998 \times 10^8 \text{ m s}^{-1}$). For any wave, its frequency (ν) (in units of s^{-1}) multiplied by its wavelength (λ) (in units of m) equals its speed c (m s^{-1}), that is:

$$c = \nu \lambda$$

FIGURE 4.2

A light wave can be described by its wavelength or frequency. As wavelength increases, frequency decreases, and vice versa.

FIGURE 4.3

The amplitude of a light wave determines the intensity of the light. A bright light is more intense, that is, has a higher amplitude, than a dim light.

FIGURE 4.4

Phase refers to the starting position of a wave with respect to one wavelength. The waves in (a) and (b) have different phases; (c) shows an overlap of (a) and (b).

**WORKED EXAMPLE 4.1****Wavelength–frequency conversion**

An FM radio station transmits its signal at 103.4 MHz. What is the wavelength of the signal?

Analysis

The link between wavelength (λ) and frequency (ν) is given by $c = \nu\lambda$.

Solution

First, we summarise the data.

$$c = 2.998 \times 10^8 \text{ m s}^{-1} \quad \nu = 103.4 \text{ MHz}$$

Next, we rearrange the equation to solve for wavelength.

$$c = \nu\lambda \quad \text{so} \quad \lambda = \frac{c}{\nu}$$

To obtain equivalent units, convert the frequency units from MHz to Hz. The prefix ‘M’ stands for ‘mega’, which is a factor of 10^6 . Remember that Hz is equivalent to s^{-1} .

$$\lambda = \frac{2.998 \times 10^8 \text{ m s}^{-1}}{103.4 \times 10^6 \text{ s}^{-1}} = 2.899 \text{ m}$$

Is our answer reasonable?

The wavelength of 2.899 m may seem rather long, but radio waves are known as long wavelength radiation. See figure 4.5 for a sense of the wavelengths of electromagnetic radiation.

PRACTICE EXERCISE 4.1

What is the frequency of electromagnetic radiation that has a wavelength of 1.40 cm?

The wavelengths or frequencies of electromagnetic radiation cover an immense range. Figure 4.5 shows that the visible spectrum covers the wavelength range from about 380 nm (violet) to 780 nm (red). The centre of this range is yellow light, with a wavelength of about 580 nm and a frequency around $5.2 \times 10^{14} \text{ s}^{-1}$. Although visible light is extremely important to living creatures for vision, the whole electromagnetic spectrum from gamma rays to radio waves also has diverse effects on, and uses in, our lives.

Radiation with short wavelengths, in the X-ray and gamma ray regions, can generate ions by removing electrons from atoms and molecules. These ions are highly reactive and can cause serious damage to the material that absorbs the radiation. However, under closely controlled conditions, X-rays are used in medical imaging, and gamma rays are used to treat cancer. The wavelength of ultraviolet (UV) radiation lies between that of X-rays and visible light. UV radiation can also damage materials, especially in high doses. High rates of skin cancer in Australia and New Zealand are a direct result of exposure to damaging UV radiation in sunlight.

Radiation with long wavelengths falls in the infrared, microwave or radio frequency regions. Heat lamps make use of infrared radiation, microwave ovens cook with microwave radiation, and radio and television signals are transmitted by radio waves.

What we perceive as white light actually contains a range of wavelengths. This becomes apparent when white light passes through a prism or through water droplets, which creates a rainbow (see figure 4.1b). These objects refract different wavelengths of light through different angles, so the light that passes through spreads out in space, with each wavelength appearing at its own characteristic angle.

FIGURE 4.5

The electromagnetic spectrum, showing its various regions and the associated wavelengths and frequencies

Particle properties of light

Light carries energy. When our bodies absorb sunlight, for example, we feel warm because energy from the sunlight has been transferred to our skin. A phenomenon known as the **photoelectric effect** shows how the energy of light depends on its frequency and intensity. The photoelectric effect is the basis for many light-sensing devices, such as automatic door openers and camera exposure meters. Figure 4.6 illustrates a photoelectric experiment in which a beam of light strikes the surface of a metal. Under the right conditions, the light causes electrons to be ejected from the metal surface. A detailed study of the photoelectric effect reveals how the behaviour of these electrons is related to the characteristics of light.

1. Below a characteristic threshold frequency, ν_0 , no electrons are observed, regardless of the light's intensity.
2. Above the threshold frequency, the maximum kinetic energy of ejected electrons increases linearly with the frequency of the light, as shown in figure 4.7. Kinetic energy is a function of the electron's speed. We will learn more about kinetic energy in the chapter on gases.
3. Above the threshold frequency, the *number* of emitted electrons increases with the light's intensity, but the *kinetic energy* per electron does not depend on the light's intensity.
4. All metals exhibit the same behaviour, but, as figure 4.7 indicates, each metal has a different threshold frequency.

FIGURE 4.6

A diagrammatic view of the photoelectric effect. When light of a high enough frequency strikes a metal, electrons are ejected from the surface.

FIGURE 4.7

Variation in the maximum kinetic energy of electrons ejected from two different metal surfaces (a and b) as a function of the frequency of incoming light

In 1905, Albert Einstein postulated that light comes in ‘packets’ or ‘bundles’, called **photons**. Each photon has an energy that is directly proportional to its frequency.

$$E_{\text{photon}} = h\nu_{\text{photon}}$$

In this equation, E is the energy of a photon of light and ν is its frequency. The proportionality constant between energy and frequency is known as **Planck’s constant** (h) and has a value of $6.626\,069\,57(29) \times 10^{-34} \text{ J s}$ (we will use $6.626 \times 10^{-34} \text{ J s}$).

WORKED EXAMPLE 4.2

The energy of light

What is the energy of a photon of blue light with a wavelength of 475 nm?

Analysis

This conversion problem requires two steps. We do not have an equation that will calculate E based on the data we have, but, by combining the two equations we do know, we can relate the energy of a photon to its frequency and wavelength.

Solution

We combine the equations into an equation that relates energy to wavelength.

$$E = h\nu \quad \text{and} \quad \nu = \frac{c}{\lambda} \quad \text{so} \quad E = \frac{hc}{\lambda}$$

We summarise the data.

$$h = 6.626 \times 10^{-34} \text{ J s} \quad \lambda = 475 \text{ nm} \quad c = 2.998 \times 10^8 \text{ m s}^{-1}$$

Substituting our data, we find:

$$\begin{aligned} E_{\text{photon}} &= \frac{(6.626 \times 10^{-34} \text{ J s})(2.998 \times 10^8 \text{ m s}^{-1})}{475 \times 10^{-9} \text{ m}} \\ &= \frac{(6.626 \times 10^{-34} \text{ J s})(2.998 \times 10^8 \text{ m s}^{-1})}{475 \times 10^{-9} \text{ m}} \\ &= 4.18 \times 10^{-19} \text{ J} \end{aligned}$$

Is our answer reasonable?

An energy of 10^{-19} J seems very small, but we must remember that this is the energy of a single photon. If we want to calculate the energy of 1 mol of these photons, we need to multiply our result by the Avogadro constant.

$$\begin{aligned} E_{1 \text{ mol of photons}} &= E_{\text{photon}} \times N_{\text{A}} \\ &= (4.18 \times 10^{-19} \text{ J}) \times (6.022 \times 10^{23} \text{ mol}^{-1}) \\ &= 251 \times 10^3 \text{ J mol}^{-1} = 251 \text{ kJ mol}^{-1} \end{aligned}$$

This energy is comparable to the energies of chemical bonds.

PRACTICE EXERCISE 4.2

What is the energy of a photon with a wavelength of 254 nm (UV radiation)?

Einstein concluded that the energy of a photon that has the threshold frequency (ν_0) corresponds to the binding energy of the electron. Energy beyond the threshold frequency increases the electron’s kinetic energy as shown in figure 4.8. This can be described by:

electron kinetic energy = photon energy – binding energy

$$E_{\text{kinetic(electron)}} = h\nu - h\nu_0$$

Einstein's explanation accounts for the observed properties of the photoelectric effect. When the energy of the photon is less than $h\nu_0$ (low-frequency light), no electrons can escape from the metal surface, no matter how intense the light. When the energy of the photon is greater than $h\nu_0$, an electron is ejected and any excess energy is transferred to that electron as kinetic energy. The intensity of a light beam is a measure of the number of photons per unit time; light of a higher amplitude carries more photons than light of lower amplitude. The intensity of the light *does not* determine the amount of energy per photon. More photons striking the metal result in more electrons being ejected, but the energy of each photon and each electron is unchanged. Finally, the fact that each metal has its own characteristic threshold frequency suggests that electrons are bound more tightly to some metals than to others.

Einstein's explanation of the photoelectric effect showed that light has some properties of particles. A complete description of light includes both wave-like and particle-like properties. When light interacts with a relatively large body such as a raindrop or a prism, its wave properties dominate the interaction. On the other hand, when light interacts with a small body such as an atom or an electron, particle properties dominate the interaction. Each view provides different information about the properties of light, and, when we think about light, we must think of *particle–waves* that combine both types of features.

FIGURE 4.8

Diagram of the energy balance for the photoelectric effect

CHEMICAL CONNECTIONS

ANSTO, the Australian Synchrotron

Electromagnetic radiation in its many forms is frequently used to probe the nature of chemical compounds, whether they are employed as materials for electronic devices, newly developed drugs or anything in between. The detailed information that can be extracted and used to advance chemistry in all its forms is strongly influenced by the intensity, coherence and wavelength of the available radiation. Important properties of electromagnetic radiation can be maximised using a synchrotron source. ANSTO, the Australian Synchrotron in Melbourne is one of about 50 of these facilities in the world.

Figure 4.9 shows Dr Pimm Vongsivut, a beamline scientist working on the infrared microscopy (IRM) beamline at the Australian Synchrotron. So far, more than 8000 scientists, mainly from Australia and New Zealand, have used beamlines at the Australian Synchrotron for their research. Many of these users are students working on their Honours or PhD theses, and one day you might use the facility yourself.

Australian scientists are able to use synchrotron light radiation — X-rays and infrared — to understand in precise detail, the structure of materials or the workings of whole systems, and then apply that valuable information to their work. This synchrotron radiation is applied across ten different beamlines currently operating at the Australian Synchrotron, grouped by technique: spectroscopy, microscopy, imaging, scattering, diffraction and crystallography. A further eight beamlines are currently under construction, each providing complementary capability to the existing beamlines and due for completion in 2024.

FIGURE 4.9

Dr Pimm Vongsivut, beamline scientist, aligning a sample for analysis using the infrared/visible microscope at the Australian Synchrotron

All beamlines are extremely versatile in their applications. For example, researchers have ‘seen’ the structure of milk fat when it’s digested and how it might be used for drug delivery; discovered the trigger for coeliac disease to help develop a vaccine; observed how some native plants immobilise heavy metals and how they might remediate contaminated soils (see the chemical connections feature on bushfires and soil later in the chapter); better understood complex viruses and disease to develop more effective and affordable drugs; and determined under which conditions fat is absorbed into potatoes, to create a low-fat chip.

Synchrotron light is also used in archaeology and cultural studies in, for example: determining the source of ochre in rock painting in the Northern Territory; digitally reproducing hidden paintings by famous artists such as Australian Arthur Streeton, Picasso and Degas; or even discovering what a Victorian dinosaur had for its last meal without breaking bedrock.

In order to understand synchrotron science we need to discuss the origin of synchrotron radiation. When electrons are forced to travel in a circular orbit at speeds approaching the speed of light, they emit radiation in the form of photons of various wavelengths, ranging from infrared to hard X-rays (wavelengths of 10^{-6} to 10^{-11} m, respectively, see figure 4.5). This radiation is called synchrotron radiation and is characterised by its high intensity (figure 4.10), making it very useful for studying the absorption, reflection and diffraction properties of matter.

FIGURE 4.10 Comparison of brightness (intensity) of radiation from a range of sources

Figure 4.11 shows a schematic of the Australian Synchrotron. Electrons are generated by a central electron gun and are accelerated to almost the speed of light by the linear accelerator (linac) and the booster ring. They are then transferred to the outer storage ring. The electrons are confined to the circular orbit by a series of powerful bending magnets. As the electrons are deflected through the magnetic field created by the bending magnets, they give off electromagnetic radiation, so that a beam of synchrotron radiation is produced at each bending magnet. These intense beams of ‘white’ radiation (i.e. with a spectrum of wavelengths from infrared to hard X-rays) can be captured and directed to a beamline end station where a specific wavelength appropriate for a particular technique or specific experiment can be selected.

The Australian Synchrotron is an advanced third-generation design. It accommodates three different types of light sources (bending magnets, multipole wigglers and undulators) to enable a wide range of advanced experiments and measurements to be carried out.

Recent advances in accelerator design and magnet fabrication have led to the commissioning of fourth-generation synchrotron light sources around the world. The fourth-generation machines feature much smaller, more collimated electron beams that generate corresponding orders of magnitude increases in the brightness of the synchrotron light. This increased brightness allows for the investigation of smaller samples and higher resolution data as well as unlocking previously unfeasible analysis techniques. These advances will ensure that synchrotron light sources will have an important place in chemistry and physics for many years to come.

Absorption and emission spectra

In the photoelectric effect, when photons strike a metal surface, the energy absorbed provides information about the binding energies of electrons at metal surfaces. When light interacts with free atoms, the interaction reveals information about electrons within individual atoms.

Light and atoms

Attractive electrostatic forces hold an electron within an atom. Energy must be supplied to remove the electron from the atom. The lower the atom's energy state, the more energy is required to remove its electron. The energy required is measured relative to the energy of a free electron. We define the energy of a hypothetical free stationary electron to be zero. As figure 4.12 indicates, the kinetic energy of a freely moving electron is positive relative to this conventional zero point. In contrast, bound electrons are lower in energy than the hypothetical free stationary electron, so we assign them negative energy values.

The absorption of photons by free atoms has two possible results, depending on the energy of the photon. When an atom absorbs a photon of sufficiently high energy, an electron is ejected (i.e. the atom ionises). This process is described later in this chapter. Here, we focus on the second type of result, in which the atom gains energy, but does not ionise. Instead, the atom moves from the lowest energy or **ground state** to a higher energy state called an **excited state**. As we saw in the introductory chapter on the atom, this process is called an electronic transition. Excited states are not stable and atoms in excited states subsequently give up their excess energy to return to lower energy states, and eventually the ground state. Atoms lose their excess energy in collisions with other atoms or by emitting photons.

The key feature in the exchange of energy between atoms and light (photons) is that energy is conserved. This requires that the change in energy of the atom exactly equals the energy of the photon.

$$\Delta E_{\text{atom}} = \pm h\nu_{\text{photon}}$$

When an atom *absorbs* a photon, the atom gains the photon's energy, so ΔE_{atom} is positive. When an atom *emits* a photon, the atom loses the photon's energy, so ΔE_{atom} is negative. As an atom returns from an excited state to the ground state, it must lose exactly the amount of energy that it originally gained. However, excited atoms usually lose excess energy in several steps involving small energy changes, so the frequencies of emitted photons are often lower than those of absorbed photons.

FIGURE 4.12

By convention, a free stationary electron has zero energy, and bound electrons have negative energies.

WORKED EXAMPLE 4.3

Emission energies

A sodium-vapour street lamp emits yellow light at a wavelength of 589 nm. What is the energy change for a sodium atom involved in this emission? How much energy is released per mole of sodium atoms?

Analysis

This problem relates energies of photons to energy changes of atoms. The solution requires a conversion involving wavelength and energy.

Solution

Sodium atoms lose energy by emitting photons of light ($\lambda = 589 \text{ nm}$). We can relate the wavelength of one of these photons to its energy.

$$E_{\text{photon}} = h\nu = \frac{hc}{\lambda}$$

Energy is conserved, so the energy of the emitted photon must exactly equal the energy lost by the atom.

$$\Delta E_{\text{atom}} = -E_{\text{photon}} = -\frac{hc}{\lambda}$$

The equation includes a negative sign because the atom *loses* energy.

To calculate the energy of a photon, we substitute our data into the equation.

$$h = 6.626 \times 10^{-34} \text{ J s}$$

$$c = 2.998 \times 10^8 \text{ m s}^{-1}$$

$$\lambda = 589 \text{ nm} = 589 \times 10^{-9} \text{ m}$$

$$\Delta E_{\text{atom}} = -E_{\text{photon}} = -\frac{hc}{\lambda}$$

$$= -\frac{(6.626 \times 10^{-34} \text{ J s})(2.998 \times 10^8 \text{ m s}^{-1})}{589 \times 10^{-9} \text{ m}}$$

$$= -3.37 \times 10^{-19} \text{ J}$$

This calculation gives the energy change for one sodium atom emitting one photon. We multiply this value by the Avogadro constant to convert from energy per atom to energy per mole.

$$\Delta E_{\text{mol}} = (\Delta E_{\text{atom}})(N_{\text{A}})$$

$$= (-3.37 \times 10^{-19} \text{ J})(6.022 \times 10^{23} \text{ mol}^{-1})$$

$$= -2.03 \times 10^5 \text{ J mol}^{-1}$$

$$= -203 \text{ kJ mol}^{-1}$$

Remembering that the negative sign simply means that the atom is losing energy, the actual energy released is the absolute value of this, that is, 203 kJ mol^{-1} .

PRACTICE EXERCISE 4.3

Mercury lamps emit photons with a wavelength of 436 nm. Calculate the energy change of the mercury atoms in J atom^{-1} and kJ mol^{-1} .

Atomic spectra

When a light beam passes through a tube containing a gas consisting of atoms of a single element, the atoms absorb specific frequencies of light characteristic of that element. As a result, the beam emerging from the sample tube has fewer photons at these specific frequencies. The frequencies with diminished intensity in the visible portion of the spectrum can be detected by passing the emerging light through a prism. The prism diffracts the light, with different frequencies diffracting through different angles. After leaving the prism, the beam strikes a screen, where the frequencies with diminished intensity appear as gaps or dark bands called ‘lines’, which are images of the slit. These are the frequencies of light absorbed by the atoms in the sample tube. The resulting pattern, shown schematically in figure 4.13, is called an **absorption spectrum**.

FIGURE 4.13

Schematic representation of an apparatus that measures the absorption spectrum of a monatomic gas. The gas in the tube absorbs light at specific wavelengths, called lines, so the intensity of transmitted light is low and, therefore, dark lines appear at these wavelengths.

An absorption spectrum is used to determine the frequencies of the photons that an atom *absorbs*. A similar experiment can be used to measure the energies of the photons *emitted* by atoms in excited states. Figure 4.14 outlines the features of an apparatus that measures these emitted photons. An electrical discharge excites a collection of atoms from their ground state into higher energy states. These excited atoms then lose all, or part of, their excess energy by emitting photons. This emitted light can be analysed by passing it through a prism to give an **emission spectrum**. This is a plot of the intensity of light emitted

as a function of frequency. The emission spectrum for atomic hydrogen, illustrated in figure 4.14, shows several sharp emission lines of high intensity. The frequencies of these lines correspond to photons emitted by the hydrogen atoms as they return to their ground state.

FIGURE 4.14

Schematic representation of an apparatus that measures the emission spectrum of a gaseous element. Emission lines appear bright against a dark background. The spectrum shown is the emission spectrum for hydrogen atoms.

Each element has unique absorption and emission spectra.

Each frequency absorbed or emitted by an atom corresponds to a particular energy change for the atom. These characteristic patterns of energy gains and losses provide information about atomic structure. Figure 4.15 shows the emission spectra for selected atoms.

FIGURE 4.15

Emission patterns for hydrogen, neon, sodium and mercury. Each element has a unique emission pattern that provides valuable clues about its atomic structure.

Quantisation of energy

When an atom absorbs a photon of light of frequency ν , the light beam loses energy equal to $h\nu$, and the atom gains that amount of energy. What happens to the energy that the atom gains? As mentioned earlier, when the frequency of the incoming (or absorbed) light is high enough, it produces cations and free electrons. In other words, a photon with high enough energy can cause an atom to lose one of its electrons, that is, ionise. This implies that absorption of a photon results in an energy gain for an electron in the atom. Stated as an equation:

$$\Delta E_{\text{atom}} = \Delta E_{\text{electron}} = h\nu$$

The atomic spectra of most elements are complex and show little apparent regularity. However, in 1885, the Swiss mathematician and physicist Johann Balmer was able to propose a single equation that could describe the emission spectrum of the hydrogen atom. The equation was as follows.

$$\nu_{\text{emission}} = (3.29 \times 10^{15} \text{ s}^{-1}) \left(\frac{1}{n_1^2} - \frac{1}{n_2^2} \right)$$

In this equation n_1 and n_2 are integers (1, 2, 3 etc.). In 1913, the Danish physicist Niels Bohr used Einstein's postulate ($E = h\nu$) to interpret Balmer's observations. Combining the two equations, Bohr was able to describe the energy levels of the electron in the hydrogen atom with the following equation, where n is a positive integer.

$$E_n = -\frac{2.18 \times 10^{-18} \text{ J}}{n^2}$$

As previously stated, the negative sign in the equation reflects the fact that bound electrons are lower in energy than a stationary free electron (with its energy defined as zero).

Bohr realised that the emission frequencies have specific values because the electron in a hydrogen atom is restricted to specific energies. Bohr's idea of restricted energy levels was revolutionary because scientists at that time thought that the electron in a hydrogen atom could have any energy. In contrast, Bohr interpreted the hydrogen emission spectrum to mean that electrons bound to atoms can have only certain specific energy values. He was awarded the Nobel Prize in physics in 1922 for this interpretation. A property that cannot change continuously, and is restricted to specific values, is said to be **quantised**. The atomic energy levels of hydrogen (and other elements) are quantised. Each integer value of n describes one of the allowed energy levels of the hydrogen atom. For example, the energy of an electron in hydrogen's fourth level is:

$$E_4 = -\frac{2.18 \times 10^{-18} \text{ J}}{4^2} = -1.36 \times 10^{-19} \text{ J}$$

When an electron changes energy levels, the change is an electronic transition between quantised levels. When a hydrogen atom absorbs or emits a photon, its electron moves from one energy level to another. Thus, the change in energy (ΔE) of the atom for this process is the energy difference between the two levels.

$$\Delta E_{\text{atom}} = E_{\text{final}} - E_{\text{initial}}$$

Photons always have positive energies, but energy changes (ΔE) can be positive or negative. When a photon is absorbed, an electron is promoted to a higher energy level, the atom gains energy and ΔE for the atom is positive.

$$E_{\text{absorbed photon}} = \Delta E_{\text{atom}}$$

When a photon is emitted, an electron falls from a higher energy level to a lower one, the atom loses energy and ΔE for the atom is negative.

$$E_{\text{emitted photon}} = -\Delta E_{\text{atom}}$$

We can combine these two equations by using absolute values.

$$E_{\text{photon}} = |\Delta E_{\text{atom}}|$$

WORKED EXAMPLE 4.4

Energy levels of the hydrogen atom

What is the energy change when the electron in a hydrogen atom undergoes a transition from the fourth energy level to the second energy level? What is the wavelength of the photon emitted?

Analysis

The question asks about energy and the wavelength of a photon emitted by a hydrogen atom. Wavelength is related to energy, and photon energy is determined by the difference in energy between the two levels involved in the transition. In this case, the electron moves from the fourth to the second energy level. The energy difference between these two states is given by:

$$\Delta E_{\text{atom}} = E_{\text{final}} - E_{\text{initial}} = E_2 - E_4$$

Solution

As shown above, $E_4 = -1.36 \times 10^{-19} \text{ J}$. A similar calculation gives the energy of the second level.

$$E_2 = -\frac{2.18 \times 10^{-18} \text{ J}}{2^2} = -5.45 \times 10^{-19} \text{ J}$$

This energy change is negative because the atom loses energy. The energy difference between the two levels is:

$$\begin{aligned}\Delta E_{\text{atom}} &= E_{\text{final}} - E_{\text{initial}} \\ &= (-5.45 \times 10^{-19} \text{ J}) - (-1.36 \times 10^{-19} \text{ J}) \\ &= -4.09 \times 10^{-19} \text{ J}\end{aligned}$$

The negative sign for the energy change is consistent with the atom losing energy. This lost energy appears as a photon with energy of:

$$E_{\text{photon}} = |\Delta E_{\text{atom}}| = |-4.09 \times 10^{-19} \text{ J}| = 4.09 \times 10^{-19} \text{ J}$$

To determine the wavelength of the photon, we use:

$$E_{\text{photon}} = h\nu = \frac{hc}{\lambda}$$

Solving for λ gives:

$$\begin{aligned}\lambda_{\text{photon}} &= \frac{hc}{E_{\text{photon}}} = \frac{(6.626 \times 10^{-34} \text{ J s})(2.998 \times 10^8 \text{ m s}^{-1})}{4.09 \times 10^{-19} \text{ J}} \\ &= 486 \times 10^{-9} \text{ m} = 486 \text{ nm}\end{aligned}$$

Is our answer reasonable?

The signs of the energies are consistent — the atom loses energy and the photon emitted has positive energy. From figure 4.5 we can see that light with a wavelength of 486 nm has a blue-green colour. Cross-checking against the emission spectrum of hydrogen (figure 4.15), we can see that it has such a blue-green line. Therefore, we can be confident that our answer is correct.

PRACTICE EXERCISE 4.4

What minimum energy must a photon have to excite a hydrogen atom from its ground state, that is, $n = 1$, to the $n = 4$ level? What is the corresponding wavelength?

Energy level diagrams

Electronic transitions in atoms can be represented using an **energy level diagram** such as the one shown in figure 4.16b. Energy level diagrams are a concise way to summarise information about atomic energies. They show energy along the vertical axis and each energy state of the atom is represented by a horizontal line.

We can begin to understand the quantum levels of an electron bound to an atom by picturing a ball on a staircase. This analogy is illustrated in figure 4.16. A ball may sit on any of the steps. To move a ball from the bottom of the staircase to step 5 requires the addition of a specific amount of energy, $\Delta E = E_5 - E_1$. If too little energy is supplied, the ball cannot reach this step. Conversely, if a ball moves down the staircase, it releases specific amounts of energy. If a ball moves from step 5 to step 3, it loses energy, $\Delta E = E_3 - E_5$. Although a ball may rest squarely on any step, it cannot be suspended between the steps. Electrons in atoms, like balls on steps, cannot exist ‘between steps’, but must occupy one of the specific, quantised energy levels. *Remember that this is an analogy; atomic energy levels are not at all similar to staircases except in being quantised.*

A hydrogen atom has a regular progression of quantised energy levels. Figure 4.17 shows the energy level diagram for hydrogen atoms; arrows represent some of the possible absorption and emission transitions. Notice that the energies of absorption from the lowest energy level are identical to the energies of emission to the lowest energy level. This means that the wavelengths of light absorbed in these upward transitions are identical to the wavelengths of light emitted in the corresponding downward transitions. It is important to note that figures 4.13, 4.14 and 4.15 show only the visible portions of the absorption and emission spectra. Electronic transitions also take place in regions of the electromagnetic spectrum that the human eye cannot detect (as shown in figure 4.17). Instruments allow scientists to observe electromagnetic radiation in these regions.

FIGURE 4.16

(a) A ball on a staircase shows some of the properties of quantised energy levels. (b) Quantised energy levels can be depicted using an energy level diagram. (c) Electronic transitions occur between quantised energy levels through either absorption or emission of photons.

**FIGURE 4.17**

Energy levels for the hydrogen atom and some of the transitions that occur between levels, as well as the resulting emission spectrum. Upward arrows represent absorption transitions, and downward arrows represent emission transitions.

Elements other than hydrogen also have quantised energy levels, but as we will see later in this chapter they cannot be so simply described because they have more than one electron. In these cases, scientists use experimental values for observed absorption and emission lines to calculate the allowed energy levels for each different element.

WORKED EXAMPLE 4.5

Energy level diagrams

Ruby lasers use crystals of Al_2O_3 that contain small amounts of Cr^{3+} ions, which absorb light between 400 and 560 nm. The excited-state ions lose some energy as heat. After losing heat, the Cr^{3+} ions return to the ground state by emitting red light with a wavelength of 694 nm.

- Calculate the energy in kJ mol^{-1} of the 525 nm radiation used to excite the Cr^{3+} ions.
- Calculate the energy in kJ mol^{-1} of the emitted light.
- Calculate the fraction of the excitation energy emitted as red photons and the fraction lost as heat.
- Draw an energy level diagram that summarises these processes.

Analysis

This problem asks about energies and light. With multipart problems, the best strategy is to work through the parts one at a time. Parts (a) and (b) concern the link between light and energy as discussed earlier in this section. Once the transition energies have been determined, we can calculate the fraction of the excited-state energy lost as heat for part (c), and we can also draw an energy level diagram that shows how the levels are related for part (d).

Solution

We solve (a) using the following equations and the Avogadro constant.

$$E_{\text{photon}} = h\nu \quad \text{and} \quad c = \nu\lambda \quad \text{so} \quad E_{\text{photon}} = \frac{hc}{\lambda}$$

$$E_{\text{photon absorbed}} = \frac{(6.626 \times 10^{-34} \text{ J s})(2.998 \times 10^8 \text{ m s}^{-1})}{525 \times 10^{-9} \text{ m}} \\ = 3.78 \times 10^{-19} \text{ J}$$

This is the energy change per ion. To calculate the change per mole, we multiply by the Avogadro constant. We also need to convert from J to kJ.

$$E_{\text{photon absorbed}} = (3.78 \times 10^{-19} \text{ J})(6.022 \times 10^{23} \text{ mol}^{-1}) \\ = 228 \times 10^3 \text{ J mol}^{-1} = 228 \text{ kJ mol}^{-1}$$

Apply the same approach to (b). The result gives the energy of the red photon.

$$E_{\text{photon emitted}} = 172 \text{ kJ mol}^{-1}$$

To solve (c), remember that energy is conserved. The sum of the emitted heat and the emitted photon must equal the energy absorbed by the ion.

$$E_{\text{photon absorbed}} = E_{\text{photon emitted}} + E_{\text{heat emitted}}$$

Because 228 kJ mol^{-1} is absorbed and 172 kJ mol^{-1} is emitted, the fraction of the excitation energy re-emitted is $\frac{172}{228} = 0.754$. The fraction converted to heat is the difference between this value and 1.000, which is 0.246. In other words, 75.4% of the energy absorbed by the chromium ion is emitted as red light, and the other 24.6% is lost as heat.

Part (d) asks for an energy level diagram for this process. The electron starts in the ground state. On absorption of a photon, the electron moves to an energy level that is higher by 228 kJ mol^{-1} . The chromium ion loses 24.6% of its excited-state energy as heat as the electron moves to a level that is 172 kJ mol^{-1} above the ground state. Finally, emission of the red photon returns the Cr^{3+} ion to the ground state. The numerical values allow us to construct an accurate diagram.

Is our answer reasonable?

When Cr^{3+} ions absorb light, they are promoted to an energy level higher than the energy that they later emit. If calculations had shown that the emitted light had a larger energy than the absorbed light, the result would have been unreasonable because the system would violate the law of conservation of energy.

PRACTICE EXERCISE 4.5

After excitation in an electric discharge, an atom of Hg returns to the ground state by emitting two photons with

wavelengths of 436 nm and 254 nm. Calculate the excitation energy of the excited state in kJ mol^{-1} .

4.3 Properties of electrons

LEARNING OBJECTIVE 4.3 Describe the properties of electrons.

The energies of electrons in atoms play a central role in determining chemical behaviour. Several other properties of electrons also influence the physical and chemical characteristics of atoms and molecules. Some properties are characteristic of all electrons, but others arise only when electrons are bound to atoms or molecules. In this section, we describe the properties characteristic of all electrons.

Every electron has a mass of 9.109×10^{-31} kg and a charge of 1.602×10^{-19} C. Electrons have magnetic properties that arise from a property called spin, which we met briefly in the introductory chapter on the atom and will describe in more detail in section 4.4.

The French physicist Louis de Broglie (1892–1987; Nobel Prize in physics, 1929) was the first to suggest that, like photons, electrons also display wave–particle duality, which means that they have both particle and wave properties. Experiments have shown that a beam of light shining on an object exerts a pressure, which implies that a photon has momentum. Quantitative measurements of the pressure exerted by light showed that a simple equation relates the momentum of light (p) to its energy.

$$E = pc$$

As we have already described, light energy is also related to its wavelength.

$$E = h\nu = \frac{hc}{\lambda}$$

Combining these two energy expressions gives an expression relating p to λ .

$$pc = \frac{hc}{\lambda}$$

The speed of light cancels, leaving an equation that de Broglie suggested should apply to electrons and other particles as well as to photons.

$$p = \frac{h}{\lambda}$$

The momentum of a particle is the product of its mass and velocity (u).

$$p = mu$$

Substituting this and solving for λ gives a form of the de Broglie equation that links the wavelength of a particle with its mass and velocity.

$$\lambda_{\text{particle}} = \frac{h}{mu}$$

De Broglie's theory predicted that electrons are wave-like. How might this prediction be confirmed? Figure 4.18 shows examples of the characteristic intensity patterns displayed by waves. In figure 4.18a, water waves radiate away from two bobbing floats and form a standing pattern. In figure 4.18b, diffracted X-rays form a similar wave pattern. High-energy photons have passed through the regular array of atoms in a crystal, whose electron clouds scatter the photon waves. If electrons have wave properties, they should display regular wave patterns like these.

In 1927, American physicists Clinton Davisson and Lester Germer, and British physicist George Thomson, separately carried out experiments in which they exposed metal films to electron beams with well-defined kinetic energies. Both experiments generated patterns like those shown in figure 4.18b, confirming the validity of the de Broglie equation for electron wavelengths. This established the wave nature of electrons. Davisson and Thomson were awarded the Nobel Prize in physics in 1937 for this discovery.

In recent years, scanning tunnelling electron microscopes have produced images of electron waves, an example of which appears in figure 4.18c. Here, two atoms on an otherwise smooth metal surface act like the floats in figure 4.18a, and cause the electrons in the metal to set up a standing wave pattern.

Both photons and electrons have wave and particle properties, but different equations describe their properties. Table 4.1 summarises the properties of photons and free electrons.

The de Broglie equation predicts that every particle has wave characteristics. The wave properties of subatomic particles such as electrons and neutrons play important roles in their behaviour, but for larger objects, such as table tennis balls or cars, they do not. The reason is the scale of the waves. For all except subatomic particles, the wavelengths involved are so short that we are unable to detect the wave properties.

FIGURE 4.18

Examples of wave patterns. (a) Floats produce standing water waves. (b) X-rays generate wave interference patterns. (c) Protruding atoms on a metal surface generate standing electron waves.

(a)

(b)

(c)

TABLE 4.1 Equations for photons and free electrons

Property	Photon equation	Electron equation
energy	$E = h\nu$	$E_{\text{kinetic}} = \frac{1}{2}mu^2$
wavelength	$\lambda = \frac{hc}{E}$	$\lambda = \frac{h}{mu}$
speed	$c = 2.998 \times 10^8 \text{ m s}^{-1}$	$u = \sqrt{\frac{2E_{\text{kinetic}}}{m}}$

h : Planck's constant; ν : frequency; m : mass; u : velocity

WORKED EXAMPLE 4.6**Wavelengths**

The structure of a crystalline material can be studied by observing the wave interference patterns that result from passing particle-waves through a crystal. To generate well-defined patterns, the wavelength of the particle-wave must be similar to the distances between atoms in the crystal. Determine the energy of a photon particle-wave beam with a wavelength of 0.25 nm and the energy of an electron particle-wave beam with this wavelength.

Analysis

This problem has two parts, one dealing with photons and the other with electrons. We are asked to relate the wavelengths of the particle-waves to their corresponding energies. Table 4.1 emphasises that photons and electrons have different relationships between energy and wavelength. Thus, we use different equations for the two calculations.

Solution

Photon energy is given by $E = h\nu = \frac{hc}{\lambda}$. We substitute and evaluate, being careful with units.

$$E_{\text{photon}} = \frac{(6.626 \times 10^{-34} \text{ J s})(2.998 \times 10^8 \text{ m s}^{-1})}{0.25 \times 10^{-9} \text{ m}} = 7.9 \times 10^{-16} \text{ J}$$

For an electron, we need to work with two equations. The de Broglie equation links the velocity of an electron with its wavelength.

$$\lambda_{\text{particle}} = \frac{h}{mu}$$

The kinetic energy equation links the velocity of an electron with its kinetic energy.

$$E_{\text{kinetic}} = \frac{1}{2}mu^2$$

Begin by determining the velocity of the electron, recalling from the chapter on the language of chemistry that $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$.

$$u_{\text{electron}} = \frac{h}{m\lambda} = \frac{6.626 \times 10^{-34} \text{ kg m}^2 \text{ s}^{-1}}{(9.109 \times 10^{-31} \text{ kg})(0.25 \times 10^{-9} \text{ m})} = 2.91 \times 10^6 \text{ m s}^{-1}$$

Next, use the velocity to find the kinetic energy of the electron.

$$E_{\text{kinetic}} = \frac{1}{2}mu^2 = \frac{(9.109 \times 10^{-31} \text{ kg})(2.91 \times 10^6 \text{ m s}^{-1})^2}{2} = 3.9 \times 10^{-18} \text{ kg m}^2 \text{ s}^{-2} = 3.9 \times 10^{-18} \text{ J}$$

Is our answer reasonable?

The energy of the photon is higher than the kinetic energy of the electron, which is reasonable since the electron has a mass.

PRACTICE EXERCISE 4.6

In a photoelectric-effect experiment, a photon with an energy of 1.25×10^{-18} J is absorbed, causing the ejection of

an electron with a kinetic energy of 2.5×10^{-19} J. Calculate the wavelength (in nm) associated with each.

WORKED EXAMPLE 4.7

Matter waves

Calculate the wavelengths of an electron travelling at 1.00×10^5 m s⁻¹ and a table tennis ball with a mass of 12 g travelling at 2.3 m s⁻¹.

Analysis

This problem deals with particle–waves that have mass. The de Broglie equation relates the mass and speed of an object to its wavelength.

Solution

For the electron:

$$m_{\text{electron}} = 9.109 \times 10^{-31} \text{ kg}, u = 1.00 \times 10^5 \text{ m s}^{-1}$$

$$\lambda_{\text{electron}} = \frac{h}{mu} = \frac{6.626 \times 10^{-34} \text{ kg m}^2 \text{ s}^{-1}}{(9.109 \times 10^{-31} \text{ kg})(1.00 \times 10^5 \text{ m s}^{-1})} = 7.27 \times 10^{-9} \text{ m}$$

For the table tennis ball:

$$m_{\text{ball}} = 12 \text{ g}, u = 2.3 \text{ m s}^{-1}$$

$$\lambda_{\text{ball}} = \frac{h}{mu} = \frac{6.626 \times 10^{-34} \text{ kg m}^2 \text{ s}^{-1}}{(12 \times 10^{-3} \text{ kg})(2.3 \text{ m s}^{-1})} = 2.4 \times 10^{-32} \text{ m}$$

Is our answer reasonable?

The wavelength of the electron is in the order of the atomic size, which is consistent with the fact that electrons have particle–wave duality. The wavelength of the table tennis ball is extremely small, which is expected as we do not observe wave characteristics for the table tennis ball.

PRACTICE EXERCISE 4.7

Calculate the wavelength associated with a proton that is moving at a speed of 2.85×10^5 m s⁻¹.

The Heisenberg uncertainty principle

A particle occupies a particular location, but a wave has no exact position. A wave extends over some region of space. Because of their wave properties, electrons are always spread out rather than located in one particular place. As a result, *the position of a moving electron cannot be precisely defined*.

Mathematically, the position and momentum of a particle–wave are linked. Werner Heisenberg (1901–1976; Nobel Prize in physics, 1932), a German physicist, showed in the 1920s that the momentum and position of a particle–wave cannot be simultaneously determined. If a particular particle–wave can be pinpointed in a specific location, its momentum cannot be known accurately. Conversely, if the momentum of a particle–wave is known precisely, its location cannot be identified. Heisenberg summarised this uncertainty in what has become known as the **uncertainty principle**: the more accurately we know position, the more uncertain we are about momentum, and vice versa. Uncertainty is a feature of all objects, but it becomes important only for very tiny objects like electrons.

4.4 Quantisation and quantum numbers

LEARNING OBJECTIVE 4.4 Explain the properties of bound electrons.

The properties of electrons mentioned so far (mass, charge, spin and wave nature) apply to all electrons. Electrons travelling freely in space, electrons moving in a copper wire and electrons bound to atoms all have these characteristics. Bound electrons, those held in a specific region of an atom by electrostatic forces, have additional important properties relating to their energies and the shapes of their waves. These additional properties can have only certain specific values; that is, they are quantised.

As described in section 4.2, atoms of each element have unique, quantised electronic energy levels (see figures 4.16 and 4.17). This quantisation of energy is a property of bound electrons. The absorption and emission spectra of atoms consist of specific discrete energies because electrons undergo transitions

from one bound state to another. In contrast, if an atom absorbs enough energy to remove an electron completely, the electron is no longer bound and can take on any amount of kinetic energy. *Bound* electrons have quantised energies; *free* electrons can have any amount of energy.

Experimental values for the quantised energies of atomic electrons can be calculated from absorption and emission spectra. The theory of quantum mechanics provides a mathematical explanation that links quantised energies to the wave characteristics of electrons. These wave properties of atomic electrons are described by the Schrödinger equation below, where $\hat{H}$ is the Hamiltonian operator for the system (containing terms for the kinetic and potential energy), E is the energy of the system and ψ is the wavefunction for the system.

$$\hat{H}\psi = E\psi$$

In particular, ψ is the amplitude of the electron's matter wave. As with light, the amplitude itself does not have any physical meaning, but its square represents the electron density distribution or probability of finding an electron. A wavefunction is a mathematical function that gives us information about an electron's position in an atom. The solution of the Schrödinger equation gives us both the energies and the associated wavefunctions of a chemical system. Despite its concise form, the Schrödinger equation can be solved *exactly* only for systems containing one electron.

The Schrödinger equation has solutions only for specific, quantised energy values. For each quantised energy value, the Schrödinger equation generates a wavefunction that describes how the electrons are distributed in space. A one-electron wavefunction is called an **atomic orbital**. We will describe the properties of atomic orbitals in section 4.5.

Each described property can be identified, or indexed, using a **quantum number**. These are numbers that specify the values of the electron's quantised properties. Each electron in an atom has three quantum numbers that specify its three variable properties: energy (or orbital size), angular momentum (or orbital shape) and orbital orientation. A fourth quantum number describes the spin of an electron. To describe an atomic electron completely, chemists specify a value for each of its four quantum numbers: the principal quantum number, azimuthal quantum number, magnetic quantum number and spin quantum number.

Principal quantum number (n)

The most important quantised property of an atomic electron is its energy. The quantum number that indexes energy for an atom or ion containing only a single electron is the **principal quantum number (n)**.

For the simplest atom, hydrogen, we can use $E_n = \frac{-2.18 \times 10^{-18} \text{ J}}{n^2}$ to calculate the energy of the electron if we know n (as seen in section 4.2). However, that equation applies only to the hydrogen atom and, in slightly modified form, to other one-electron systems such as He^+ and Li^{2+} .

No known equation provides the exact energies of an atom that has more than one electron. Nevertheless, each electron in a multi-electron atom can be assigned a value of n that is a positive integer and which broadly correlates with the energy of the electron. The lowest energy for an atomic electron corresponds to $n = 1$, and each successively higher value of n describes a higher energy state. *The principal quantum number must be a positive integer: $n = 1, 2, 3$ etc.*

The principal quantum number also tells us something about the size of an atomic orbital, because the energy of an electron is correlated with its distribution in space. The higher the principal quantum number, the more energy the electron has and the greater its average distance from the nucleus.

In summary, the principal quantum number (n) can have any positive integer value. It indexes the energy of the electron and is correlated with orbital size. As n increases, the energy of the electron increases, its orbital gets bigger and the electron is less tightly bound to the atom.

Azimuthal quantum number (l)

A second quantum number indexes the angular momentum of an atomic orbital. This quantum number is the **azimuthal quantum number (l)**. The solutions for the Schrödinger equation and experimental evidence show that the electron distribution associated with orbitals can be described by a variety of shapes. Note that it is technically incorrect to talk about the 'shape' of an orbital itself. An orbital is a mathematical function that describes the amplitude of an electron's three-dimensional matter wave. Because the amplitude can fluctuate between positive and negative values (just like any other wave), it has no physical meaning by itself. We can, however, talk about the shape of the electron distribution associated with a particular orbital, and this tells us where we are most likely to find an electron within this orbital.

We can categorise the shapes of objects, such as the soccer ball, rugby ball and four-leaf clover shown in figure 4.19, according to their preferred axes. A preferred axis is a line through the centre of mass of an object or shape, about which the shape can be aligned or distributed. A soccer ball has no preferred axis because its mass is distributed equally in all directions about its centre. A rugby ball has one preferred axis, with more mass along this axis than in any other direction. A four-leaf clover has two preferred axes, at right angles to each other. In an analogous fashion, electron density in an orbital can be concentrated along preferred axes.

FIGURE 4.19

Some everyday objects have their masses concentrated along preferred axes. A soccer ball has no such axis, but a rugby ball has one and a four-leaf clover has two.

The value of l correlates with the number of preferred axes of a particular orbital and thereby identifies the shape of the electron distribution for that orbital. According to quantum theory, these shapes are highly restricted. These restrictions are linked to energy, so the value of the principal quantum number (n) limits the possible values of l . The smaller the value of n is, the more compact the orbital and the more restricted its possible electron distributions. *The azimuthal quantum number (l) can be zero or any positive integer smaller than n : $l = 0, 1, 2, \dots, (n - 1)$; that is, there are n values of l .*

Historically, orbitals have been identified with letters rather than numbers. These letter designations correspond to the values of l as shown below.

Value of l	0	1	2	3	4
Orbital designation	s	p	d	f	g

An orbital is named by listing the numerical value for n , followed by the letter that corresponds to the numerical value for l . Thus, a $3s$ orbital has quantum numbers $n = 3, l = 0$. A $5f$ orbital has $n = 5, l = 3$. Notice that the restrictions on l mean that, when $n = 1$, l can only be zero. In other words, $1s$ orbitals exist, but there are no $1p, 1d, 1f$ or $1g$ orbitals. Similarly, there are $2s$ and $2p$ orbitals but no $2d, 2f$ or $2g$ orbitals.

Magnetic quantum number (m_l)

A sphere has no preferred axis, so it has no directionality in space. When there is a preferred axis, as for a rugby ball, figure 4.20 shows that the axis can point in many different directions relative to an xyz coordinate system. Thus, objects with preferred axes have directionality as well as shape.

FIGURE 4.20

A rugby ball has directionality and shape. The figure shows three of the many ways in which a rugby ball can be oriented relative to a set of x, y and z axes.

The electron distribution within an s orbital is spherical and has no directionality. Electron distributions in other orbitals are non-spherical and therefore have a directional dependence. Like energy and orbital electron distribution, this directional dependence is quantised. Unlike rugby balls, the electron distributions within p, d and f orbitals have restricted numbers of possible orientations. The **magnetic quantum number (m_l)** indexes these restrictions.

The number of preferred axes (l) limits the possible orientations of the preferred axes (m_l). When $l = 0$, there is no preferred axis and therefore no preferred orientation, so $m_l = 0$ for s orbitals. One preferred axis ($l = 1$) can orient in any of three directions, giving three possible values for m_l : $+1, 0$ and -1 . Two preferred axes ($l = 2$) can orient in any of five ways, giving five possible values for m_l : $+2, +1, 0, -1$

and -2 . Each time l increases in value by one unit, two additional values of m_l become possible, and the number of possible orientations increases by two. The magnetic quantum number (m_l) can be any positive or negative integer between 0 and l : $m_l = 0, \pm 1, \pm 2, \dots, \pm l$; that is, there are $(2l + 1)$ values of m_l .

Spin quantum number (m_s)

All electrons have a property called **spin**. When a beam of silver atoms is passed through a magnetic field (similar to the experiment carried out by Otto Stern and Walter Gerlach in 1921, see figure 4.21), the atom beam is split, some atoms are deflected in one direction and the rest are deflected in the opposite direction. Since classical physics associates a spinning electric charge with a magnetic field, the experimental observation was explained by the Dutch physicists George Uhlenbeck and Samuel Goudsmit with a property they called electron spin. (Note: There is no physical evidence that an electron actually spins.) The fact that only two responses are observed demonstrates that spin is quantised. The **spin quantum number** (m_s) indexes this behaviour. The two possible values of m_s are $+\frac{1}{2}$ and $-\frac{1}{2}$.

FIGURE 4.21 Schematic diagram of the set-up for the Stern–Gerlach magnetic field experiment

The Pauli exclusion principle

A complete description of an atomic electron requires a set of four quantum numbers: n , l , m_l and m_s , which must meet all the restrictions mentioned earlier and summarised in table 4.2. In addition, no two electrons in an atom can have exactly the same set of quantum numbers; that is, each electron in an atom has a unique set of quantum numbers. This was first postulated by the Austrian physicist Wolfgang Pauli (1900–1958, Nobel Prize in physics, 1945) and is known as the **Pauli exclusion principle**. The principle is derived from quantum mechanics and supported by all experimental evidence.

TABLE 4.2 Restrictions on quantum numbers for electrons in atoms

Quantum number	Restrictions	Range
n	positive integers	$1, 2, \dots, \infty$
l	positive integers less than n	$0, 1, \dots, (n - 1)$
m_l	integers between $-l$ and l	$-l, \dots, -1, 0, +1, \dots, +l$
m_s	$-\frac{1}{2}$ or $+\frac{1}{2}$	$-\frac{1}{2}, +\frac{1}{2}$

The number of possible sets of quantum numbers increases rapidly as n increases. An atomic orbital is designated by its n and l values, such as $1s$, $3d$, $4p$ and so on. When $l > 0$, there is more than one orbital of each designation; that is, when $l = 1$, there are three p orbitals and for $l = 2$ there are five d orbitals.

An electron in any orbital can have a spin quantum number (m_s) of either $+\frac{1}{2}$ or $-\frac{1}{2}$. Thus, there are many sets of valid quantum numbers. An electron in a $3p$ orbital, for example, can have any one of six valid sets of quantum numbers.

$$\begin{array}{ll}
 n = 3, l = 1, m_l = +1, m_s = +\frac{1}{2} & n = 3, l = 1, m_l = +1, m_s = -\frac{1}{2} \\
 n = 3, l = 1, m_l = 0, m_s = +\frac{1}{2} & n = 3, l = 1, m_l = 0, m_s = -\frac{1}{2} \\
 n = 3, l = 1, m_l = -1, m_s = +\frac{1}{2} & n = 3, l = 1, m_l = -1, m_s = -\frac{1}{2}
 \end{array}$$

A direct consequence of the Pauli exclusion principle is that any orbital can contain a maximum of two electrons (we say that an orbital containing two electrons is full) and that the two electrons in a full orbital must be of opposite spin.

WORKED EXAMPLE 4.8

Valid quantum numbers

How many valid sets of quantum numbers exist for 4d electrons? Give two complete examples.

Analysis

The question asks for the sets of quantum numbers that have $n = 4$ and $l = 2$. Each set must meet all the restrictions listed in table 4.2. The easiest way to see how many valid sets there are is to list all the valid quantum numbers.

Solution

Because this is a 4d orbital, n and l are specified and cannot vary. The other two quantum numbers, however, have several acceptable values. For each value of m_l , either value of m_s is acceptable, so the total number of possibilities is the product of the number of possible values for each quantum number. This is shown below.

Quantum number	N	l	m_l	m_s
Possible values	4	2	2, 1, 0, -1, -2	$+\frac{1}{2}, -\frac{1}{2}$
Number of possible values	1	1	5	2

Possible sets of values for a 4d electron: $(1)(1)(5)(2) = 10$

There are 10 sets of quantum numbers that can describe a 4d electron. Two of them are shown below.

$$n = 4, l = 2, m_l = 1, m_s = +\frac{1}{2}$$

$$n = 4, l = 2, m_l = -2, m_s = -\frac{1}{2}$$

You should be able to list the other eight sets.

Is our answer reasonable?

If you write down all the possible sets, you will find that there are 10. Notice that there are always $2l + 1$ possible values of m_l and 2 possible values of m_s , so every nd set of electrons has 10 possible sets of quantum numbers.

PRACTICE EXERCISE 4.8

Write all the valid sets of quantum numbers of the 5p electrons.

4.5 Atomic orbital electron distributions and energies

LEARNING OBJECTIVE 4.5 Describe atomic orbitals in terms of electron distributions and energies.

The chemical properties of atoms are determined by the behaviour of their electrons. Because atomic electrons are described by atomic orbitals, the interactions of electrons can be described in terms of orbital interactions. The two characteristics of orbitals that determine how they interact are their electron distributions in three-dimensional space and their energies.

Atomic orbital electron distributions

Wave-like properties cause electrons to be smeared out rather than localised at an exact position. This smeared-out distribution can be described using electron density. Where electrons are most likely to be found, there is high electron density. Low electron density occurs in regions where electrons are less likely

to be found. Each electron, rather than being a point charge, is a three-dimensional particle–wave that is distributed over space as an orbital. Orbitals describe the delocalisation of electrons. Moreover, when the energy of an electron changes, the size and shape of its distribution in space change as well. Each atomic energy level is associated with a specific three-dimensional atomic orbital.

An atom that contains many electrons can be described by superimposing (adding together) the orbitals for all of its electrons to obtain the overall size and ‘shape’ of the atom.

The quantum numbers n and l determine the size and electron distribution of an orbital. As n increases, the size of the orbital increases, and, as l increases, the electron distribution of the orbital becomes more elaborate. Orbitals can have nodal planes or radial nodes, and the number of these depends on n and l ; that is, for every orbital, there are $n - 1$ nodes, of which l are nodal planes and the remainder are spherical (radial) nodes.

Orbital depictions

We need ways to visualise electrons as particle–waves delocalised in three-dimensional space. Orbital pictures provide maps of how an electron wave is distributed in space. There are several ways to represent these three-dimensional maps. Each one shows some important orbital features, but none shows all of them. We use three different representations: radial distribution function plots, electron density pictures and boundary surface diagrams.

A **radial distribution function plot** represents the electron distribution in an orbital as a two-dimensional graph. These graphs show the probability distribution of finding an electron at a certain distance from the nucleus, r . Figure 4.22a shows a radial distribution function plot for the 2s orbital.

Radial distribution function plots are useful because plots for several orbitals can be superimposed to indicate the relative sizes of various orbitals. They do not, however, show the three-dimensionality of an orbital.

Electron density pictures can indicate the three-dimensional nature of orbitals. One type of orbital picture is a two-dimensional colour pattern in which the density of the colour represents electron density. Figure 4.22b shows such an electron density picture of the 2s orbital. This two-dimensional pattern of colour density shows a cross-sectional slice through the middle of the orbital. Figures 4.22a and 4.22b show that the 2s orbital has one spherical node.

A **boundary surface diagram** provides a simplified orbital picture. In this representation, we draw a solid surface that encloses most (usually 90%) of the electron density. Thus, the electron density is high inside the boundary surface but very low outside. Figure 4.22c shows a boundary surface diagram of the 2s orbital. One drawback of boundary surface diagrams is that they do not show details of electron density below the surface, including spherical nodes. They do, however, show all planar nodes, and from those it is possible to deduce the number of hidden spherical nodes.

A useful analogy for understanding the value of boundary surfaces is a swarm of bees around a hive. At any one time, some bees will be off foraging for nectar, so a boundary surface drawn around all the bees might cover several hectares. This would not be a very useful map of bee density. A boundary surface containing 90% of the bees, on the other hand, would be only slightly bigger than the hive itself. This

FIGURE 4.22

Different depictions of the 2s orbital. (a) A plot of the probability of finding the electron a certain distance from the nucleus. (b) An electron density picture. (c) A boundary surface diagram.

would be a very useful map of bee density, because anyone inside that boundary surface would surely interact with bees.

The advantages and disadvantages of the three types of plots can be seen by how they show one characteristic feature of orbitals. Figure 4.22a shows clearly that there is a value for where the probability of finding the electron falls to zero. A place where this probability (the radial distribution function) is zero is called a **node**. Figure 4.22b shows the node for the $2s$ orbital as a white ring. In three dimensions, this node is a spherical surface. Figure 4.22c does not show the node, because the spherical nodal surface is hidden inside the 90% boundary surface. The two-dimensional graph shows the location of the node most clearly, the electron density picture gives the best sense of the shape of the node, while the boundary surface diagram provides the best three-dimensional view of an orbital. Thus, if we want to convey the maximum information about orbitals, we must use combinations of the various depictions.

Orbital size

Experiments that determine atomic radii provide information about the sizes of orbitals. In addition, theoretical models of the atom can predict how the electron density of a particular orbital changes with distance from the nucleus.

In any particular atom, orbitals get larger as the value of n increases. The $n = 2$ orbitals are larger than the $n = 1$ orbital, the $n = 3$ orbitals are larger than the $n = 2$ orbitals, and so on. The plots of the radial distribution functions in figure 4.23 show this trend for the first three s orbitals of the hydrogen atom. This plot also shows that the number of nodes increases as n increases.

FIGURE 4.23

Radial distribution function plots for the $1s$, $2s$ and $3s$ atomic orbitals of the hydrogen atom. The vertical lines indicate the values of r where the 90% boundary surface would be located.

In any particular atom, all orbitals with the same principal quantum number are similar in size. As an example, figure 4.24 shows that the $n = 3$ orbitals of the copper atom have their maximum probability of finding an electron at similar distances from the nucleus. The same regularity holds for all other atoms. The quantum numbers other than n affect orbital size only slightly. We describe these small effects in the context of orbital energies later in this section.

FIGURE 4.24

Radial distribution function plots for the $3s$ (red line), $3p$ (blue line), and $3d$ (green line) orbitals for the copper atom. All three orbitals are nearly the same size.

A specific orbital becomes smaller as the atomic nuclear charge increases. As the positive charge of the nucleus increases, the electrostatic force exerted by the nucleus on the negatively charged electrons increases and electrons become more tightly bound. This reduces the radius of the orbital. As a result, each orbital shrinks in size as atomic number increases. For example, figure 4.25 shows that the 2s orbital steadily decreases in size across the second row of the periodic table from Li ($Z = 3$) to Ne ($Z = 10$). The atomic number, Z , is equal to the number of protons in the nucleus, so increasing Z means increasing nuclear charge.

Details of orbital electron distributions

The shapes and orientations of orbitals strongly influence chemical interactions. Hence, we need to have detailed pictures of these electron distributions to understand the chemistry of the elements.

The quantum number $l = 0$ corresponds to an s orbital. According to the restrictions on quantum numbers, there is only one s orbital for each value of the principal quantum number. The electron distribution of s orbitals is spherical, as we have seen in figure 4.22c, with radii and number of nodes that increase as n increases.

We introduced the concept of the phase of a wave in section 4.2, and this concept also applies to orbitals. An s orbital has a single phase, which we refer to as either positive (+) or negative (−). We generally depict different phases using + and − signs superimposed on the orbital electron distribution, or by using different colours corresponding to + and − phases.

The quantum number $l = 1$ corresponds to a p orbital. An electron in a p orbital can have any of three values for m_l , so for each value of n there are three different p orbitals. Figure 4.26 shows boundary surface diagrams of the $2p$ orbitals. The three different orbitals can be represented so that each has its electron density concentrated on both sides of the nucleus along a preferred axis, perpendicular to the other two orbitals. We can write subscripts on the orbitals to distinguish the three distinct orientations: p_x , p_y and p_z . Each p orbital also has a nodal plane that passes through the nucleus. The nodal plane for the p_x orbital is the yz plane, for the p_y orbital the nodal plane is the xz plane and for the p_z orbital it is the xy plane. The two lobes of a single p orbital have opposite phases; this is shown in figure 4.26 by using a different colour for each lobe.

FIGURE 4.25

The radius of the 2s orbital decreases as Z increases. The number at the bottom of each column is the radius of the 2s orbital in picometres (pm).

FIGURE 4.26

Boundary surface diagrams of the three $2p$ orbitals. The three orbitals have the same overall electron distribution, but each is oriented perpendicular to the other two. The nodal plane in each case is illustrated by the grey hatched surface.

As n increases, the number of nodes within each p orbital increases, just as for s orbitals. Nevertheless, the directionality of the electron distribution does not change. Each p orbital is perpendicular to the other two in its set and has its lobes along its preferred axis, where electron density is high. To an approaching

atom, therefore, an electron in a $3p$ orbital presents the same characteristics as one in a $2p$ orbital, except that the $3p$ orbital is bigger. Consequently, the electron distributions and relative orientations of the $2p$ orbitals in figure 4.26 represent the prominent spatial features of all p orbitals.

The quantum number $l = 2$ corresponds to a d orbital. An electron in a d orbital can have any of five values for m_l ($-2, -1, 0, +1$ and $+2$), so there are five different orbitals in each set. Each d orbital has two nodal planes. Consequently, the electron distributions of the d orbitals are more complicated than their s and p counterparts. The boundary surface diagrams in figure 4.27 show these orbitals in the most convenient way. In these drawings, three orbitals have electron distributions that look like three-dimensional ‘clover leaves’ lying in a plane with the lobes pointed between the axes. A subscript identifies the plane in which each lies: d_{xy} , d_{xz} and d_{yz} . A fourth orbital has an electron distribution that is a cloverleaf in the xy plane, but its lobes point along the x and y axes. This orbital is designated $d_{x^2 - y^2}$. In each of these ‘cloverleaf’ orbitals, the lobes situated opposite each other have the same phases, as shown in figure 4.27. The electron distribution in the fifth orbital is quite different. Its major lobes point along the z -axis, but there is also a ‘doughnut’ of electron density in the xy plane. This orbital is designated d_{z^2} . The two lobes have the same phase, while the ‘doughnut’ is of opposite phase.

FIGURE 4.27

Boundary surface diagrams of the d orbitals. Four of the five have the same cloverleaf shape with two nodal planes at right angles to each other. The d_{z^2} orbital has the z -axis as its preferred axis. It has two nodes that are shaped like cones, one above and one below the xy plane.

The quantum number $l = 3$ corresponds to an f orbital. The possible values of m_l ($-3, -2, -1, 0, +1, +2$ and $+3$) mean that there are seven f orbitals, but as they become important only for the lanthanoid elements and beyond, we will not detail their properties here.

Orbital energies

A hydrogen atom can absorb a photon and change from its most stable, lowest energy state (ground state) to a less stable, higher energy state (excited state), as described in section 4.2. We can explain this process using atomic orbitals. When a hydrogen atom absorbs a photon, its electron can undergo a transition to an orbital that has a larger principal quantum number, that is, a higher energy. Figure 4.28 illustrates this process for the $1s \rightarrow 2p$ transition in the hydrogen atom.

Electronic transitions cannot necessarily occur between any set of orbitals; in the hydrogen atom, and other one-electron systems, they are governed by the following selection rules.

1. $\Delta n = \text{any value}$. There is no restriction on the values of the initial and final principal quantum numbers.
2. $\Delta l = \pm 1$. The azimuthal quantum number must increase or decrease by 1. This means that we cannot have a transition from an s orbital to another s orbital, or from a p orbital to another p orbital.
3. $\Delta m_l = 0, \pm 1$. The magnetic quantum number may stay the same, or it can increase or decrease by 1.

The atomic orbital model explains the spectra and energy levels of the hydrogen atom perfectly. For a one-electron system like the hydrogen atom, the energy levels for all orbitals depend only on the principal quantum number, n . All orbitals having the same value of n have the same energy and are said to be **degenerate**. For multi-electron systems, experiments show that the underlying principles are the same, although the details for each kind of atom are different. Variations in nuclear charge and the number of electrons change the magnitudes of the electrical forces which causes changes in orbital energies that can be understood qualitatively using forces of electrical attraction and repulsion, as we describe later in this chapter. As a consequence, the degeneracy of orbitals for each level of n is partially removed.

FIGURE 4.28

When a hydrogen atom in its ground state absorbs light of wavelength 121.6 nm, it is converted to an excited state, in which the electron occupies a 2*p* orbital.

The effect of nuclear charge

A helium +1 cation, like a hydrogen atom, has one electron. Absorption and emission spectra show that He^+ has energy levels that depend on n only, just like those of the hydrogen atom. Nevertheless, figure 4.29 shows that the emission spectra of He^+ and H differ, which means that these two species must have different energy levels. We conclude that something besides n influences orbital energy.

The difference between He^+ and H is in their nuclei. A hydrogen nucleus is a single proton with a +1 charge, whereas a helium nucleus contains two protons (and two neutrons) and has a charge of +2. The larger nuclear charge of He^+ attracts its single electron more strongly than the smaller charge of H. As a result, He^+ binds the electron with a stronger force. Thus, any given energy level in the helium ion is lower in energy than the corresponding level in the hydrogen atom.

The energy of an orbital can be determined by measuring the amount of energy required to remove an electron completely from that orbital. This is the **ionisation energy (E_i)**.

The ionisation energy of He^+ is four times that of H. Thus, the ground state orbital for He^+ must be four times lower in energy than the ground state orbital for H. Spectral analysis shows that each orbital of a helium cation is four times lower in energy than its counterpart orbital in a hydrogen atom, showing that orbital energy depends on Z^2 in a one-electron system. While the energy levels in H and He^+ are different for corresponding orbitals due to the Z^2 relationship, there are some orbital energies that coincide and hence we can get emission energies that are identical for both species. The emission lines at 656.2 nm in figure 4.29, for example, are due to the transitions from $n=3$ to 2 and $n=6$ to 4 for H and He, respectively.

Figure 4.30 shows the relationship between the energy levels of He^+ and H. The diagram is in exact agreement with calculations based on the Schrödinger equation.

FIGURE 4.29

The emission spectra of He^+ and H reveal transitions at characteristic energies. Most of the emitted photons have different energies because He^+ has quantised energy levels that are different from those of H.

The effect of other electrons

A hydrogen atom or a helium cation are rare examples of one-electron systems; most other atoms and ions contain collections of electrons. In a multi-electron atom, electrons affect each other's properties. These electron–electron interactions make the orbital energies of every element unique.

A given orbital is of higher energy in a multi-electron atom than it is in the single-electron ion with the same nuclear charge. For instance, figure 4.31 shows that it takes more than twice as much energy to remove the electron from He^+ (one electron) as it does to remove one of the electrons from a neutral He atom (two electrons).

FIGURE 4.30

An energy level diagram for He^+ and H. Each species has one electron, but the different nuclear charges make each He^+ orbital four times lower in energy than the corresponding H orbital.

FIGURE 4.31

Ionisation energies

This demonstrates that the $1s$ orbital in He^+ is more than two times lower in energy than the $1s$ orbital in neutral He. The nuclear charge of both species is $+2$, so the smaller ionisation energy for He must result from the presence of the second electron. A negatively charged electron in a multi-electron atom is attracted to the positively charged nucleus, but it is repelled by the other negatively charged electrons. This electron–electron repulsion contributes to the lower ionisation energy of the helium atom.

Shielding

Figure 4.32 shows a free electron approaching a He^+ cation. The $+2$ charge of the nucleus attracts the incoming electron, but the negative charge of the He^+ $1s$ electron repels it. As electrons have a like charge, electron–electron repulsion cancels a portion of the attraction between the nucleus and the incoming electron. Chemists call this partial cancellation **shielding**.

FIGURE 4.32

As a free electron approaches a He^+ cation, it is attracted to the $+2$ charge on the nucleus but repelled by the -1 charge on the $1s$ electron. When it is far from the cation, the free electron experiences a net charge of $+1$.

With its -1 charge, a bound electron could reduce the total charge by a maximum of 1 charge unit. Indeed, when an approaching electron is far enough away from a He^+ ion, it feels an attraction due to the net charge on the ion, $+1$. However, the $1s$ orbital is spread out all around the nucleus. This means that, as an approaching electron gets close enough, the $1s$ electron shields a smaller part of the total nuclear charge. Consequently, an approaching electron is subject to a net attraction resulting from some **effective nuclear charge** (Z_{eff}) less than $+2$ but greater than $+1$.

Incomplete shielding can be seen in the ionisation energies of hydrogen atoms, helium atoms and helium ions (see figure 4.31). Without shielding, the ionisation energy of a helium atom would be the same as that of a helium ion; both would be $8.72 \times 10^{-18} \text{ J}$. With *complete* shielding, one helium electron would compensate for one of the protons in the nucleus, making $Z_{\text{eff}} = +1$. The energy required to remove an electron from a helium atom would then be the same as the energy required to remove an electron from a hydrogen atom, $2.18 \times 10^{-18} \text{ J}$. The actual ionisation energy of a helium atom is $3.94 \times 10^{-18} \text{ J}$, about twice the fully shielded value and about half the totally unshielded value. Shielding is incomplete because both electrons in helium occupy the same extended region of space, so neither is completely effective at shielding the other from the $+2$ charge of the nucleus.

Electrons in compact orbitals pack around the nucleus more tightly than electrons in large, diffuse orbitals. As a result, the effectiveness in shielding nuclear charge decreases as orbital size increases. Because the size of an orbital increases with n , an electron's ability to shield decreases as n increases. In a multi-electron atom, lower n electrons are concentrated between the nucleus and higher n electrons. The negative charges of these inner electrons partially counteract the positive charge of the nucleus.

The efficient shielding by electrons with small values of n can be appreciated by comparing the ionisation energies of electrons in the $2p$ orbitals in figure 4.31. Consider an excited-state helium atom that has one of its electrons in the $1s$ orbital and its other electron in a $2p$ orbital. It takes 0.585×10^{-18} J to remove the $2p$ electron from this excited-state helium atom. This value is close to that of an excited hydrogen atom with its lone electron in a $2p$ orbital, 0.545×10^{-18} J. It is much less than the $2p$ orbital ionisation energy of an excited He^+ ion, 2.18×10^{-18} J. These data show that Z_{eff} is quite close to +1 for the $2p$ orbital of an excited He atom. The electron in the $1s$ orbital is very effective at shielding the electron in the $2p$ orbital from the full +2 charge of the nucleus.

In multi-electron atoms, electrons with a given value of n generally provide effective shielding for orbitals with a larger value of n . That is, $n = 1$ electrons shield the $n = 2$, $n = 3$ and larger orbitals, whereas $n = 2$ electrons provide effective shielding for the $n = 3$, $n = 4$ and larger orbitals but provide little shielding for the $n = 1$ orbital. The amount of shielding also depends on the electron distribution of the shielded orbital and increases with increasing azimuthal quantum number, l . The shaded area of the radial distribution function plot in figure 4.33 emphasises that the $2s$ orbital has a region of significant electron density near the nucleus. A $2p$ orbital lacks this inner layer, so virtually all of its electron density lies outside the region occupied by the $1s$ orbital. Consequently, a $1s$ orbital shields the $2p$ orbital more effectively than the $2s$ orbital, even though both $n = 2$ orbitals are about the same size. Thus, a $2s$ electron is subject to a larger effective nuclear charge than a $2p$ electron. This results in stronger electrostatic attraction to the nucleus, which makes the $2s$ orbital lower in energy than the $2p$ orbitals. The $2p$ orbitals of any multi-electron atom are always slightly higher in energy than the $2s$ orbital.

FIGURE 4.33

Radial distribution function plots for the $1s$, $2s$ and $2p$ orbitals. Unlike the $2p$ orbital, the $2s$ orbital has significant electron density very near the nucleus (shaded region).

The shielding differences experienced by the $2s$ and $2p$ orbitals also extend to larger values of n . The $3s$ orbital is of lower energy than the $3p$, the $4s$ orbital is of lower energy than the $4p$, and so on. Orbitals with higher l values show similar effects. The $3d$ orbitals are always higher in energy than the $3p$ orbitals, and the $4d$ orbitals are higher in energy than the $4p$ orbitals. These effects can be summarised in a single general statement: *The higher the value of the l quantum number, the more that orbital is shielded by electrons in smaller, lower energy orbitals.*

In a one-electron system (H , He^+ , Li^{2+} and so on) the energy of the orbitals depends only on Z and n . In multi-electron systems, orbital energy depends primarily on Z and n , but it also depends significantly on l . In a sense, l finetunes orbital energies and as a consequence there are fewer degenerate orbitals. Whereas in a one-electron system the ns , np and nd orbitals are degenerate, this is not the case in a multi-electron atom. The energetic ordering of the orbitals is explained in section 4.6.

Electrons with the same l value but different values of m_l do not shield one another effectively. For example, when electrons occupy different p orbitals, the amount of mutual shielding is slight. This is because shielding is effective only when much of the electron density of one orbital lies between the nucleus and the electron density of another. Recall from figure 4.26 that the p orbitals are perpendicular to one another, with high electron densities in different regions of space. The electron density of the $2p_x$ orbital does not lie between the $2p_y$ orbital and the nucleus, so there is little shielding. The d orbitals also occupy different regions of space from one another (figure 4.27), so mutual shielding among electrons in these orbitals is small as well.

WORKED EXAMPLE 4.9

Shielding

Draw a qualitative plot showing radial distribution functions for the $1s$, $2p$ and $3d$ orbitals to scale. Label the plot in a way that summarises the shielding properties of these orbitals.

Analysis

This is a qualitative problem that asks us to combine information about three different orbitals on a single plot. We need to find information about the radial distribution functions and draw a single graph to scale.

Solution

Figures 4.23, 4.24 and 4.33 show radial distribution functions of the $n = 1$, $n = 2$ and $n = 3$ orbitals. We extract the radial distribution functions of the $1s$, $2p$ and $3d$ orbitals from these graphs. Then we add labels that summarise the shielding properties of these orbitals. Shielding is provided by small orbitals whose highest probability of finding an electron is closer to the nucleus than that of larger orbitals. In this case, $1s$ shields both $2p$ and $3d$; $2p$ shields $3d$, but not $1s$; and $3d$ shields neither $1s$ nor $2p$. The shielding patterns can be labelled as shown.

Is our answer reasonable?

We know that the most important factor for orbital size is the value of n and that small orbitals shield better than large ones, so the shielding sequence makes sense.

PRACTICE EXERCISE 4.9

Construct and label a graph illustrating that the $2s$ orbital shields the $3s$ orbital more effectively than the $3s$ shields the $2s$.

4.6 Structure of the periodic table

LEARNING OBJECTIVE 4.6 Explain the structure of the periodic table in terms of electrons.

The periodic table lists the elements in order of increasing atomic number. Because the number of electrons in a neutral atom is the same as its atomic number, this list is also in order of increasing number of atomic electrons. The periodic table organises atoms in rows (periods) and groups such that atoms with similar chemical properties are located in the same group. We have since learned that the electrons are mainly responsible for an atom's chemical properties, and equipped with the knowledge of orbital electron distributions and energies we can now start to understand the reasons for the placement of atoms in the periodic table.

The Aufbau principle and order of orbital filling

The most stable arrangement of an atom's electrons is called its ground state. *Most stable* means that the electrons occupy the lowest energy orbitals available. We construct the ground-state configuration of an atom by placing electrons in the orbitals starting with the lowest in energy and moving progressively upward. In accordance with the Pauli exclusion principle, each successive electron is placed in the lowest energy orbital whose quantum numbers are not already assigned to another electron. This is called the **Aufbau principle** (from the German word *Aufbauprinzip*, meaning 'construction principle'). We have seen earlier that for multi-electron atoms shielding causes the orbitals with the same principal quantum number to increase in energy as l increases. Consequently, the $2s$ orbital, being of lower energy than the $2p$ orbital, fills first. Similarly, $3s$ fills before $3p$. The energy differences between orbitals become less pronounced the further away the orbitals are from the nucleus. The consequence of this is that, for orbitals with principal quantum numbers larger than $n = 2$, the order of orbital energies is not determined by n alone. For example, the $4s$ orbital fills before the $3d$ orbitals. Therefore, the order of orbital filling is as given in figure 4.34a. The sequence of orbital energies is determined by a combination of $n + l$, and figure 4.34b shows a way to remember that sequence. The orbitals are listed in increasing order of n (bottom

to top) and l (right to left) with the red arrows indicating the directions where $n + l$ is constant. For equal values of $n + l$, lower values of n are filled first. When orbitals are close in energy, anomalies may occur in the order of filling suggested by figure 4.34. While the $4s$ orbital is lower in energy than the empty $3d$ orbital, once $3d$ states are populated the energy order switches and now the $4s$ electrons are higher in energy than the $3d$ electrons. We shall look at this in more detail in section 4.7 and in the chapter on transition metal chemistry.

FIGURE 4.34

(a) The order of filling orbitals with electrons. (b) An easy way to remember the general order of electron filling. Orbitals fill in order of increasing $(n + l)$. Where orbitals have the same value of $(n + l)$, the one with the lowest n will fill first, followed by the others in increasing order of n . Note, however, for higher values of n , there are a number of exceptions to this general order (see the electron configurations given in figure 4.36).

In applying the Aufbau principle, remember that a full description of an electron requires four quantum numbers: n , l , m_l and m_s . Each combination of n and l describes one quantised energy level. Moreover, each level with $l > 0$ includes multiple orbitals, each with a different value of m_l . For any combination of n and l , all orbitals with the same value of l are degenerate, that is, in an atom they have the same energy. For example, the $2p$ energy level ($n = 2$, $l = 1$) consists of three distinct p orbitals ($m_l = -1, 0$ and $+1$), all with the same energy. In addition, the spin quantum number, m_s , describes the two possible different spin orientations of an electron.

In other words, the $2p$ energy level consists of 3 orbitals with different m_l values that can accommodate as many as 6 electrons without violating the Pauli exclusion principle. The same is true of every set of p orbitals ($3p$, $4p$ etc.). Each set can be described by 6 different sets of quantum numbers and can therefore accommodate 6 electrons. A similar analysis for other values of l shows that each s energy level contains a single orbital and can accommodate up to 2 electrons, each d energy level consists of 5 different orbitals that can accommodate up to 10 electrons, and each f energy level consists of 7 different orbitals that can accommodate up to 14 electrons.

The Pauli exclusion and Aufbau principles dictate the length of the periods in the periodic table. After 2 electrons have been placed in the $1s$ orbital (He), the next electron must go in a higher energy $2s$ orbital (Li). After 8 additional electrons have been placed in the $2s$ and $2p$ orbitals (Ne), the next electron must go in a higher energy $3s$ orbital (Na). The periodic table organises atoms in rows (periods) and groups such that atoms with similar chemical properties, as indicated by their valence electron configurations, are

FIGURE 4.36

The periodic table with its rows and blocks labelled to show the relationship between sectors of the table and ground-state configurations. Rows are labelled with the highest principal quantum number of the occupied orbitals, and each block is labelled with the letter (*s*, *p*, *d*, *f*) indicating the orbital set that is filling. Electron configurations for elements 103–118 are tentative, and are based on the electron configurations of other elements in the same group.

WORKED EXAMPLE 4.10

Orbital filling sequence

Which orbitals are filled, and which set of orbitals is partially filled, in a selenium atom?

Analysis

For this qualitative problem, use the periodic table to determine the order of orbital filling. Locate the element in a block and identify its row and column, then use figure 4.35 to establish the sequence of filled orbitals.

Solution

Selenium is element 34. Consult figure 4.35 to determine that Se is in group 16, row 4 of the *p* block.

Starting from the top left of the periodic table and working left to right across the rows until we reach Se, we identify the filled orbitals: $1s$, $2s$, $2p$, $3s$, $3p$, $4s$ and $3d$. Selenium is in row 4 of the *p* block, so the $4p$ set of orbitals is partially filled.

Is our answer reasonable?

Se has $Z = 34$, meaning its neutral atoms contain 34 electrons. We can count how many electrons each orbital can hold: 2 for each *s* orbital, 6 for each *p* orbital set and 10 for each *d* orbital set. $2(1s) + 2(2s) + 6(2p) + 2(3s) + 6(3p) + 2(4s) + 10(3d) = 30$ electrons, leaving 4 in the partially filled $4p$ orbital set.

PRACTICE EXERCISE 4.10

Determine which orbitals are filled and which set is partially filled for the element Zr.

Valence electrons

The chemical behaviour of an atom is determined by its size and the electrons that are accessible to an approaching chemical reagent. Accessibility can be considered from a spatial or an energetic point of view. An electron is accessible *spatially* when it occupies one of the largest orbitals of the atom. Electrons on the perimeter of the atom, farthest from the nucleus, are the first ones encountered by an incoming chemical reagent. An electron is accessible *energetically* when it occupies one of the highest energy occupied orbitals of the atom. Electrons in high-energy orbitals are more chemically active than electrons in lower energy orbitals.

Similar electron accessibility generates similar chemical behaviour. For example, iodine has many more electrons than chlorine, but these two elements display similar chemical behaviour, as reflected by their placement in the same group of the periodic table. This is because the chemistry of chlorine and iodine is determined by the number of electrons in their largest and highest energy occupied orbitals: $3s$ and $3p$ for chlorine, and $5s$ and $5p$ for iodine. Each of these elements has seven accessible electrons, and this accounts for their chemical similarities.

Accessible electrons are called **valence electrons**, and inaccessible electrons are called **core electrons**. Valence electrons may participate in chemical reactions, while core electrons do not. In general, valence electrons are those that have been added in the period of the periodic table (see figure 4.36) that the atom is located in. For example, carbon with $Z = 6$ is located in period 2, so its valence electrons are those in the $2s$ and $2p$ orbitals (totalling 4). The situation is similar for phosphorus in period 3, which has $3s$ and $3p$ valence electrons (totalling 5). Manganese in period 4 has valence electrons in the $4s$ and $3d$ orbitals (totalling 7).

The nearly equal energies of ns and $(n - 1)d$ orbitals create some ambiguity about valence and core electrons for elements in the d and f blocks. For example, titanium forms a chloride and an oxide with chemical formulae consistent with four valence electrons: TiCl_4 and TiO_2 . This shows that the two $3d$ electrons of titanium participate in chemical reactions. On the other hand, zinc forms compounds, such as ZnCl_2 and ZnO , with only two electrons involved in its chemistry. This chemical behaviour indicates that zinc's ten $3d$ electrons, which completely fill the $3d$ orbitals, are inaccessible for chemical reactions. When the d orbitals are partially filled, the d electrons participate in chemical reactions, but, when the d orbitals are completely filled, the d electrons do not generally participate in reactions (see below for a few exceptions). The predominant oxidation state of $3+$ throughout the f -block elements also suggests that generally only one d or f electron (see ground state configurations in figure 4.36) is accessible for chemical reactions. The definitions of core and valence electrons do not depend on whether the electrons are used in chemical reactions, but rather whether they are in an accessible energy level or not.

We find that the number of valence electrons can be determined easily from group numbers in the periodic table. For groups 1–10, the number of valence electrons equals the group number. As examples, potassium and rubidium, members of group 1, have just one valence electron each. Tungsten, in group 6, has six valence electrons: two $6s$ electrons and four $5d$ electrons. For groups 12–18, the number of valence electrons equals the group number minus 10 (the number of electrons it takes to fill the d orbitals). Thus, antimony and nitrogen, in group 15, have $15 - 10 = 5$ valence electrons each (two s and three p). For group 11, the number of valence electrons is expected to be 1 (the one s electron). However, often compounds of these elements involve their d electrons.

4.7 Electron configurations

LEARNING OBJECTIVE 4.7 Write electron configurations.

A complete specification of which energy levels an atom's electrons populate is called an **electron configuration**. There are three common ways to represent electron configurations. One is a complete specification of quantum numbers. The second is a shorthand notation from which the quantum numbers can be inferred. The third is a diagrammatic representation of orbital energy levels and their occupancies.

A list of the values of all quantum numbers is easy for the single electron in a hydrogen atom.

$$n = 1, l = 0, m_l = 0, m_s = +\frac{1}{2}$$

$$n = 1, l = 0, m_l = 0, m_s = -\frac{1}{2}$$

Either designation is equally valid, because under normal conditions these two states are equal in energy. In a large collection of hydrogen atoms, half the atoms have one designation and the other half have the other designation.

As the number of electrons in an atom increases, a listing of all quantum numbers quickly becomes tedious. For example, iron, with 26 electrons, would require the specification of 26 sets of four quantum numbers. To save time and space, chemists have devised a shorthand notation to write electron configurations. The orbital symbols ($1s$, $2p$, $4d$ etc.) are followed by superscripts designating how many electrons are in each set of orbitals. The compact configuration for a hydrogen atom is $1s^1$, indicating 1 electron in the $1s$ orbital. For an iron atom the compact configuration is $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^6$.

The third way to represent an electron configuration uses an energy level diagram to designate orbitals. Orbital energy levels are indicated by a horizontal line, and these are arranged vertically in order of increasing energy. Each electron is represented by an arrow and is placed on the appropriate horizontal line. The direction of the arrow indicates the value of m_s . By convention, we fill orbitals starting from the left-hand side, and the arrow points upward for $m_s = +\frac{1}{2}$ and downward for $m_s = -\frac{1}{2}$. The configuration of hydrogen can be represented by a single arrow in a $1s$ orbital.

A neutral helium atom has two electrons. To write the ground-state electron configuration of He, we apply the Aufbau principle. One unique set of quantum numbers is assigned to each electron, moving from the lowest energy orbital upward until all electrons have been assigned. The lowest energy orbital is always $1s$ ($n = 1, l = 0, m_l = 0$). Both helium electrons can occupy the $1s$ orbital, provided one of them has $m_s = +\frac{1}{2}$ and the other has $m_s = -\frac{1}{2}$. Below are the three representations of helium's ground-state electron configuration.

The two electrons in this configuration are said to be paired electrons, meaning that they are in the same orbital, with opposing spins. Opposing spins cancel, so paired electrons have zero net spin.

A lithium atom has three electrons. The first two electrons fill lithium's lowest possible energy level, the $1s$ orbital, and the third electron occupies the $2s$ orbital. The three representations for the ground-state electron configuration of a lithium atom are shown below.

The set $n = 2, l = 0, m_l = 0, m_s = -\frac{1}{2}$ is equally valid for the third electron.

The next atoms of the periodic table are beryllium and boron. You should be able to write the three different representations (the set of quantum numbers, the shorthand notation and the energy level diagram) for the ground-state configurations of these elements. The filling principles are the same as we move to higher atomic numbers.

WORKED EXAMPLE 4.11

An electron configuration

Construct an energy level diagram and the compact notation of the ground-state configuration of aluminium. Provide one set of valid quantum numbers for the highest-energy electron.

Analysis

First consult the periodic table to locate aluminium and determine how many electrons are present in a neutral atom. Then construct the electron configuration using the patterns of the periodic table.

Solution

Aluminium has $Z = 13$, so a neutral atom of Al has 13 electrons. Place the 13 electrons sequentially, using arrows, into the lowest energy orbitals available. The $n = 1$ orbital is filled by two electrons, eight electrons fill the $n = 2$ orbitals, two electrons fill the $3s$ orbital, and one electron goes in a $3p$ orbital.

The last electron could be placed in any of the $3p$ orbitals, because these three orbitals are equal in energy. The final electron could also be given either spin orientation. By convention, we place electrons in unfilled orbitals starting with the left-hand side, with spins pointed up.

The compact notation is $1s^2 2s^2 2p^6 3s^2 3p^1$.

The highest energy electron is in a $3p$ orbital, meaning $n = 3$ and $l = 1$. The value of m_l can be any of three values: $+1$, -1 or 0 . The spin quantum number, m_s , can be $+\frac{1}{2}$ or $-\frac{1}{2}$. One valid set of quantum numbers is:

$$n = 3, l = 1, m_l = 1, m_s = +\frac{1}{2}$$

You should be able to write the other five possible sets.

Is our answer reasonable?

Aluminium, in group 13, has three valence electrons. The configurations show three electrons with $n = 3$, so the configuration is consistent with the valence electron count.

PRACTICE EXERCISE 4.11

Determine the energy level diagram as well as the compact notation for the electron configuration of the fluorine atom.

Electron configurations become longer as the number of electrons increases. To avoid the need to write long configurations, chemists make use of the regular pattern for the electrons with lower principal quantum numbers. Compare the compact electron configurations of neon and aluminium shown below.

The description of the first 10 electrons in the configuration of aluminium is identical to that of neon. We can take advantage of this pattern and represent that portion as [Ne]. With this notation, we can write the abbreviated compact electron configuration of Al as [Ne] $3s^2 3p^1$. The element at the end of each row of the periodic table has a **noble gas configuration**, that can be written in the following notation.

Notation	Configuration	Element
[He]	$1s^2$	He (2 electrons)
[Ne]	[He] $2s^2 2p^6$	Ne (10 electrons)
[Ar]	[Ne] $3s^2 3p^6$	Ar (18 electrons)
[Kr]	[Ar] $4s^2 3d^{10} 4p^6$	Kr (36 electrons)
[Xe]	[Kr] $5s^2 4d^{10} 5p^6$	Xe (54 electrons)
[Rn]	[Xe] $6s^2 5d^{10} 4f^{14} 6p^6$	Rn (86 electrons)

To write the abbreviated compact electron configuration of any other element, we first consult the periodic table to find its location relative to the noble gases. Then we specify the configuration of the preceding noble gas and build the remaining portion of the configuration according to the Aufbau principle.

WORKED EXAMPLE 4.12

A shorthand electron configuration

Determine the electron configuration of indium, first in abbreviated compact form and then in compact form, and draw the energy level diagram.

Analysis

Locate the element in the periodic table, and find the nearest noble gas with a smaller atomic number. Start with the electron configuration of that noble gas, and add enough additional electrons to the next-filling orbitals to give the neutral atom.

Solution

Indium, In ($Z = 49$), is in row 5, group 13. The nearest noble gas of smaller Z is Kr ($Z = 36$). Thus, the configuration of In has 36 electrons in the Kr configuration and 13 additional electrons. The last orbital to fill in Kr is $4p$, and the periodic table shows that the next orbitals to fill are the $5s$, $4d$ and $5p$ orbitals.

The abbreviated compact electron configuration of indium is:

To write the compact configuration, expand the krypton configuration.

The compact configuration of In (49 electrons) is:

The energy level diagram is as shown.

Note that it is usual to indicate empty orbitals in an energy level diagram when they are part of a set of degenerate orbitals. For example, in the energy level diagram above, we show the two empty p orbitals of the $5p$ set because one orbital of the set contains a single electron.

Is our answer reasonable?

Indium, in group 13, has three valence electrons. The configurations show three electrons with $n = 5$, so the configuration is consistent with the valence electron count.

PRACTICE EXERCISE 4.12

Determine the abbreviated compact notation for the electron configuration of the cadmium atom.

Electron–electron repulsion

The Aufbau principle allows us to assign quantum numbers to aluminium's 13 electrons without ambiguity. The first 12 electrons fill the $1s$, $2s$, $2p$ and $3s$ energy levels, and the last electron can occupy any $3p$ orbital with either spin orientation. But what happens when more than one electron must be placed in a p energy level? Carbon atoms, for example, have six electrons, two of which occupy $2p$ orbitals. How should these two electrons be arranged in the $2p$ orbitals?

1. The electrons could be paired in the same $2p$ orbital (same m_l value but different m_s values).
2. The electrons could occupy different $2p$ orbitals with opposite spin orientations (different m_l values and different m_s values).
3. The electrons could occupy different $2p$ orbitals with the same spin orientation (different m_l values but the same m_s value).

Figure 4.37 shows three arrangements (of 15 that are possible) of the two $2p$ electrons that obey the Pauli exclusion principle.

These three arrangements have different energies because electrons that are close together repel each other more than electrons that are far apart. As a

FIGURE 4.37

Three different arrangements of two $2p$ electrons that obey the Pauli exclusion principle

result, for two or more degenerate orbitals, the lowest energy situation results when electrons occupy the orbitals that keep them furthest apart. Placing two electrons in different p orbitals keeps them relatively far apart, so an atom is of lower energy with the two electrons in different p orbitals. Thus, arrangements 2 and 3 are of lower energy than arrangement 1.

Arrangements 2 and 3 look spatially equivalent, but experiments show that a configuration that gives unpaired electrons the same spin orientation is always of lower energy than one that gives them opposite orientations. **Hund's rule** summarises the way in which electrons occupy orbitals of equal energies. *The lowest energy configuration involving orbitals of equal energies is the one with the maximum number of unpaired electrons with the same spin orientation.*

According to Hund's rule, arrangement 3 of figure 4.37 is consistent with the ground-state configuration for carbon atoms.

WORKED EXAMPLE 4.13

Applying Hund's rule

Write the compact electron configuration and draw the ground-state orbital energy level diagram for the valence electrons in a sulfur atom.

Analysis

From the periodic table, we see that sulfur has 16 electrons and is in the p block, group 16. To build the ground-state configuration, apply the Aufbau and the Pauli exclusion principles and then apply Hund's rule if needed.

Solution

The first 12 electrons fill the orbitals of the four lowest energy levels.

Sulfur's remaining four electrons occupy the three $3p$ orbitals. The complete configuration is $1s^2 2s^2 2p^6 3s^2 3p^4$ or, in abbreviated form, $[\text{Ne}] 3s^2 3p^4$.

To minimise electron–electron repulsion, put three of the $3p$ electrons in different orbitals, all with the same spin, and then place the fourth electron, with opposite spin, in the first orbital. In accord with Hund's rule, this gives the same value of m_s to all electrons that are not paired. Below is the energy level diagram for sulfur's valence electrons.

Is our answer reasonable?

Sulfur, in row 3 and group 16, has six valence electrons. The configurations show six electrons with $n = 3$, so the configuration is consistent with the valence electron count. The electrons are spread among the three $3p$ orbitals, which minimises electron–electron repulsion.

PRACTICE EXERCISE 4.13

Determine the abbreviated compact electron configuration for the nitrogen atom and write one valid set of quantum numbers for its valence electrons.

Orbitals with nearly equal energies

The filling order embodied in the periodic table predicts a regular progression of ground-state configurations. Experiments show, however, that some elements have ground-state configurations different from the predictions of the regular progression. Among the first 40 elements, there are only two exceptions: copper and chromium. Chromium is in group 6, four elements into the d block. We would predict that the ground-state valence electron configuration of chromium should be $4s^2 3d^4$. Instead, experiments show that the ground-state configuration of this element is $4s^1 3d^5$. Likewise, the configuration of copper ($Z = 29$) is $4s^1 3d^{10}$ rather than the predicted $4s^2 3d^9$.

Look again at figure 4.34a, which shows that these two sets of orbitals are nearly the same in energy. Each $(n - 1)d$ orbital has nearly the same energy as its ns counterpart. In addition, each $(n - 2)f$ orbital has nearly the same energy as its $(n - 1)d$ counterpart. Table 4.3 lists these orbitals and the atomic numbers for which the filling sequence differs from the expected pattern. These configurations are also indicated in figure 4.36.

Often, an s orbital contains only one electron rather than two. Five of the exceptional ground-state configurations have a common pattern and are easy to remember: Cr and Mo are s^1d^5 , and Cu, Ag and Au are s^1d^{10} . The other exceptional cases follow no recognisable patterns, because they are generated by subtle interactions between all the electrons. Among elements with valence electrons filling orbitals with nearly equal energies, several factors help to determine the ground-state configuration. The details are beyond the scope of this text, except that you should recognise that even a subtle change can cause variations in the filling pattern predicted by the periodic table.

TABLE 4.3 Exemptions to the Aufbau principle

Atomic orbitals with nearly equal energies	Atomic numbers affected	Example
4s, 3d	24, 29	Cr: [Ar] 4s ¹ 3d ⁵
5s, 4d	41, 42, 44, 45, 46, 47	Ru: [Kr] 5s ¹ 4d ⁷
6s, 5d, 4f	57, 58, 64, 78, 79	Au: [Xe] 6s ¹ 4f ¹⁴ 5d ¹⁰
6d, 5f	89–93, 96	U: [Rn] 7s ² 5f ³ 6d ¹

Configurations of ions

The electron configurations of atomic ions are written using the same procedure as for neutral atoms, taking into account the proper number of electrons. An anion has one additional electron for each unit of negative charge. A cation has one fewer electron for each unit of positive charge.

For most atomic ions, the electron configuration can be deduced easily from that of the corresponding neutral atom. For example, Na⁺, Ne and F[−] all contain 10 electrons, and each has the configuration 1s²2s²2p⁶. Atoms and ions that have the same number of electrons are said to be **isoelectronic**.

In general, you would expect that the last electron to be added would be the first electron to be lost on ionisation. The nearly equal energies of ns and $(n-1)d$ orbitals cause the configurations of transition metal cations to differ from the configurations predicted by the filling pattern of the periodic table. Remember that the energy ranking of orbitals such as 4s and 3d depends on a balance of several factors, and that even a small variation in that balance can change the order of the orbitals. This feature is particularly important for the transition metals, for which the d orbitals are occupied. Experiments show that in transition metals the $(n-1)d$ orbitals are *always* of lower energy than the ns orbitals, meaning that the ns electrons are removed first on ionisation. For example, an Fe³⁺ cation contains 23 electrons. The first 18 electrons fill the 1s, 2s, 2p, 3s and 3p orbitals, as predicted by the periodic table. However, the five remaining electrons populate the 3d set, leaving the 4s orbital empty. Thus, the configuration of the Fe³⁺ cation is [Ar] 3d⁵.

Vanadium, V, atoms ([Ar] 4s²3d³) and Fe³⁺ cations ([Ar] 3d⁵) have different configurations, even though each has 23 electrons.

We can summarise the discussion in this section into guidelines for determining electron configurations for atoms and ions.

- Count the total number of electrons for a neutral atom.
 - Add electrons for anions.
 - Subtract electrons for cations.
- Fill orbitals to match the nearest noble gas of smaller atomic number.
- Add remaining electrons to the next orbitals to be filled according to the Aufbau and Pauli exclusion principles, as well as Hund's rule.
 - For neutral atoms and anions, place electrons in ns before $(n-1)d$ and $(n-2)f$, keeping in mind that the order changes once the d and f levels are at least partially occupied.
 - For cations, start with the configuration of the neutral atom and then remove electrons from the ns before the $(n-1)d$ and $(n-2)f$ orbitals.
- Look for exceptions and correct the configuration if necessary.

WORKED EXAMPLE 4.14

Configuration of a cation

What is the ground-state electron configuration of a Mn^{4+} cation?

Analysis

Use the Aufbau principle, remembering that for transition metals, the 4s orbital and 3d orbitals swap positions once the levels are populated. Thus 4s electrons will be lost before 3d electrons.

Solution

A neutral manganese atom has 25 electrons, with the following electron configuration: $[\text{Ar}]4s^23d^5$. The corresponding Mn^{4+} cation has 21 electrons. Removing both 4s electrons and two of the 3d electrons leaves three electrons in the 3d set of orbitals, following Hund's rule: $[\text{Ar}]3d^3$.

PRACTICE EXERCISE 4.14

Determine the ground-state electron configuration (abbreviated compact form) of a Ru^{3+} cation.

Magnetic properties of atoms

How do we know that an Fe^{3+} ion in its ground state has the configuration $[\text{Ar}]3d^5$ rather than the $[\text{Ar}]4s^23d^3$ configuration predicted by the orbital filling sequence? Remember that electron spin gives rise to magnetic properties. Consequently, any atom or ion with unpaired electrons has non-zero net spin and is attracted by a strong magnet. We can divide the electrons of an atom or ion into two categories with different spin characteristics. In filled orbitals, all the electrons are paired. Each electron with spin orientation $+\frac{1}{2}$ has a partner with spin orientation $-\frac{1}{2}$. The spins of these electrons cancel each other, giving a net spin of zero. An atom or ion with all electrons paired is not attracted by strong magnets and is termed **diamagnetic**. In contrast, spins do not cancel when unpaired electrons are present with spins aligned in the same direction. An atom or ion with unpaired electrons is attracted to strong magnets and is called **paramagnetic**. Moreover, the spins of all the unpaired electrons are additive, so the amount of paramagnetism shown by an atom or ion is proportional to the number of unpaired spins.

In Fe^{3+} , Hund's rule dictates that the five d electrons all have the same spin orientation. For these five electrons, the spins all act together, giving a net spin of $5 \times \frac{1}{2} = \frac{5}{2}$. The alternative configuration for Fe^{3+} , $[\text{Ar}]4s^23d^3$, is paramagnetic, too, but its net spin is $3 \times \frac{1}{2} = \frac{3}{2}$ as it has only three unpaired electrons. Experiments show that Fe^{3+} has a net spin of $\frac{5}{2}$. In fact, magnetic measurements on a wide range of transition metal cations are all consistent with the $(n-1)d$ orbitals being occupied rather than the ns orbital.

The ground-state configurations of most neutral atoms and many ions contain unpaired electrons, so we might expect most materials to be paramagnetic. On the contrary, most substances are diamagnetic. This is because stable substances seldom contain free atoms. Instead, in molecular substances, atoms are bonded together through pairing of electrons to give molecules (see the chapter on chemical bonding and molecular structure), and such bonding results in the cancellation of overall spin. This is different for compounds of transition metals, lanthanoids or actinoids, since they often have unpaired electrons left over (in partially filled d and f orbitals). We will examine the magnetic properties of transition metal complexes in detail in the chapter on transition metal chemistry.

WORKED EXAMPLE 4.15

Unpaired electrons

Which of these species is paramagnetic: F^- , Zn^{2+} or Ti?

Analysis

Paramagnetism results from unpaired spins, which exist only in partially filled sets of orbitals. We need to build

the configurations and then look for any orbitals that are partially filled.

Solution

- F^- : A fluorine atom has 9 electrons, so F^- has 10 electrons. The configuration is $1s^22s^22p^6$. There are no partially filled orbitals, so the fluoride ion is diamagnetic.

- Zn^{2+} : The parent zinc atom has 30 electrons, and the cation has 28, so the configuration for Zn^{2+} is $[\text{Ar}] 3d^{10}$. Again, there are no partially filled orbitals, so this ion is also diamagnetic.
- Ti: A neutral titanium atom has 22 electrons. The ground-state configuration is $[\text{Ar}] 4s^2 3d^2$. The spins of the 4s electrons cancel. The two electrons in 3d orbitals have the same spin orientation, so their effect is additive.

This atom is paramagnetic, with a net spin of $\frac{1}{2} + \frac{1}{2} = 1$.

Is our answer reasonable?

Filled orbitals always have all electrons paired, and two of these three species have no partially filled orbitals. Only Ti has a partially filled orbital set.

PRACTICE EXERCISE 4.15

Most transition metal cations are paramagnetic. Which cations in the 3d transition metal series have net charges less than +4 and are exceptions to this generalisation?

Excited states

The ground-state configuration is the lowest energy arrangement of electrons, so an atom or ion will usually have this configuration. When an atom absorbs energy, however, it can reach an excited state with a new electron configuration. For example, sodium atoms normally have the ground-state configuration $[\text{Ne}] 3s^1$, but when sodium atoms are in the gas phase, an electrical discharge can induce transfer of the 3s electron to a higher energy orbital, such as 4p. Excited atoms are unstable and spontaneously return to the ground-state configuration, giving up their excess energy in the process.

Excited-state configurations are perfectly valid as long as they meet the restrictions given in table 4.2. In the electrical discharge of a sodium-vapour lamp, for instance, we find some sodium atoms in excited states with configurations such as $1s^2 2s^2 2p^6 3p^1$ or $1s^2 2s^2 2p^6 4d^1$. These configurations use valid orbitals and are in accord with the Pauli exclusion principle, but they describe atoms that are of higher energy than those in the ground state. It should be noted that both the Aufbau principle and Hund's rule can be violated when writing excited-state electronic configurations, but the Pauli exclusion principle always holds.

Excited states play important roles in chemistry. Properties of atoms can be studied by observing excited states. In fact, chemists and physicists use the characteristics of excited states extensively to probe the structure and reactivity of atoms, ions and molecules. Excited states also have practical applications. For example, sodium-vapour lamps, which are used for street lighting, use the emissions from excited sodium atoms returning to their ground states, and the dazzling colours of a fireworks display come from photons emitted by various metal ions in excited states.

4.8 Periodicity of atomic properties

LEARNING OBJECTIVE 4.8 Describe periodic trends in chemical and physical properties.

The periodicity of physical and chemical properties, which underlies the periodic table of the elements, is one of the most useful organising principles in chemistry. The regular periodic trends can be explained using electron configurations and effective nuclear charges. The most important of those trends is the atomic radius, which we will discuss first, since it influences all other periodic trends.

Atomic radii

The size of an atom is determined by its electron cloud and therefore by the sizes of its orbitals. As we have seen earlier, these sizes are determined by a number of factors, including effective nuclear charge (Z_{eff}), orbital energy and electron distribution.

Assume you are moving from left to right across period 2 of the periodic table ($n = 2$). While Z increases, the electrons that are added do not shield the increasing nuclear charge effectively, so Z_{eff} increases.

A larger Z_{eff} exerts a stronger electrostatic attraction on the electron cloud, and this results in smaller orbitals. Moving from *left to right* across that period, orbitals become *smaller*, that is, *have lower energy*.

Now assume you proceed down group 1 of the periodic table. As n increases, we would expect orbitals to increase in energy and become larger. However, as Z_{eff} increases, we would expect orbitals to become smaller and decrease in energy. Which trend dominates here? Recall that the number of core electrons increases as we move down any group. For example, sodium ($Z = 11$) has 10 core electrons and 1 valence electron. In the next period, potassium ($Z = 19$) has 18 core electrons and 1 valence electron. The shielding provided by potassium's additional 8 core electrons largely cancels the effect of the additional 8 protons in its nucleus.

Consequently, increased shielding largely offsets the increase in Z value from one period to the next and, therefore, valence orbitals become larger and increase in energy from top to bottom of a group.

In summary we can say that *atomic size decreases from left to right and increases from top to bottom of the periodic table* (figure 4.38).

A convenient measure of atomic size is the **atomic radius**, also called metallic radius for metals or covalent radius for nonmetals. The atomic radius is determined by taking half the distance between nuclei of neighbouring atoms in an element. As noble gases exist as monatomic gases only, atomic radii are not available for these. Figure 4.39 shows the trends found in atomic radii. For example, the atomic radius decreases smoothly across the third period, from 186 pm for sodium to 99 pm for chlorine (blue arrow). The atomic radius increases smoothly down group 1, from 152 pm for lithium to 265 pm for caesium (red arrow).

FIGURE 4.38

Representation of the periodic table showing that atomic size decreases from left to right within a row and increases from top to bottom within a group

FIGURE 4.39

The radii of atoms vary in periodic fashion (data are for atoms in the gas phase; the group 18 elements are not shown). Atomic radius generally decreases from left to right within any row (blue arrow) and increases from top to bottom within any group (red arrow).

Notice, however, that the atomic radius changes much less and in a less regular pattern across the d and f blocks. This is due to shielding. For these elements, the largest orbital is the filled ns orbital. Moving from left to right across a row, Z increases, but electrons add to the smaller $(n-1)d$ or $(n-2)f$ orbitals. An increase in Z by 1 unit is matched by the addition of 1 shielding electron. From the perspective of the outlying s orbital, the increases in Z are balanced by increased shielding from the added d or f electrons. Thus, the electron in the outermost occupied orbital, ns , is subject to an effective nuclear charge that changes very little across these blocks. As a consequence, the relative changes in atomic size across the d and f blocks are much smaller than those found in the s and p blocks.

A knowledge of periodic trends in physical and chemical properties and an understanding of the principles that give rise to these trends are important since they enable you, for example, to predict certain chemical behaviours, even if you are not familiar with a particular element.

WORKED EXAMPLE 4.16

Trends in atomic radii

For each of the following pairs, predict which atom is larger and explain why.

- (a) Si or Cl
- (b) S or Se
- (c) Mo or Ag

Analysis

Qualitative predictions about atomic size can be made on the basis of an atom's position in the periodic table.

Solution

(a) Silicon and chlorine are in the third row of the periodic table. Chlorine's nuclear charge (+17) is larger than silicon's (+14), so chlorine's nucleus exerts a stronger pull on its electron cloud. Chlorine also has three more electrons than silicon, which increases the possibility that shielding effects could counter the extra nuclear charge. Remember, however, that electrons in the same type of orbital do a poor job of shielding one another from the nuclear charge. For Si and Cl, shielding comes mainly from the core electrons, not from the electrons in the 3p orbitals. Because shielding effects are similar for these elements, the effective nuclear charge increases from Si to Cl. Therefore, we conclude that chlorine, with its greater nuclear attraction for the electron cloud, is the smaller atom.

	p^1	p^2	p^3	p^4	p^5	p^6
$n = 3$		Si			Cl	
Z:	13	14	15	16	17	18

(b) Sulfur and selenium are in group 16 of the periodic table. Although they both have the s^2p^2 valence configurations, selenium's least stable electrons are in orbitals with a larger n value. Orbital size increases with n . Selenium also has a greater nuclear charge than sulfur, which raises the possibility that nuclear attraction could offset increased n . Remember, however, that much of this extra nuclear charge is offset by the shielding influence of the core electrons. Selenium has 18 core

electrons and sulfur has 10. Thus, we conclude that selenium, with its larger n value, is larger than sulfur.

	group 16
n	
2	
3	S
4	Se

(c) Molybdenum and silver are in the same row of the d block.

			Mo					Ag	
--	--	--	----	--	--	--	--	----	--

They have the following configurations.

In each case, 5s is the largest occupied orbital. The 4d orbitals are smaller, with their electron density located mostly inside the 5s orbital. Consequently, 4d is effective at shielding 5s. The nuclear charge of silver is five units larger than that of molybdenum, but silver also has five extra shielding electrons in d orbitals. These offset the extra nuclear charge, making Mo and Ag nearly the same size.

Is our answer reasonable?

The trends in figure 4.39 confirm the results. Chlorine lies to the right of silicon in the same row of the periodic table. Size decreases from left to right in any row; thus, chlorine is smaller than silicon. Selenium is immediately below sulfur in the same column of the periodic table. Size increases down a column; thus, selenium is larger than sulfur. Molybdenum and silver occupy the same row of the d block of the periodic table, across which size changes relatively little; thus, molybdenum and silver are nearly the same size.

PRACTICE EXERCISE 4.16

Use periodic trends to determine which of the following are smaller than As and which are larger: P, Ge, Se and Sb.

Ionisation energy

When an atom absorbs a photon, the gain in energy promotes an electron to a higher energy orbital in which the electron is, on average, further from the nucleus and therefore experiences less electrical attraction to the nucleus. If the absorbed photon has enough energy, an electron can be ejected from the atom.

The minimum amount of energy needed to remove an electron from a neutral atom is the first ionisation energy (E_{i1}). Ionisation energies are measured for gaseous elements to ensure that the atoms are isolated from one another.

Variations in ionisation energy mirror variations in orbital energy, because an electron in a higher energy orbital is easier to remove than one in a lower energy orbital.

Figures 4.40 and 4.41 show how the first ionisation energies of gaseous atoms vary with atomic number. Notice the general trends in ionisation energy. Ionisation energy increases from left to right across each period (third period: 496 kJ mol^{-1} for Na to 1520 kJ mol^{-1} for Ar) and decreases from top to bottom of each group (group 18: 2372 kJ mol^{-1} for He to 1037 kJ mol^{-1} for Rn). As with atomic radius, ionisation energy changes less for elements in the *d* and *f* blocks, because increased shielding from the *d* and *f* orbitals offsets increases in *Z*. As a rule of thumb, the trend in the ionisation energies is inverse to that of the atomic radii, that is, smaller atoms have higher ionisation energies. Therefore, the trend in the ionisation energies can be rationalised in similar fashion.

FIGURE 4.40

Representation of the periodic table showing that first ionisation energy increases from left to right within a row and decreases from top to bottom within a group

FIGURE 4.41

The first ionisation energy generally increases from left to right across a period (blue arrow) and decreases from top to bottom down a group (red arrow) of the periodic table.

Higher ionisations

A multi-electron atom can lose more than one electron, but ionisation becomes more difficult as positive charge increases. The first three ionisation energies for a magnesium atom in the gas phase provide an illustration.

Process	Configurations	E_i
$\text{Mg(g)} \longrightarrow \text{Mg}^+(\text{g}) + \text{e}^-$	$[\text{Ne}] 3s^2 \longrightarrow [\text{Ne}] 3s^1$	738 kJ mol^{-1}
$\text{Mg}^+(\text{g}) \longrightarrow \text{Mg}^{2+}(\text{g}) + \text{e}^-$	$[\text{Ne}] 3s^1 \longrightarrow [\text{Ne}]$	1450 kJ mol^{-1}
$\text{Mg}^{2+}(\text{g}) \longrightarrow \text{Mg}^{3+}(\text{g}) + \text{e}^-$	$[\text{Ne}] \longrightarrow [\text{He}] 2s^2 2p^5$	7730 kJ mol^{-1}

Notice that the second ionisation energy of magnesium is almost twice as large as the first, even though each electron is removed from a $3s$ orbital. This is because Z_{eff} increases as the number of electrons decreases. That is, the positive charge on the magnesium nucleus remains the same throughout the ionisation process, but the net charge of the electron cloud decreases with each successive ionisation. As the number of electrons decreases, each electron feels a greater electrostatic attraction to the nucleus (due to minimised electron–electron repulsion), resulting in a larger ionisation energy.

The third ionisation energy of magnesium is more than 10 times the first ionisation energy. This large increase occurs because the third ionisation removes a core electron ($2p$) rather than a valence electron ($3s$). Removing core electrons from any atom requires much more energy than removing valence electrons. The second ionisation energy of any group 1 metal is substantially larger than the first ionisation energy; the third ionisation energy of any group 2 metal is substantially larger than the first or second ionisation energy, and so on. Appendix G gives the first three ionisation energies for the first 36 elements.

Irregularities in ionisation energies

Ionisation energies deviate somewhat from smooth periodic behaviour. These deviations can be attributed to shielding effects and electron–electron repulsion. Aluminium, for example, has a smaller first ionisation energy than either of its neighbours in row 3 (see figure 4.35).

Element	Z	Atom configuration	E_{i1}	Cation configuration
Mg	12	$[\text{Ne}] 3s^2$	738 kJ mol^{-1}	$[\text{Ne}] 3s^1$
Al	13	$[\text{Ne}] 3s^2 3p^1$	577 kJ mol^{-1}	$[\text{Ne}] 3s^2$
Si	14	$[\text{Ne}] 3s^2 3p^2$	786 kJ mol^{-1}	$[\text{Ne}] 3s^2 3p^1$

The configurations of these elements show that a $3s$ electron must be removed to ionise magnesium, whereas a $3p$ electron must be removed to ionise aluminium or silicon. Shielding makes the $3p$ orbitals of higher energy than a $3s$ orbital, and this difference in energy more than offsets the increase in nuclear charge in going from magnesium to aluminium. A second electron in a different $3p$ orbital does not contribute to the shielding of the other $3p$ electron and thus the increased Z_{eff} means that it is harder to remove an electron from Si than from Al.

As another example, oxygen has a smaller ionisation energy than either of its neighbours in row 2.

Element	Z	Atom configuration	E_{i1}	Cation configuration
N	7	$1s^2 2s^2 2p^3$	1402 kJ mol^{-1}	$1s^2 2s^2 2p^2$
O	8	$1s^2 2s^2 2p^4$	1314 kJ mol^{-1}	$1s^2 2s^2 2p^3$
F	9	$1s^2 2s^2 2p^5$	1681 kJ mol^{-1}	$1s^2 2s^2 2p^4$

Remember that electron–electron repulsion has a destabilising effect. The ionisation energy of oxygen is less than that of nitrogen, despite the increased nuclear charge, because the p^4 configuration in the O atom has significantly greater electron–electron repulsion than the p^3 configuration in the N atom.

Electron affinity

A neutral atom can add an electron to form an anion. The energy change when an electron is added to an atom in the gas phase is called the **electron affinity** (E_{ea}).

Both ionisation energy (E_{i}) and electron affinity measure the stability of a bound electron, but for different species. Below, for example, are the values for fluorine.

Energy is released when an electron is added to a fluorine atom to form a fluoride anion. This means that a fluoride anion is of lower energy than a fluorine atom plus a free electron. Another way of saying this is that fluorine atoms have an affinity for electrons.

The energy associated with removing an electron to convert an anion to a neutral atom (i.e. the reverse of electron attachment) has the same magnitude as the electron affinity, but the opposite sign. Removing an electron from F^- , for example, requires energy, giving a positive energy change.

The Aufbau principle must be obeyed when an electron is added to a neutral atom, so the electron goes into the lowest energy orbital available. Hence, we expect trends in electron affinity to parallel trends in orbital energy. However, electron–electron repulsion and shielding are more important for negative ions than for neutral atoms, so there is no clear trend in electron affinities as n increases. Thus, there is only one general pattern: *Electron affinity tends to become more negative from left to right across a period of the periodic table.*

Figure 4.42 shows how electron affinity changes with atomic number. Electron affinity increases in magnitude across each period of the periodic table. This trend is due to increasing effective nuclear charge, which binds the added electron more tightly to the nucleus. Notice that, in contrast to the pattern for ionisation energies (see figure 4.41), values for electron affinities remain nearly constant among elements occupying the same group of the periodic table.

FIGURE 4.42

The electron affinity of atoms varies with atomic number. In moving across any period, the electron affinity becomes more negative, but this is the only clear trend.

The electron affinity values for many of the elements shown in figure 4.42 appear to lie on the x -axis. Actually, these elements have positive electron affinities, meaning the resulting anion is of higher energy than the neutral atom. Moreover, the second electron affinity of every element is large and positive. Positive electron affinities cannot be measured directly. Instead, these values are estimated using other methods.

Although electron affinity values show only one clear trend, there is another recognisable pattern for the atoms that have positive electron affinities. When the electron that is added must occupy a new orbital, the resulting anion is unstable. Thus, all the elements of group 2 have positive electron affinities because their valence ns orbitals are filled. Similarly, all the noble gases have positive electron affinities because their valence np orbitals are filled. Elements with half-filled orbitals also have less negative electron affinities than their neighbours. As examples, N (half-filled $2p$ orbital set) has a positive electron affinity, as does Mn (half-filled $3d$ orbital set).

Sizes of ions

An atomic cation is always smaller than the corresponding neutral atom. Conversely, an atomic anion is always larger than the neutral atom. Figure 4.43 illustrates these trends, and electron–electron repulsion explains them. A cation has fewer electrons than its parent neutral atom. This reduction in the number of electrons means that the cation’s remaining electrons experience less electron–electron repulsion. Consequently, orbitals are held more tightly, a fact that can be detected using X-ray absorption spectroscopy (see the chemical connections feature on the soil chemistry impacts of bushfires). An anion has more electrons than its parent neutral atom. This increase means that there is more electron–electron repulsion in the anion than in the parent neutral atom.

Figure 4.43 also highlights the relationships between isoelectronic species, that is, those that possess equal numbers of electrons. As noted earlier, the F^- anion and the Na^+ cation are isoelectronic, each having 10 electrons and the configuration $[He]2s^22p^6$. For isoelectronic species, properties change regularly with Z . For example, table 4.4 shows two properties of the 10-electron isoelectronic sequence. A progressive increase in nuclear charge results in a corresponding decrease in ionic radius, a result of stronger electrical force between the nucleus and the electron cloud. For the same reason, as Z increases, it becomes progressively more difficult to remove an electron.

FIGURE 4.43

Comparison of the sizes (radius, r , in pm) of neutral atoms (brown) and their ions (cations yellow; anions black) for some elements. The blue highlight indicates isoelectronic ions.

TABLE 4.4 Trends in an isoelectronic sequence

Property	Species			
	O ²⁻	F ⁻	Na ⁺	Mg ²⁺
Z	8	9	11	12
radius (pm)	140	133	102	72
ionisation energy (kJ mol ⁻¹)	< 0 (−E _{ea2})	322 (−E _{ea})	4560 (E _{i2})	7730 (E _{i3})

CHEMICAL CONNECTIONS**Soil chemistry after bushfires**

Bushfires (figure 4.44) are a common and sometimes devastating natural hazard in Australia and to a lesser — but growing — extent in New Zealand. While the impacts on wildlife, vegetation and livelihoods are clear to see, we are still learning about the effects on soil chemistry. During bushfires, soil temperatures commonly reach 700 °C and can reach up to 850 °C for short periods. Temperatures in this range alter the properties of the soil and can even transform minerals to different phases.

FIGURE 4.44

Bushfires can alter soil chemistry, potentially creating an environmental hazard.

Chromium is naturally present as a trace metal in soil. The Cr³⁺ form is relatively benign, immobile at the pH range of most soils, and an essential nutrient for human health. However, the oxidised form, Cr⁶⁺, is very mobile due to its solubility in water, highly carcinogenic and toxic. In uncontaminated soils, chromium is usually present as Cr³⁺.

Researchers from Southern Cross University used the Australian Synchrotron to investigate how the chemistry of chromium in soil might be altered after exposure to bushfires. Soil from Lismore, NSW, contains 220 mg/kg Cr, which is a typical concentration for soil and, prior to exposure to fire, 100% of this chromium was in the form of Cr^{3+} . X-ray absorption spectroscopy (XAS) can distinguish between the forms (oxidation states) of chromium, even at the low concentrations present in natural soils. At the XAS beamline (figure 4.45), an element-specific energy range of the incident beam is scanned through. When the X-ray beam reaches an energy high enough to excite core-level electrons, the incident X-rays are absorbed. As outer electrons fill the core-hole vacancy, they emit photons with an energy that is equal to the difference in binding energy between those orbital levels. We can measure these fluorescent X-rays with a detector. The absorption spectra can look different depending on the electronic state of the atom, and are sensitive to things such as oxidation state (e.g. Cr^{3+} or Cr^{6+}), coordination (e.g. tetrahedral or octahedral) and speciation (e.g. Cr-oxide or Cr-carbonate).

FIGURE 4.45

Dr Niloofar Karimian adjusting a sample on the XAS beamline of the Australian Synchrotron

Figure 4.46 shows the XAS spectra for chromium in two oxidation states, and you can see the difference between these chemical forms is distinctive.

This technique is useful because, just by looking at the spectra, we can detect whether chromium is present in its benign or toxic form. The height of the pre-edge peak is proportional to the concentration of Cr^{6+} , so we can also use this to calculate how much Cr^{6+} is in natural soil samples.

The researchers from Southern Cross University heated soil to 800 °C, and found that up to 80% of Cr^{3+} became oxidised to Cr^{6+} . Exchangeable Cr (which is the Cr that can leach out with water) was approximately half of that. This was the first time that chromium in soil was shown to convert into a toxic form at temperatures representative of a bushfire (typically 200–700 °C). This was a previously unrecognised environmental risk. The finding will help identify areas that may be sensitive to potentially toxic runoff following bushfire events.

FIGURE 4.46

Compared to Cr^{3+} , the spectrum for Cr^{6+} has a prominent pre-edge peak (narrow green peak), and the main rising absorption edge is also shifted slightly to the right. The more oxidised a material is, the more difficult it is to eject inner-shell electrons. As such, the main absorption edge is shifted to higher energy.

Note: eV is electron volt. 1 eV is approximately equal to 10^{-19} J.

Source: Information from Burton, ED, Choppala, G, Karimian, N & Johnston, SG 2019, 'A new pathway for hexavalent chromium formation in soil: Fire-induced alterations of iron oxides', *Environmental Pollution*, vol. 247, pp. 618–625.

4.9 Ions and chemical periodicity

LEARNING OBJECTIVE 4.9 Describe periodic trends in relation to ions.

The elements that form ionic compounds are found in specific places in the periodic table. Atomic anions are restricted to elements on the right side of the table: the halogens, oxygen and sulfur. All the elements in the *s*, *d* and *f* blocks form compounds containing atomic cations.

Cation stability

Knowing that the energy cost of removing core electrons is always very large, we can predict that the ionisation process will stop when all valence electrons have been removed. Thus, a knowledge of ground-state configurations is all that we need to make qualitative predictions about cation stability.

Each element in group 1 of the periodic table has one valence electron. These elements form ionic compounds containing M^+ cations. Examples are KCl and Na_2CO_3 . Each element in group 2 of the periodic table has two valence electrons and forms ionic compounds containing M^{2+} cations. Examples are CaCO_3 and MgCl_2 .

Beyond these two groups, the removal of all valence electrons is usually not energetically possible. For example, iron has eight valence electrons but forms only two stable cations, Fe^{2+} and Fe^{3+} . Compounds of iron containing these ions are abundant in the Earth's crust.

Other metallic elements form ionic compounds with cation charges ranging from +1 to +3. Aluminium nitrate nonahydrate, $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$, (the word 'nonahydrate' means nine water molecules are associated with the compound) is

Group 1		Group 2																			
H																					
Li	Be																				
Na	Mg																				
K	Ca																				
Rb	Sr																				
Cs	Ba																				
Fr	Ra																				

composed of Al^{3+} cations, NO_3^- anions, and water molecules. Silver nitrate, AgNO_3 , which contains Ag^+ cations, is a water-soluble silver salt that is used in silver plating.

Anion stability

Halogens, the elements in group 17 of the periodic table, have the largest electron affinities of all the elements. So halogen atoms (ns^2np^5) readily accept electrons to produce halide anions (ns^2np^6). This allows halogens to react with many metals to form binary compounds, called halides, which contain metal cations and halide anions. Examples include NaCl (chloride anion), CaF_2 (fluoride anion), AgBr (bromide anion) and KI (iodide anion).

Isolated atomic anions with charges more negative than -1 are always unstable, but oxide (O^{2-} , $1s^22s^22p^6$) and sulfide (S^{2-} , $[\text{Ne}] 3s^23p^6$) are found in many ionic solids, such as CaO and Na_2S . The lattice energies (see the chapter on condensed phases) of these solids are large enough to stabilise these compounds despite the large positive second electron affinity of the anions. In addition, three-dimensional arrays of surrounding cations stabilise the -2 anions in these solids.

Metals, nonmetals and metalloids

Ion formation is only one pattern of chemical behaviour. Many other chemical trends can be traced to valence electron configurations, but we need the description of chemical bonding from the chapter on chemical bonding and molecular structure to explain such periodic properties. Nevertheless, we can relate important patterns in chemical behaviour to the ability of some elements to form ions. One example is the subdivision of the periodic table into metals, nonmetals and metalloids, first introduced in the chapter on the atom.

The elements that can form cations relatively easily are metals. All metals have similar properties, in part because their outermost s electrons are relatively easy to remove. All elements in the s block have ns^1 or ns^2 valence configurations. The d -block elements have one or two ns electrons and various numbers of $(n-1)d$ electrons. Examples are titanium ($4s^23d^2$) and silver ($5s^14d^{10}$). Elements in the f block have two ns electrons and a number of $(n-2)f$ electrons. Samarium, for example, has the valence configuration $6s^24f^6$. The metallic behaviour of these elements occurs partly because the s electrons are shared readily among all atoms. Metals form ionic salts because s electrons (and some p , d and f electrons) can be readily removed from the metal atoms to form cations.

Whereas the other blocks contain only metals, elemental properties vary widely within the p block. We have already noted that aluminium ($3s^23p^1$) can lose its three valence electrons to form Al^{3+} cations. The six elements within the triangle in figure 4.47 also lose p electrons easily and therefore have metallic properties. Examples are tin ($5s^25p^2$) and bismuth ($6s^26p^3$).

In contrast, the halogens and noble gases on the right of the p block are distinctly nonmetallic. The noble gases, group 18 of the periodic table, are monatomic gases that resist chemical attack because their electron configurations involve completely filled s and p orbitals.

Elements in any intermediate column of the p block display a range of chemical properties even though they have the same valence configurations. Carbon, silicon, germanium and tin all have ns^2np^2 valence configurations; yet carbon is a nonmetal, silicon and germanium are metalloids, and tin is a metal.

Qualitatively, we can understand this variation by recalling that, as the principal quantum number increases, the valence orbitals increase in energy. In tin, the four $n = 5$ valence electrons are bound relatively loosely to the atom, resulting in the metallic properties associated with electrons that are easily removed. In carbon, the four $n = 2$ valence electrons are bound relatively tightly to the atom, resulting in nonmetallic behaviour. Silicon ($n = 3$) and germanium ($n = 4$) fall in between these two extremes.

FIGURE 4.47

These six elements lose p electrons easily and so have metallic properties.

Classifying elements

Nitrogen is a colourless diatomic gas. Phosphorus has several elemental forms, one being a red solid. Arsenic and antimony are grey solids, and bismuth is a silvery solid. Classify these elements of group 15 as metals, nonmetals or metalloids.

Analysis

All elements except those in the p block are metals. Group 15, however, is part of the p block, within which elements display all forms of elemental behaviour. To decide on the classifications of these elements, we must first examine this group relative to the diagonal arrangement of the metalloids (see the chapter on the atom).

Solution

We see that group 15 passes through all three classes of elements. The elements with the lowest Z values, nitrogen and phosphorus, are nonmetals. The element with highest Z value, bismuth, is a metal, and the two elements with intermediate Z values, arsenic and antimony, are metalloids.

Is our answer reasonable?

As the principal quantum number increases, valence electrons become progressively easier to remove, and metals are those elements with valence electrons that are easily removed.

PRACTICE EXERCISE 4.17

Classify the 4p set of elements, from Ga to Kr as metals, nonmetals or metalloids.

s-block elements

The electron configuration of any element in groups 1 and 2 of the periodic table contains a core of tightly bound electrons and one or two s electrons that are loosely bound. The group 1 metals (ns^1 configuration) and the group 2 metals (ns^2 configuration) form stable ionic salts because their valence electrons are easily removed. Nearly all salts of group 1 metals and many salts of group 2 metals dissolve readily in water, so naturally occurring sources of water frequently contain these ions.

The four most abundant *s*-block elements in the Earth's crust are sodium, potassium, magnesium and calcium (table 4.5). These elements are found in nature in salts such as NaCl, KNO₃, MgCl₂, MgCO₃ and CaCO₃. Portions of these solid salts dissolve in rainwater as it percolates through the Earth's crust. The resulting solution of anions and cations eventually finds its way to the oceans. When water evaporates from the oceans, the ions are left behind. Over many aeons the continual influx of river water containing these ions has built up the substantial salt concentrations found in the oceans.

TABLE 4.5 **Abundance of s-block elements**

Element	Abundance in Earth's crust (% by mass)	Abundance in sea water (mol L ⁻¹)	Abundance in human blood plasma (mol L ⁻¹)
Na	2.27	0.462	0.142
K	1.84	0.097	0.005
Mg	2.76	0.053	0.003
Ca	4.66	0.100	0.005

Table 4.5 shows that each of the four common *s*-block ions is abundant not only in sea water but also in body fluids, where they play essential biochemical roles. Sodium is the most abundant cation in fluids that are outside of cells, and proper functioning of body cells requires that sodium concentrations be maintained within a narrow range. One of the main functions of the kidneys is to control the excretion of sodium. Whereas sodium cations are abundant in the fluids outside cells, potassium cations are the

most abundant ions in the fluids inside cells. The difference in ion concentration across cell membranes is responsible for the generation of nerve impulses that drive muscle contraction. If the difference in potassium ion concentration across cell membranes deteriorates, muscular activity, including the regular muscle contractions of the heart, can be seriously disrupted.

The cations Mg^{2+} and Ca^{2+} are major components of bones. Calcium occurs in hydroxyapatite, $\text{Ca}_5(\text{PO}_4)_3(\text{OH})$. The structural function of magnesium in bones is not fully understood. In addition to being essential ingredients of bone, these two cations play key roles in various biochemical reactions, including photosynthesis, transmission of nerve impulses, muscle contraction and the formation of blood clots.

Beryllium behaves differently from the other *s*-block elements because its $n = 2$ orbitals are more compact than orbitals with higher principal quantum numbers. The first ionisation energy of beryllium, 899 kJ mol^{-1} , is comparable with those of nonmetals, so beryllium does not form compounds that are clearly ionic.

Some compounds of the *s*-block elements are important industrial and agricultural chemicals. For example, K_2CO_3 (potassium carbonate or potash) is obtained from mineral deposits and is the most common source of potassium for fertilisers. Potassium is essential for healthy plant growth. However, potassium salts are highly soluble in water, so potassium quickly becomes depleted from the soil. Consequently, agricultural land requires frequent addition of potassium fertilisers.

Three other compounds of *s*-block elements — calcium oxide, CaO or ‘lime’, sodium hydroxide, NaOH , and sodium carbonate, Na_2CO_3 — are major industrial chemicals. For example, lime is the key ingredient in construction materials such as concrete, cement, mortar and plaster. Two other compounds, calcium chloride, CaCl_2 , and sodium sulfate, Na_2SO_4 , are also of industrial importance.

Many industrial processes make use of anions such as hydroxide, OH^- , carbonate, CO_3^{2-} , and chlorate, ClO_3^- . These anions must be supplied as chemical compounds that include cations. Sodium is most frequently used as this spectator cation because it is abundant, inexpensive and relatively non-toxic. The hydroxide ion is industrially important because it is a strong base (see the chapter on acids and bases). Sodium hydroxide is used to manufacture other chemicals, textiles, paper, soaps and detergents. Sodium carbonate and sand are the major starting materials in the manufacture of glass. Glass contains sodium and other cations embedded in a matrix of silicate, SiO_3^{2-} , anions. About half the sodium carbonate produced in the world is used in glass making.

p-block elements

The properties of elements in the *p* block vary across the entire spectrum of chemical possibilities. The elements in group 13, with a single electron in a *p* orbital as well as two valence *s* electrons, display chemical reactivity characteristic of three valence electrons. Except for boron, the elements of this group are metals that form stable +3 cations. Examples are $\text{Al}(\text{OH})_3$ and GaF_3 . Metallic character diminishes rapidly as additional *p* electrons are added. This change culminates in the elements in group 18. With filled *p* orbitals, these elements are so unreactive that for many years they were thought to be completely inert. Xenon is now known to form compounds with the most reactive nonmetals: oxygen, fluorine and chlorine; krypton also forms a few highly unstable compounds with these elements.

Although the nonmetals do not readily form cations, many of them combine with oxygen to form polyatomic oxoanions. These anions have various stoichiometries, but there are some common patterns. Two second-row elements form oxoanions with three oxygen atoms: carbon (four valence electrons) forms carbonate, CO_3^{2-} , and nitrogen (five valence electrons) forms nitrate, NO_3^- . In the third row, the most stable oxoanions contain four oxygen atoms: SiO_4^{4-} , PO_4^{3-} , SO_4^{2-} and ClO_4^- .

Many of the minerals that form the Earth's crust contain oxoanions. Examples of carbonates are CaCO_3 (limestone) and $\text{MgCa}(\text{CO}_3)_2$ (dolomite). Barite, BaSO_4 , is a sulfate mineral. An important phosphate is $\text{Ca}_5(\text{PO}_4)_3\text{F}$ (apatite). Two silicates are zircon, ZrSiO_4 , and olivine, a mixture of MgSiO_4 and FeSiO_4 .

Several leading industrial chemicals contain oxoanions or are acids resulting from addition of H^+ to the anions. Sulfuric acid, H_2SO_4 , nitric acid, HNO_3 , and phosphoric acid, H_3PO_4 , are all industrially important. Heating CaCO_3 drives off CO_2 to form CaO , the essential ingredient of building materials mentioned earlier. Other industrially important salts include ammonium sulfate, $(\text{NH}_4)_2\text{SO}_4$, aluminium sulfate, $\text{Al}_2(\text{SO}_4)_3$, sodium carbonate, Na_2CO_3 , and ammonium nitrate, NH_4NO_3 . We will learn more about these in the chapter on the *p*-block elements.

SUMMARY

4.1 List some basic properties of atoms.

All atoms display certain basic characteristics. They possess mass, occupy volume, attract one another and can combine with one another. Atoms contain positively charged nuclei and negatively charged electrons, and the properties of elements are determined by variations in nuclear charges and numbers of electrons.

4.2 Explain the wave-like and particle-like properties of light, and how light interacts with atoms.

Electromagnetic radiation in the form of light may be used to probe the structure of atoms. Light has both wave- and particle-like properties. The wave properties are characterised by:

- frequency (ν): the number of wave crests passing a given point in 1 second
- wavelength (λ): the distance between successive wave crests
- amplitude: the height of the wave
- phase: the starting position of the wave with respect to one wavelength.

The intensity (or brightness) of light is proportional to the square of the amplitude. Light waves move at the speed of light, c (approximately $2.998 \times 10^8 \text{ m s}^{-1}$), in a vacuum. The relationship between speed, frequency and wavelength of light is $c = \nu\lambda$. Visible light has wavelengths between 380 and 780 nm. The energy of light is inversely related to its wavelength — the shorter the wavelength, the higher the energy.

The particle properties of light are demonstrated by the photoelectric effect, where light striking the surface of a metal causes electrons to be ejected from the metal. Einstein postulated that this behaviour could be explained by ‘packets’ or ‘bundles’ of light called photons. The energy of a photon is given by the equation $E_{\text{photon}} = h\nu_{\text{photon}}$, where h is Planck’s constant (approximately $6.626 \times 10^{-34} \text{ J s}$). An atom can absorb a photon of a particular energy and form a higher energy excited state. The excited-state atom can then release the excess energy by emitting a photon and returning to its ground state. These photon absorption and emission processes can be observed in atomic spectra. An absorption spectrum gives dark lines in the visible spectrum where light of a particular wavelength has been absorbed, while an emission spectrum gives coloured lines on a dark background which correspond to emission of photons. Atoms can absorb or emit photons of only certain definite energies, meaning that the electrons in atoms have only certain specific energy values — that is, their energies are quantised. Many of the electronic transitions have energies that do not fall into the visible part of the electromagnetic spectrum. We show the quantised energy levels within an atom by means of an energy level diagram.

4.3 Describe the properties of electrons.

All electrons display certain basic characteristics. Every electron has a mass of $9.109 \times 10^{-31} \text{ kg}$ and a charge of $1.602 \times 10^{-19} \text{ C}$. Electrons have magnetic properties and, like light, electrons also display particle–wave duality. The wavelength associated with an electron is given by the equation $\lambda = \frac{h}{mu}$. The Heisenberg uncertainty principle states that we cannot simultaneously know both the position and the momentum of any particle, and this is particularly important for electrons.

4.4 Explain the properties of bound electrons.

Electrons bound to atoms have quantised energies, while free electrons can have any energy. The quantised energies of bound electrons are linked to their wave properties by the Schrödinger equation $\hat{H}\psi = E\psi$, which gives both the energies and wave-functions of a chemical system. This equation can be solved

exactly only for systems containing one electron, and a one-electron wavefunction is called an orbital.

Quantised properties of an atom can be indexed using quantum numbers. The principal quantum number (n) can have only positive integer values, and indexes both the energy of the electron and orbital size. The size of an orbital increases as n increases. The azimuthal quantum number (l) indexes the angular momentum of an atomic orbital and identifies the shape of the electron distribution of an orbital; it can be zero or any positive integer value smaller than n . Atomic orbitals are labelled according to their l value; s orbitals have $l = 0$, p orbitals have $l = 1$, d orbitals have $l = 2$ and f orbitals have $l = 3$. The magnetic quantum number (m_l) indexes the different possible orientations of the electron distribution of an orbital; it can have any positive or negative integer value from 0 to l . The spin quantum number (m_s) has possible values of $+\frac{1}{2}$ and $-\frac{1}{2}$, corresponding to the two possible spin states of an electron. All electrons within an atom can be described using sets of these four quantum numbers, and the Pauli exclusion principle states that each electron has a unique set.

4.5 Describe atomic orbitals in terms of electron distributions and energies.

The electron distribution of an orbital can be depicted in a variety of ways. A radial distribution function plot shows the distribution graphically in two dimensions, an electron density picture shows a cross-section of the distribution, while a boundary surface diagram shows the surface which encompasses (usually) 90% of the electron density. Areas of zero probability of finding an electron within an orbital are called nodes, and the number of these increase as n increases. The electron distribution of an s orbital is spherical, while those of p orbitals and four of the five d orbitals are dumbbell and cloverleaf shaped, respectively. The electron distribution of the d_{z^2} orbital resembles that of a p orbital surrounded by a doughnut. The two lobes of p orbitals have opposite phases, while the phases of the four lobes of a cloverleaf-shaped d orbital alternate. The doughnut of a d_{z^2} orbital is of opposite phase to the rest of the orbital.

The energy of an orbital in a one-electron system is determined by both the atomic number Z and the principal quantum number n . All orbitals in a one-electron system with the same value of n have the same energy — they are degenerate. This degeneracy is destroyed in multi-electron atoms. The energy of an orbital can be determined by measuring the ionisation energy, which is the energy required to remove an electron completely from that (usually valence) orbital. Ionisation energies are dependent on many factors, one of which is the shielding of the valence electrons from the nuclear charge by core electrons. Consequently, a valence electron in a multi-electron atom experiences a charge less than the full nuclear charge; this is called the effective nuclear charge (Z_{eff}). Electrons with a lower n shield electrons of higher n very efficiently, while, within groups of electrons of the same n , those having the lowest value of l shield those of higher l .

4.6 Explain the structure of the periodic table in terms of electrons.

The ground-state configuration of an atom is the lowest possible energy arrangement of the electrons. The order of filling atomic orbitals with electrons is dictated by: the Aufbau principle, which states that orbitals are filled in order of increasing energy; the Pauli exclusion principle, which states that no two electrons in an atom can have identical sets of the four quantum numbers; and Hund’s rule, which states that electrons occupy

sets of degenerate orbitals so as to give the maximum number of unpaired parallel spins. The s orbitals can accommodate 2 electrons, a set of p orbitals 6 and a set of d orbitals 10.

The shape of the periodic table of the elements derives from these orbital occupancies and the order in which the electrons are added. Elements with the same valence-electron configurations lie in the same group of the periodic table and have similar chemical properties. Valence electrons largely determine the chemistry of an element, while core electrons do not participate in chemical reactions.

4.7 Write electron configurations.

The electron configuration of an atom can be written by recording quantum numbers for all electrons in the atom, using a compact notation which shows the electron occupancy of each orbital type, or through an energy level diagram which shows the energy and occupancy of each orbital. In the last, electrons are depicted as arrows pointing either up ($m_s = +\frac{1}{2}$) or down ($m_s = -\frac{1}{2}$). We can also use an abbreviated compact notation that does not explicitly include the core electrons, but abbreviates them using the noble gas configuration of the nearest noble gas with lower Z . Some exceptions to the order of orbital filling occur, most notably for Cr and Cu. For anions, electrons are added to the electron configuration of the neutral atom, while for cations electrons are removed from that configuration. Atoms or ions having unpaired electrons are paramagnetic and will be attracted to a magnetic field, while species having all electrons paired are diamagnetic and are not attracted to a magnetic field. The electron configurations of excited states can

violate Hund's rule and the Aufbau principle but not the Pauli exclusion principle.

4.8 Describe periodic trends in chemical and physical properties.

The size of an atom is determined by factors such as nuclear charge, orbital energy and electron distribution, and shielding. Atomic radii give us a measure of the sizes of atoms. Atomic radii become smaller across a period and larger down a group of the periodic table. The first ionisation energies of the elements generally increase across a period and decrease down a group of the periodic table. Exceptions to these general trends occur when p orbitals are occupied by 1 or 4 electrons. Electron affinities become more negative across a period, but there is no clear trend down a group of the periodic table. Atomic cations are always smaller than the neutral atom and atomic anions are always larger than the neutral atom.

4.9 Describe periodic trends in relation to ions.

The nature of cations and anions is determined by the electron configuration of the neutral atom. Group 1 and group 2 elements form $1+$ and $2+$ cations, respectively, while group 17 elements form $1-$ anions. Isolated atomic anions with charges more negative than $1-$ are always unstable, and O^{2-} and S^{2-} are found only in combination with cations in ionic solids. Metals generally form cations readily through loss of s or d electrons. The p -block elements may be metals, metalloids or nonmetals. The s -block elements are found in the Earth's crust and also in living systems, and p -block elements display a wide variety of chemical properties.

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation										
Wavelength–frequency relationship	4.2	The product of wavelength (λ) and frequency (ν) is the speed of light (c). $c = \nu\lambda$										
Energy of a photon	4.2	This equation is used to calculate the energy carried by a photon of frequency ν . Also, ν can be calculated if E is known. $E = h\nu$										
de Broglie equation	4.3	This links the wavelength of a particle with its speed and mass. $p = \frac{h}{\lambda}$ $\lambda_{\text{particle}} = \frac{h}{mu}$										
Quantum numbers for atoms	4.4	Each electron in an atom is described by a unique set of four quantum numbers. The allowed values of these quantum numbers are as follows. <table><tr><th>Quantum number</th><th>Range</th></tr><tr><td>principal quantum number (n)</td><td>1, 2, ... , ∞</td></tr><tr><td>azimuthal quantum number (l)</td><td>0, 1, ... , ($n-1$)</td></tr><tr><td>magnetic quantum number (m_l)</td><td>$-l, \dots, -1, 0, +1, \dots, +l$</td></tr><tr><td>spin quantum number (m_s)</td><td>$-\frac{1}{2}, +\frac{1}{2}$</td></tr></table>	Quantum number	Range	principal quantum number (n)	1, 2, ... , ∞	azimuthal quantum number (l)	0, 1, ... , ($n-1$)	magnetic quantum number (m_l)	$-l, \dots, -1, 0, +1, \dots, +l$	spin quantum number (m_s)	$-\frac{1}{2}, +\frac{1}{2}$
Quantum number	Range											
principal quantum number (n)	1, 2, ... , ∞											
azimuthal quantum number (l)	0, 1, ... , ($n-1$)											
magnetic quantum number (m_l)	$-l, \dots, -1, 0, +1, \dots, +l$											
spin quantum number (m_s)	$-\frac{1}{2}, +\frac{1}{2}$											

(continued)

(continued)

Concept	Section	Description/equation
Periodic table	4.6	The periodic table is an aid in writing electron configurations of the elements. An element's location in the table is related to properties such as atomic radius, ionisation energy and electron affinity.
Electron configurations	4.7	These guidelines help us to write electron configurations for atoms or ions. - Count the total number of electrons for a neutral atom. - Add electrons for anions. - Subtract electrons for cations. - Fill orbitals to match the nearest noble gas of smaller atomic number. - Add remaining electrons to the next orbitals to be filled according to the Aufbau and Pauli exclusion principles, as well as Hund's rule. - For neutral atoms and anions, place electrons in ns before $(n-1)d$ and $(n-2)f$, keeping in mind that the order changes once the d and f levels are at least partially occupied. - For cations, start with the configuration of the neutral atom and then remove electrons from the ns before the $(n-1)d$ and $(n-2)f$ orbitals. - Look for exceptions and correct the configuration if necessary.
Periodic trends in atomic and ionic size	4.8	Periodic trends are evident in, for example: - atomic and ionic size - ionisation energy - electron affinity.

KEY TERMS

absorption spectrum The distribution of wavelengths of light absorbed by a species.

amplitude The maximum displacement of a wave from its centre.

atomic orbital A three-dimensional wave describing a bound electron.

atomic radius The distance from the nucleus of an atom at which electron–electron repulsion prevents closer approach of another atom. Also called metallic radius for metals and covalent radius for nonmetals. The atomic radius is determined by taking half the distance between nuclei of neighbouring atoms in an element.

Aufbau principle The most stable arrangement of electrons in an atom results from placing each successive electron in the most stable (lowest energy) available atomic orbital.

azimuthal quantum number (l) The quantum number, restricted to integers from 0 to $(n-1)$, that indexes the electron distribution of an atomic orbital.

boundary surface diagram A diagram that shows a solid surface that encloses most (often 90%) of an orbital's electron density. The electron density is high inside the volume enclosed by the surface but very low outside.

core electrons The inner atomic electrons that do not participate in chemical bonding.

degenerate Different arrangements or states with the same energy; in this context orbitals.

diamagnetic The quality of not being attracted to a magnetic field. Substances with no unpaired electrons are diamagnetic.

effective nuclear charge (Z_{eff}) The net positive charge, equal to the nuclear charge minus the effects of screening, that an electron in an atomic orbital experiences.

electromagnetic radiation Energy propagated through space in the form of oscillating electric and magnetic fields.

electron affinity (E_{ea}) The energy change accompanying the attachment of an electron to an atom or anion.

electron configuration The distribution of electrons among the various orbitals of an atom, molecule or ion.

electron density picture A two-dimensional dot drawing representing the distribution of electron density in an orbital.

emission spectrum The distribution of wavelengths of light given off by a species in an excited state.

energy level diagram A diagram of the specific energy levels of a species, showing increasing energy on the y-axis.

excited state Any state in which a chemical system is not in its lowest possible energy state.

frequency (ν) The number of full cycles of a wave that pass a given point in a second.

ground state The lowest possible energy state of a chemical system.

Hund's rule The lowest energy arrangement of electrons among orbitals of equal energy is the one that maximises the number of unpaired electron spins.

intensity The brightness (number of photons) of light.

ionisation energy (E_i) The energy required to remove an electron from an isolated species.

isoelectronic Having the same number of electrons.

light Electromagnetic radiation in the visible portion of the spectrum, that is, between $\lambda = 380 \text{ nm}$ and $\lambda = 780 \text{ nm}$.

magnetic quantum number (m_l) The quantum number, restricted to integers between $+1$ and -1 , that indexes the orientation in space of an atomic orbital.

noble gas configuration A distribution of electrons among the orbitals of an atom that matches that of one of the noble gases.

node A point, line or surface where the electron density of an orbital is zero.

paramagnetic Describes substances that are attracted into a magnetic field as a result of the presence of one or more unpaired electrons.

Pauli exclusion principle No two electrons in a chemical species can be described by the same set of four quantum numbers.

phase The starting position of a wave with respect to one wavelength.

photoelectric effect The ejection of electrons from a metal surface by light.

photons Particles of light, characterised by energy $E = h\nu$.

Planck's constant (h) The physical constant, 6.626×10^{-34} J s, that relates the energy of a photon to its frequency.

principal quantum number (n) The quantum number, restricted to positive integers, that indexes the energy and size of an atomic orbital.

quantised Having discrete allowed values.

quantum number An integer or half integer describing the allowed values of some quantised property.

radial distribution function plot A plot of the probability distribution of finding the electron at a distance, r , from the nucleus.

shielding The partial cancellation of the electrostatic attraction between the nucleus and an electron within an atom, caused by one or more electrons of lower principal quantum number.

spin The intrinsic angular momentum of electrons and protons that gives them magnetism.

spin quantum number (m_s) The quantum number, restricted to either $+\frac{1}{2}$ or $-\frac{1}{2}$, which indexes the orientation of electron spin.

uncertainty principle The assertion that position and momentum cannot both be exactly known.

valence electrons The electrons of an atom that occupy orbitals of highest principal quantum number and incompletely filled orbitals.

wavelength (λ) The distance between any two consecutive identical points on a wave.

REVIEW QUESTIONS

Characteristics of atoms

LO1

- 4.1** The density of titanium is 4.5×10^4 kg m $^{-3}$. The density of tungsten is 19.3×10^4 kg m $^{-3}$. For each metal:
- calculate the volume occupied per atom
 - estimate the atomic diameter
 - using your estimate from (b), calculate the thickness of a metal foil containing 9.3×10^6 atomic layers of the metal.
- 4.2** Describe evidence that indicates that atoms have mass.
- 4.3** Describe evidence that indicates that atoms have volume.

Characteristics of light

LO2

- 4.4** Calculate the frequencies (Hz) corresponding to the following wavelengths, using scientific notation.
- 735 nm
 - 2.50×10^{-10} m
 - 6.50 nm
 - 3.57 μ m
- 4.5** Calculate the wavelengths corresponding to the following frequencies, expressing the result in the indicated units.
- 3.77 GHz (m)
 - 25.0 kHz (cm)
 - 84 Hz (mm)
 - 2.22 MHz (μ m)
- 4.6** Calculate the energy in joules per photon and in kilojoules per mole of the following.
- blue-green light with a wavelength of 490.6 nm
 - X-rays with a wavelength of 15.4 nm
 - microwaves with a frequency of 2.25×10^{10} Hz
- 4.7** What are the wavelength and frequency of photons with the following energies?
- 635 kJ mol $^{-1}$
 - 3.50×10^{-19} J photon $^{-1}$
- 4.8** When light of frequency 1.30×10^{15} s $^{-1}$ shines on the surface of caesium metal, electrons are ejected with a maximum kinetic energy of 5.2×10^{-19} J. Calculate each of the following.
- the wavelength of this light
 - the binding energy of electrons to caesium metal
 - the longest wavelength of light that will eject electrons
- 4.9** A phototube delivers an electrical current when a beam of light strikes a metal surface inside the tube. Phototubes do not respond to infrared photons. Draw an energy level diagram for electrons in the metal of a phototube and use it to explain why phototubes do not respond to infrared light.
- 4.10** Refer to figure 4.5 to answer the following questions.
- What is the wavelength range for infrared radiation?
 - What colour is light with a wavelength of 5.3×10^{-7} m?

- In what region does radiation with frequency of 1.0×10^{18} Hz lie?

- 4.11** Determine the wavelengths of radiation that hydrogen atoms absorb to reach the $n = 4$ and $n = 7$ states from the ground state. In what region of the electromagnetic spectrum do these photons lie?

Properties of electrons

LO3

- 4.12** What is the charge in coulombs of 1 mol of electrons?
- 4.13** Determine the wavelengths of electrons with the following kinetic energies.
- 1.15×10^{-19} J
 - 3.55 kJ mol $^{-1}$
 - 7.45×10^{-3} J mol $^{-1}$
- 4.14** Determine the kinetic energies in joules of electrons with the following wavelengths.
- 4.88 nm
 - 6.48 m
 - 2.95 mm

Quantisation and quantum numbers

LO4

- 4.15** List all the valid sets of quantum numbers for a 4p electron.
- 4.16** If you know that an electron has $n = 5$, what are the possible values for its other quantum numbers?
- 4.17** For the following sets of quantum numbers, determine which describe actual orbitals and which are nonexistent. For each one that is nonexistent, list the restriction that forbids it.

	n	l	m_l	m_s
(a)	4	1	2	$-\frac{1}{2}$
(b)	3	1	0	$+\frac{1}{2}$
(c)	4	2	1	$-\frac{1}{2}$
(d)	2	1	-1	$+\frac{1}{2}$

Atomic orbital electron distributions and energies

LO5

- 4.18** Refer to figure 4.26. Draw the analogous set of three depictions for an orbital that has $n = 3$, $l = 1$.
- 4.19** Shown below are electron density pictures and radial distribution function plots for the 1s, 2s, 2p and 3p orbitals. Assign the various depictions to their respective orbitals.

- 4.20** What are the limitations of radial distribution function plots versus r ?
- 4.21** The conventional method of showing the three-dimensional electron distribution of an orbital is a boundary surface diagram. What are the limitations of this representation?
- 4.22** For each of the following pairs of orbitals, determine which is more stable and explain why.
- He $1s$ and He $2s$
 - V $4s$ and V $3d$
 - He $2s$ and He⁺ $2s$
- 4.23** In a hydrogen atom the $3s$, $3p$ and $3d$ orbitals all have the same energy. In a helium atom, however, the $3s$ orbital is lower in energy than the $3p$ orbital, which in turn is lower in energy than the $3d$ orbital. Explain why the energy rankings of hydrogen and helium are different.
- 4.24** The energy of the $n = 4$ orbital of the He⁺ ion is the same as the energy of the $n = 2$ orbital of the H atom. Explain this fact.
- 4.25** Refer to figure 4.31 to answer the following questions. In each case, provide a brief explanation of your choice.
- Which ionisation energies show that an electron in a $1s$ orbital provides nearly complete shielding of an electron in a $2p$ orbital?
 - Which ionisation energies show that the stability of $n = 2$ orbitals increases with Z^2 ?

Structure of the periodic table

LO6

- 4.26** Draw the periodic table in block form, and outline and label each of the following sets.
- elements that have half-filled p orbitals
 - elements for which $n = 4$ orbitals are filling

- elements that are two electrons short of filled d orbitals
- the first element that contains a $5p$ electron

4.27 How many valence electrons does each of the following atoms have?

- F
- Ti
- Ba
- Pb
- Hg

Electron configurations

LO7

4.28 Write the compact electron configuration, and list a correct set of quantum numbers for each of the valence electrons in the ground-state configurations of the following.

- Al
- S
- Ne
- N

4.29 Which of the atoms from question 4.28 are paramagnetic? Draw orbital energy level diagrams to support your answer.

4.30 The following are hypothetical configurations for a beryllium atom.

- $1s^3 2s^1$
- $1s^1 2s^3$
- $1s^1 2p^3$
- $1s^2 2s^1 2p^1$
- $1s^2 2s^2$
- $1s^2 1p^2$
- $1s^2 2s^1 2d^1$

- Which use nonexistent orbitals?
- Which are forbidden by the Pauli principle?
- Which are excited states?
- Which is the ground-state configuration?

4.31 Write the ground-state electron configurations, in abbreviated compact form, for O, Nb, As and Pb.

Periodicity of atomic properties

LO8

4.32 Arrange the following atoms in order of decreasing first ionisation energy (smallest last): Ar, Cl, Cs and K.

4.33 One element has these ionisation energies and electron affinity (all in kJ mol^{-1}): $E_{i1} = 376$, $E_{i2} = 2420$, $E_{i3} = 3400$, $E_{ea} = -45.5$. In which column of the periodic table is this element found? Give your reasoning.

4.34 According to appendix G, each of the following elements has a positive electron affinity. For each one, construct its valence orbital energy level diagram and use it to explain why the anion is unstable.

- N
- Mg
- Zn

4.35 From the following list, select the elements that form ionic compounds: Sr, C, Ag, Cs, Cl and Cr. Indicate whether each forms a stable cation or a stable anion.

Ions and chemical periodicity

LO9

4.36 Classify each of the elements from group 15 of the periodic table as a metal, a nonmetal or a metalloid.

4.37 Classify each of the elements listed in question 4.35 as a metal, a nonmetal or a metalloid.

REVIEW PROBLEMS

4.38 Redraw the first light wave in figure 4.4 to show a wave with amplitude twice as large as that shown in the figure, but with the same frequency.

LO2

4.39 A minimum of $216.4 \text{ kJ mol}^{-1}$ is required to remove an electron from a potassium metal surface. What is the longest wavelength of light that can do this?

LO2

4.40 In a photoelectric effect experiment, the minimum frequency needed to eject electrons from a metal is $7.5 \times 10^{14} \text{ s}^{-1}$.

Suppose that a 366 nm photon from a mercury discharge lamp strikes the metal. Calculate the following. **L02**

- the binding energy of the electrons in the metal
 - the maximum kinetic energy of the ejected electrons
 - the wavelength associated with those electrons
- 4.41** Microwave ovens use radiation with a wavelength of 20.0 cm. What is the frequency and energy in kJ mol^{-1} of this radiation? **L02**
- 4.42** Barium salts used in fireworks generate a yellow-green colour. Ba^{2+} ions emit light with $\lambda = 487, 514, 543, 553$ and 578 nm. Convert these wavelengths into frequencies and into energies in kJ mol^{-1} . **L02**
- 4.43** A hydrogen atom emits a photon as its electron changes from $n = 4$ to $n = 1$. What is the wavelength of the photon? In what region of the electromagnetic spectrum is this photon found? **L02**
- 4.44** List the properties of electrons and of photons, including the equations that are used to describe each. **L02,3**
- 4.45** Write a short description of each of the following. **L02,3**
- the photoelectric effect
 - particle-wave duality
 - electron spin
 - the uncertainty principle
- 4.46** Write brief explanations of each of the following. **L04,5,6**
- shielding
 - the Pauli exclusion principle
 - the Aufbau principle
 - Hund's rule
 - valence electrons
- 4.47** Describe an atomic energy level diagram and the information it incorporates. **L05**
- 4.48** Construct an orbital energy level diagram for all orbitals with $n < 5$ and $l < 4$. Use the periodic table to help determine the correct order of the energy levels. **L05**
- 4.49** Describe periodic variations in electron configurations; explain how they affect ionisation energy and electron affinity. **L07,8**
- 4.50** Write the abbreviated compact electron configuration for the Mn^{4+} ground state, and give a set of quantum numbers for all electrons in the least stable occupied orbital. **L07**
- 4.51** Which has the most unpaired electrons, S^+ , S or S^{2-} ? Use electron configurations to support your answer. **L07**
- 4.52** None of the following four electron energy diagrams describes the ground state of a sulfur atom. For each, state the reason why it is not correct. **L07**

- 4.53** Identify the ionic compounds that best fit the following descriptions. **L08,9**
- the group 2 cation with the second smallest radius combined with a group 16 anion that is isoelectronic with the noble gas from row 3
 - a +1 ion that is isoelectronic with the noble gas from row 3, combined with the anion formed from the row 2 element with the highest electron affinity
 - the group 2 metal with the highest second ionisation energy that combines in a 1 : 2 ratio with an element from row 3
- 4.54** Arrange the following in order of decreasing size (radius): Cl^- , K^+ , Cl and Br^- . Explain your rankings in terms of quantum numbers and electrical interactions. **L08**
- 4.55** Draw energy level diagrams that show the ground-state valence electron configurations for Cu^{2+} , Mn^{3+} and Ag^+ . **L07**
- 4.56** Write a brief explanation for each of the following. **L08**
- In a hydrogen atom, the 2s and 2p orbitals have identical energy.
 - In a helium atom, the 2s and 2p orbitals have different energies.
- 4.57** Refer to figure 4.41 to answer the following questions about first ionisation energies. **L08**
- Which element shows the greatest decrease from its neighbour of next lower Z ?
 - What is the atomic number of the element with the lowest value?
 - Identify three ranges of Z across which the value changes the least.
 - List the atomic numbers of all elements whose values are between 925 and 1050 kJ mol^{-1} .

ADDITIONAL EXERCISES

- 4.58** The graph shows the results of photoelectron experiments on two metals, using light of the same energy. **L02**

- (a) Calculate the binding energy of each metal. Which has the higher binding energy? Explain.
 (b) Calculate the kinetic energies of electrons ejected from each metal by photons with wavelength of 125 nm.
 (c) Calculate the wavelength range over which photons can eject electrons from one metal but not from the other.
- 4.59** Energetic free electrons can transfer their energy to bound electrons in atoms. In 1913, James Franck and Gustav Hertz passed electrons through mercury vapour at low pressure to determine the minimum kinetic energy required to produce the excited state that emits ultraviolet light at 253.7 nm. What is that minimum kinetic energy? What wavelength is associated with electrons of this energy? **L02**
- 4.60** The diameter of a typical atom is 10^{-10} m , and the diameter of a typical nucleus is 10^{-15} m . Calculate typical atomic and nuclear volumes and determine what fraction of the volume of a typical atom is occupied by its nucleus. **L05**
- 4.61** Neutrons, like electrons and photons, are particle–waves with diffraction patterns that can be used to determine the structures of crystalline solids. Calculate the kinetic energy of a neutron with a wavelength of 68 pm. **L03**
- 4.62** The human eye can detect as little as $2.35 \times 10^{-18} \text{ J}$ of green light with a wavelength of 510 nm. Calculate the minimum number of photons of green light that can be detected by the human eye. **L02**
- 4.63** Gaseous lithium atoms absorb light with a wavelength of 353 nm. The resulting excited lithium atoms lose some energy through collisions with other atoms. The atoms then return to their ground state by emitting two photons with $\lambda = 812.7$ and 670.8 nm. Draw an energy level diagram that shows this process. What fraction of the energy of the absorbed photon is lost in collisions? **L02**
- 4.64** Calculate the wavelengths associated with an electron and a proton, each travelling at 6.750% of the speed of light. **L02**
- 4.65** One hydrogen emission line has a wavelength of 434 nm. Identify the values for n_{final} and n_{initial} for the transition giving rise to this line. **L02**

- 4.66** An atomic energy level diagram, shown to scale, follows. **L02**

An excited-state atom emits photons when the electron moves in succession from level *d* to level *c*, from level *c* to level *b*, and from level *b* to the ground state (level *a*). The wavelengths of the emitted photons are 565 nm, 152 nm and 121 nm (not necessarily in the proper sequence). Match each emission with the appropriate wavelength and calculate the energies of levels *b*, *c* and *d* relative to level *a*.

- 4.67** Small helium–neon lasers emit 1.0 mJ s^{-1} of light at 634 nm. How many photons does such a laser emit in 10 s? **L02**
- 4.68** The argon-ion laser has major emission lines at 488 and 514 nm. Each of these emissions leaves the Ar^+ ion in an energy level that is $2.76 \times 10^{-18} \text{ J}$ above the ground state. **L02**
- (a) Calculate the energies of the two emission wavelengths in joules.
 (b) Draw an energy level diagram (in joules per atom) that illustrates these facts.
 (c) What is the frequency and wavelength of the radiation emitted when the Ar^+ ion returns to its lowest energy level?
- 4.69** The series of emission lines that results from excited hydrogen atoms undergoing transitions to the $n = 3$ level is called the Paschen series. Calculate the energies of the first five lines in this series of transitions, and draw an energy level diagram that shows them to scale. **L02**
- 4.70** It takes 486 kJ mol^{-1} to remove electrons completely from sodium atoms. Sodium atoms absorb and emit light of wavelengths 589.6 and 590.0 nm. **L02**
- (a) Calculate the energies of these two wavelengths in kJ mol^{-1} .
 (b) Draw an energy level diagram for sodium atoms that shows the levels involved in these transitions and the ionisation energy.
 (c) If a sodium atom has already absorbed a 590.0 nm photon, what is the wavelength of the second photon a sodium atom must absorb in order to remove an electron completely?

- 4.71** The photoelectric effect for magnesium metal has a threshold frequency of $8.95 \times 10^{14} \text{ s}^{-1}$. Can Mg be used in photoelectric devices that sense visible light? Perform a calculation to support your answer. **L02**
- 4.72** Make a plot of radial distribution functions that shows how the $3s$ and $3p$ orbitals are shielded effectively by the $2p$ orbitals. Provide a brief explanation of your plot. **L05**
- 4.73** The idea of an atomic radius is inherently ambiguous. Explain why this is so. **L05**
- 4.74** Write the electron configuration for the lowest energy excited state of each of the following: B, S^{2-} , Br^- , Mg^{2+} and Sb^{3+} . **L07**
- 4.75** Write the ground-state configurations for the isoelectronic species Ce^{2+} , La^+ and Ba. Are they the same? What features of orbital energies account for this? **L07**
- 4.76** The ionisation energy of sodium atoms in the gas phase is about 30% smaller than the ionisation energy of magnesium atoms in the gas phase. In contrast, the ionisation energy of Na^+ is about three times larger than the ionisation energy of Mg^+ . Explain the difference between the atoms and the ions. **L08**
- 4.77** The figures below show Cl^- , Ar, and K^+ drawn to scale. Decide which figure corresponds to which species and explain your reasoning. **L08**
- 4.78** Use the data in appendix G to explain why the noble gases seldom take part in chemical reactions. **L08,9**
- 4.79** From its location in the periodic table, predict some of the physical and chemical properties of radium. What element does it most closely resemble? **L08**
- 4.80** What would be the next two orbitals to fill after the $6p$ orbital? **L06**
- 4.81** Which has the less stable $3s$ orbital, a sodium atom or an Na^+ cation? Explain your reasoning. **L08**
- 4.82** The first four ionisation energies of boron are as follows. $E_{i1} = 807 \text{ kJ mol}^{-1}$, $E_{i2} = 2433 \text{ kJ mol}^{-1}$, $E_{i3} = 3666 \text{ kJ mol}^{-1}$ and $E_{i4} = 25\,033 \text{ kJ mol}^{-1}$. **L08**
- Explain the trend in ionisation energies.
 - Rank ions of boron in order of ionic radius, from largest to smallest.
 - Which ion of boron has the largest electron affinity?
- 4.83** Use electron–electron repulsion and orbital energies to explain the following irregularities in first ionisation energies. **L05,8**
- Boron has a lower ionisation energy than beryllium.
 - Sulfur has a lower ionisation energy than phosphorus.

Chemical bonding and molecular structure

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 5.1** describe qualitatively the bonding in molecules
 - 5.2** describe qualitatively the bonding in ionic compounds
 - 5.3** determine Lewis structures for molecular compounds
 - 5.4** apply the VSEPR concept to determine the geometry of molecular compounds
 - 5.5** identify and explain properties of covalent bonds
 - 5.6** analyse bonding in molecules using valence bond theory
 - 5.7** analyse bonding in molecules using molecular orbital theory.
-

Figure 5.1 shows Australia's Ash Barty on the way to winning the 2021 Championship at Wimbledon. Professional tennis racquets are strung with high-tech materials that enable power and precision.

FIGURE 5.1

The strings of tennis racquets, like the ones used by Ash Barty during her successful 2021 Wimbledon campaign, are made from a range of polymers or mixtures that underpin power and shot precision.

Producing high-tech fibres requires a thorough understanding of chemical bonding, because the fibres are constructed of polymers, large molecules that are held together by covalent bonds in which electrons are shared between atoms. The ways in which chemical bonds are formed depend on the nature of the elements involved, and chemical bonds show a variety of forms and strengths.

This chapter describes chemical bonding and its relationship to molecular structure. We discuss the two extremes of chemical bonding: ionic, in which electrostatic forces hold ionic arrangements together, and covalent, where shared electron pairs dictate the bonding and geometry of individual molecules. We show how simple Lewis theory gives a good approximation of the distribution of electrons within molecules, and how we can use this to predict molecular geometry using valence-shell-electron-pair repulsion theory. We then consider in detail the two predominant theories used to describe covalent bonding: valence bond theory and molecular orbital theory.

5.1 Fundamentals of bonding

LEARNING OBJECTIVE 5.1 Describe qualitatively the bonding in molecules.

We learned in the chapter on atomic energy levels that the size, energy levels and electron configuration of an atom determine its chemical properties. In molecular compounds, electrons on atoms interact and are shared between atoms. In ionic compounds, electrons are transferred completely between atoms to form positively and negatively charged ions. Since electrons have both particle- and wave-like properties, bonding interactions can be described from either viewpoint. Keep in mind, though, that either model might be better at explaining certain aspects of reality.

The electrostatic energy between two charged species is proportional to the magnitudes of the charges and inversely proportional to the distance between them. Charges of opposite sign attract one another, but like charges repel. The relationship is given by Coulomb's law.

$$E_{\text{electrostatic}} = k \frac{q_1 q_2}{r}$$

In this equation:

$E_{\text{electrostatic}}$ = electrostatic potential energy (J)

q_1 = charge on species 1 (C)

q_2 = charge on species 2 (C)

r = separation distance between the pair of charges (m)

$k = 9.00 \times 10^9 \text{ N m}^2 \text{ C}^{-2}$ (Coulomb's constant in vacuum)

The equation describes the potential energy of one pair of charges. Molecules, however, contain two or more nuclei and two or more electrons. To obtain the total potential energy of a molecule, the equation must be applied to every possible pair of charged species. There are three types of these pair-wise interactions (see figure 5.2).

1. Electrons and nuclei attract one another. Attractive interactions are energetically favourable, so an electron attracted to a nucleus is at a lower energy than a free electron.
2. Electrons repel each other, raising the energy and reducing the stability of a molecule.
3. Nuclei repel each other, so these interactions also reduce the stability of a molecule.

In any molecule, these three interactions are balanced to give the molecule its greatest possible stability. This balance is achieved when the electron density is situated between the nuclei of bonded atoms. We view the electrons as being shared between the nuclei and call this shared electron density a **covalent bond**. For any covalent bond, the attractive energy between nuclei and electrons exceeds the repulsive energy arising from nuclear–nuclear and electron–electron interactions.

FIGURE 5.2

When electrons are in the region between two hydrogen nuclei, attractive electrostatic forces exceed repulsive electrostatic forces, leading to the stable arrangement of a chemical bond.

The hydrogen molecule

These concepts are demonstrated below for the simplest stable neutral molecule, molecular hydrogen. A hydrogen molecule, H_2 , contains just two nuclei and two electrons.

Consider what happens when two hydrogen atoms come together and form a covalent bond. As the atoms approach, each nucleus attracts the opposite electron, pulling the two atoms closer together. At the same time, the two nuclei repel each other, as do the two electrons. These repulsive interactions tend to keep the atoms apart.

For H_2 to be a stable molecule, the sum of the attractive energies must exceed the sum of the repulsive energies. Figure 5.2 shows a static arrangement of electrons and nuclei in which the electron–nucleus distances are shorter than the electron–electron and nucleus–nucleus distances. As the charges on the hydrogen nuclei and electrons are $1+$ and $1-$ respectively, the distances between them become crucial in determining the energy of this arrangement. In this case, attractive interactions exceed repulsive interactions, leading to a stable molecule. Notice that the two electrons occupy the region between the two nuclei where they can interact with both nuclei at once; that is, the atoms share the electrons in a covalent bond.

An actual molecule is dynamic, not static, and both the electrons and nuclei move continuously. In a covalent bond, the most probable electron locations are between the nuclei, where, in this model, they can be viewed as being shared between the bonded atoms.

Bond length and bond energy

As two hydrogen atoms come together to form a molecule, attractive forces between nuclei and electrons make the hydrogen molecule more stable than the individual hydrogen atoms. The amount of increased stability depends on the distance between the nuclei, as shown in figure 5.3. At distances greater than 300 pm (300×10^{-12} m), there is almost no interaction between the atoms, so the total energy is the sum of the energies of the two individual atoms. At closer distances, the attraction between the electron of one atom and the nucleus of the other atom increases, and the combined atoms become more stable. Moving the atoms closer together generates greater stability until the nuclei are 74 pm apart. At this distance, we obtain the best possible balance between the attractive and repulsive forces in the molecule. At distances closer than 74 pm, the nucleus–nucleus repulsion begins to dominate and the energy of the system increases rapidly. Thus, at a separation distance of 74 pm, the hydrogen molecule has the maximum energetic advantage (7.22×10^{-19} J) over two separated hydrogen atoms. The atoms in the molecule are not static; instead they move continuously, oscillating about their lowest energy separation distance like two spheres attached to opposite ends of a spring.

FIGURE 5.3

The interaction energy of two hydrogen atoms depends on the distance between the nuclei.

Figure 5.3 illustrates two characteristic features of covalent bonds. The separation distance at which the molecule has the maximum energetic advantage over the separated atoms (74 pm for H_2) is known as the **bond length**. The energy difference between the molecule and the separated atoms is called the **bond energy**. **Bond energy** is defined as the energy required to break the bond and therefore is always positive. Bond lengths and energies are important properties of chemical bonds and, as we will see, they are related. It is usual to quote bond energies in units of kJ mol^{-1} . We can obtain this value for the hydrogen molecule by multiplying the energy of a single H—H bond (7.22×10^{-19} J) by N_A ($6.022 \times 10^{23} \text{ mol}^{-1}$). This gives a H—H bond energy of 435 kJ mol^{-1} . Each different chemical bond has a characteristic bond length and bond energy.

The most probable position of the electrons in the hydrogen molecule is between the nuclei. If we rotate the molecule about its internuclear axis (an imaginary line joining the two nuclei) we find that the electron distribution between the nuclei looks exactly the same, regardless of the angle through which it was rotated. In other words, the bond is symmetric with respect to rotation about the internuclear axis. Bonds for which this is true are called **sigma (σ) bonds**.

Other diatomic molecules: F_2

Bond formation in H_2 is relatively easy to describe because we need to consider just two electrons. However, even when the atoms within a molecule contain many electrons, we can still consider bond formation as the sharing of only two electrons. We will illustrate this with the fluorine molecule, F_2 .

As two fluorine atoms approach each other, the electrons of each atom feel the attraction of the nucleus of the other atom, just as in H_2 . In this case, the valence $2p$ electrons are closest to the neighbouring nucleus and experience the strongest attraction. The single electron in one of the $2p$ orbitals approaches the opposite nucleus. Consequently, we can describe the $F-F$ bond as the sharing of two electrons from the fluorine $2p$ orbitals that point directly towards each other (see figure 5.4). Note that the resulting bond is a σ bond.

FIGURE 5.4

The chemical bond in F_2 forms from strong electrostatic attraction of the electron in the fluorine $2p$ orbital that points directly at the neighbouring nucleus.

Unequal electron sharing

Each nucleus within a hydrogen molecule and each within a fluorine molecule has the same charge. Consequently, both nuclei attract electrons equally. The result is a symmetrical distribution of the electron density around the atoms. In a chemical bond between any two identical atoms, the nuclei share the bonding electrons equally.

In contrast to the symmetrical forces in H_2 and F_2 , the bonding electrons in HF experience *unsymmetrical* attractive forces. The effective nuclear charge of a fluorine atom is significantly greater than the effective charge of a hydrogen atom, as described in the chapter on atomic energy levels, so the electrons shared between H and F feel a stronger attraction to the F atom. Unequal attractive forces lead to an unsymmetrical distribution of the bonding electrons. The HF molecule is most stable when its bonding electrons are concentrated closer to the fluorine atom and away from the hydrogen atom. This unequal distribution of electron density gives the fluorine end of the molecule a small negative charge and the hydrogen end a small positive charge; however, the molecule as a whole remains electrically neutral.

These partial charges are less than one charge unit and are equal in magnitude. To indicate such partial charges, we use the symbols $\delta+$ and $\delta-$ (δ is the lower-case Greek letter delta) or an arrow pointing from the negative end towards the positive end of the molecule, or an electron density surface, which shows the spread of charge using colours, with blue being positive and red being negative as shown for HF in figure 5.5. (Refer back to figure 2.16 to remind yourself of the colours we use in this text to represent atoms of the various elements in space-filling and ball-and-stick models.) The unequal sharing of electrons results in a **polar covalent bond**. We describe bond polarity and its consequences in section 5.5.

Note that, despite being polar, the $H-F$ bond is still a σ bond, because it remains unchanged as we rotate the molecule about the $H-F$ bond axis.

FIGURE 5.5

Unequal sharing of electron density in HF results in a polar covalent bond. The colour gradient represents the variation in electron density shared between the atoms.

As elements differ in their effective nuclear charges, atoms of each element have a characteristic ability to attract electrons within a covalent bond. This ability is called **electronegativity** and is symbolised by χ (the lower-case Greek letter chi). A bond between two elements of different electronegativities will be polar, and the greater the difference ($\Delta\chi$), the more polar the bond.

Electronegativity gives a numerical value to how strongly an atom attracts the electrons in a chemical bond. This property of an atom involved in a bond is related to, but distinct from, ionisation energy and electron affinity. As described in the chapter on atomic energy levels, ionisation energy measures how strongly an atom attracts one of its own electrons. Electron affinity specifies how strongly an atom attracts a free electron.

Electronegativities, which have no units, are estimated by using combinations of atomic and molecular properties. Linus Pauling (figure 5.6) developed the commonly used values that are presented in the periodic table shown in figure 5.7, based on bond energies. These values are often called the Pauling scale of electronegativity.

FIGURE 5.6

Linus Pauling (1901–1994) was one of the most influential thinkers of twentieth-century chemistry and was awarded the Nobel Prize in chemistry in 1954 for his research into the nature of the chemical bond. He was also one of the few people to be awarded two Nobel Prizes, receiving the peace prize in 1962 for his stand against nuclear weapons, which led the US government to revoke his passport in 1952.

Figure 5.7 shows that electronegativity is a periodic property. Electronegativities generally increase from the lower left to the upper right of the periodic table. The elements francium and caesium ($\chi = 0.7$) have the lowest value, and fluorine ($\chi = 4.0$) has the highest value. Electronegativities also generally decrease down most groups and increase from left to right across the *s* and *p* blocks. As with ionisation energies, variations in effective nuclear charge and principal quantum number explain electronegativity trends. Metals generally have lower electronegativities ($\chi = 0.7$ to 2.4) compared to nonmetals ($\chi = 2.1$ to 4.0). As expected from their intermediate character between metals and nonmetals, metalloids have electronegativities that are larger than the values for most metals and smaller than those for most nonmetals.

Electronegativity differences ($\Delta\chi$) between bonded atoms indicate where a particular bond lies on the continuum of bond polarities. Three fluorine-containing substances, F_2 , HF and CsF, represent the range of variation. At one end of the continuum, the bonding electrons in F_2 are shared equally between the two fluorine atoms ($\Delta\chi = 4.0 - 4.0 = 0$). At the other limit, CsF ($\Delta\chi = 4.0 - 0.7 = 3.3$) is a compound in which electrons have been fully transferred to give Cs^+ cations and F^- anions. We call such compounds

ionic compounds, and they will be discussed in more detail in the next section. Most bonds, including the bond in HF ($\Delta\chi = 4.0 - 2.1 = 1.9$), fall between these extremes. These are polar covalent bonds, in which two atoms share electrons unequally.

FIGURE 5.7

Electronegativities of the elements vary periodically. While there are some exceptions, the general trend is that electronegativity increases from left to right and decreases from top to bottom of the periodic table. The Pauling scale omits group 18 elements (the noble gases) because they are very unreactive and, with very few exceptions, do not form covalent bonds. Some other electronegativity scales do assign values to these elements.

CHEMICAL CONNECTIONS

Electromagnetic radiation and cancer

The ability of light to provide the energy for chemical reactions enables life to exist on our planet. Green plants absorb sunlight and, with the help of chlorophyll, convert carbon dioxide and water into carbohydrates (e.g. sugars and cellulose), which are essential constituents of the food chain. However, not all effects of sunlight are so beneficial.

As we saw in the chapter on atomic energy levels, light has energy that is proportional to its frequency, and, if the photons that are absorbed by a substance have enough energy, they can rupture chemical bonds and initiate chemical reactions. The carbon-carbon and carbon-hydrogen covalent bonds in organic molecules typically have ener-

gies of at least 350 kJ mol^{-1} . Visible light, which ranges from 780 nm to 380 nm in wavelength, has a corresponding energy range of approximately 153 to 315 kJ mol^{-1} , and therefore photons of visible light are not sufficiently energetic to break such bonds. However, ultraviolet radiation, which has shorter wavelengths and hence higher energies, can be dangerous in this respect, particularly light of wavelength less than 340 nm, which has energy greater than 350 kJ mol^{-1} . The sunlight illuminating the Earth contains substantial amounts of UV radiation. Fortunately, a layer of ozone, O_3 , in the stratosphere, a region of the atmosphere extending from about 45 to 55 km altitude, absorbs most of the incoming UV, protecting life on the surface. However,

some UV radiation does get through, and the part of the spectrum of most concern is called UV-B with wavelengths between 280 and 320 nm.

What makes UV-B so dangerous is its ability to affect the DNA in our cells. Absorption of UV radiation causes constituents of the DNA, called *pyrimidine bases*, to undergo reactions that form bonds between them. This causes transcription errors when the DNA replicates during cell division, giving rise to genetic mutations that can lead to skin cancers. These skin cancers fall into three classes: basal cell carcinomas, squamous cell carcinomas and melanomas, the last being the most dangerous. Each year more than 1 million cases of skin cancer are diagnosed worldwide. It is estimated that more than 90% of skin cancers are due to absorption of UV-B radiation.

In Australia, public health campaigns encourage people to avoid exposure to the sun when the UV index is high. They are further encouraged to protect themselves with clothing, hats, sunglasses and sunblock creams (figure 5.8). Sunblock creams work by either reflecting or absorbing UV radiation before it reaches the skin.

FIGURE 5.8

Sunlight carries the risk of skin cancer to those particularly susceptible. Understanding the risk allows us to protect ourselves with clothing and sunblock creams.

5.2 Ionic bonding

LEARNING OBJECTIVE 5.2 Describe qualitatively the bonding in ionic compounds.

Compounds formed between elements of very different electronegativities are often predominantly ionic in character. For example, ionic compounds form when elements from groups 1 or 2 react with elements from groups 16 or 17 to form cations and anions, respectively. Most ionic compounds are solids with relatively high melting points, particularly if the ionic solids are composed of atomic or small molecular ions. Ionic compounds containing large molecular ions have lower melting points, and if the melting point is below 100 °C, the compounds are classified as ionic liquids. Some ionic liquids are liquid even at room temperature, and those have important applications. However, a detailed discussion of ionic liquids is beyond the scope of this text.

The bonding in ionic compounds differs fundamentally from that in covalent compounds; it does not involve the sharing of pairs of electrons. Instead, ionic compounds are held together by the non-directional attractive forces between oppositely charged ions, leading to three-dimensional arrangements rather than distinct molecules.

Consider, sodium chloride, NaCl. The structure of this compound has each Na^+ cation surrounded by six Cl^- anions and each Cl^- anion surrounded by six Na^+ cations, as shown in figure 5.9.

This arrangement of Na^+ cations and Cl^- anions was first determined in 1913 by Australian-born Sir William Lawrence Bragg, using X-ray equipment designed by his father, Sir William Henry Bragg (figure 5.10). NaCl was the first compound whose structure was determined by X-ray crystallography (see the chapter on condensed phases), a field in which the Braggs were pioneers. They were jointly awarded the Nobel Prize in physics in 1915. Crystal structures determined through analysis of X-ray diffraction data show the precise locations of atoms within a chemical species and give atomic separations accurate to about 1×10^{-12} m. X-ray crystallography is a vital part of modern chemistry and is the source of much of the structural information that you will encounter later in this text.

FIGURE 5.9

Representation of the unit cell (see the chapter on condensed phases) of sodium chloride, NaCl. In NaCl, each Na^+ cation is surrounded by six Cl^- anions, and each Cl^- anion is surrounded by six Na^+ cations.

FIGURE 5.10

Sir William Lawrence Bragg (left) and his father Sir William Henry Bragg were awarded the Nobel Prize in physics in 1915 for their work on X-ray crystallography.

The distance between the ions in NaCl is determined by a balance of the Coulombic (electrostatic) attractions and repulsions between both the electron densities and nuclei of neighbouring ions. At room temperature, the distance between the centres of neighbouring ions is 2.82×10^{-10} m. Using this number, we can calculate the magnitude of the attractive forces between two neighbouring Na^+ and Cl^- ions using the equation introduced at the start of this chapter.

$$E_{\text{electrostatic}} = k \frac{q_1 q_2}{r}$$

Given that q_1 is $+1.60 \times 10^{-19}$ C, q_2 is -1.60×10^{-19} C (-1.60×10^{-19} C is the fundamental charge of a single electron) and $k = 9.00 \times 10^9 \text{ N m}^2 \text{ C}^{-2}$, we obtain a value of -8.17×10^{-19} J, which equates to -492 kJ mol^{-1} when multiplied by the Avogadro constant. This corresponds to the energy released (hence the negative sign) when 1 mol of gaseous Na^+ and gaseous Cl^- ions are brought from an infinite distance to a separation of 2.82×10^{-10} m. However, this value takes into account only the attractive forces to one nearest neighbour, whereas each ion in the crystal has six. If we take all six interactions into account, as well as repulsive interactions between ions of the same charge in the structure, we obtain a value of -769 kJ mol^{-1} . This is a substantial amount of energy, and means that, in order to break 1 mol of the compound into its constituent gaseous ions, we would have to supply 769 kJ of energy. This is called the **lattice energy** of the compound. Among other factors, the lattice energy of a compound is dependent on the charges of the ions; as the charges increase, the lattice energy becomes more positive and the ions become harder to separate from one another. We also expect lattice energy values to decrease as the ions get larger, because r , the distance between them, will increase. These trends are illustrated in table 5.1, which gives some lattice energy values for ionic species.

The effect of ionic size on lattice energy is shown by the fact that lattice energies of the group 1 chlorides decrease as the size of the cation increases from Li^+ to Rb^+ , and the lattice energies of the sodium halides decrease as the size of the anion increases from F^- to I^- . The effect of ionic charge is seen by comparing the lattice energies of the compounds formed from the 2+ ions with halide anions. In all cases, these lattice energies are much larger than those for the 1+/1- combinations. The values for compounds containing 2+ and 2- ions are even larger, with the lattice energy of MgO being almost four times the lattice energy of LiF. The structure type of the ionic compound (see the chapter on condensed phases) also has an influence on lattice energy, but a detailed discussion is beyond the scope of this text.

TABLE 5.1 Lattice energies for a number of ionic compounds. All values are in kJ mol^{-1} .

Cation	Anion				
	F^-	Cl^-	Br^-	I^-	O^{2-}
Li^+	1030	834	788	730	2799
Na^+	910	769	732	682	2481
K^+	808	701	671	632	2238
Rb^+	774	680	651	617	2163
Mg^{2+}	2913	2326	2097	1944	3795
Ca^{2+}	2609	2223	2132	1905	3414
Sr^{2+}	2476	2127	2008	1937	3217
Ba^{2+}	2341	2033	1950	1831	3029

While the ionic model describes a number of metal halides, oxides and sulfides well, it does not describe most other chemical substances adequately. Compounds such as CaO , NaCl and MgF_2 behave like simple cations and anions held together by electrostatic attraction, but compounds such as CO , Cl_2 and HF do not. We must describe the bonding in these latter compounds in terms of the sharing of electrons between atoms. There are two predominant theories of bonding which do this. Before we study these, we will look at a simple way of determining the electron distribution in molecules and how we can use this to predict the shape of a particular molecule.

5.3 Lewis structures

LEARNING OBJECTIVE 5.3 Determine Lewis structures for molecular compounds.

In this section, we develop a process for making schematic drawings that show how the atoms in a molecule are connected. In addition, these drawings, known as **Lewis structures**, allow us to differentiate between bonding and nonbonding valence electrons in a molecule. From this perspective, writing a Lewis structure is the first step in developing a bonding description of a molecule. Lewis structures are named after their originator, the American physical chemist Gilbert N Lewis.

The conventions

Lewis structures are drawn according to the following conventions.

1. *Each atom is represented by its elemental symbol.* In this respect, a Lewis structure is an extension of the chemical formula.
2. *Only the valence electrons appear in a Lewis structure.* Recall from the chapter on atomic energy levels that only valence electrons are accessible for bonding.
3. *A line joining two elemental symbols represents one pair of electrons that is shared between two atoms.* Two atoms may share electrons in a **single bond** (2 shared electrons, 1 line), a **double bond** (4 shared electrons, 2 lines) or a **triple bond** (6 shared electrons, 3 lines).
4. *Dots placed next to an elemental symbol represent nonbonding electrons on that atom.* Nonbonding electrons usually occur in pairs.

The use of these conventions is shown, using the HF molecule as an example, in figure 5.11.

These conventions divide electrons in molecules into three groups. Core electrons do not appear in Lewis structures. Bonding valence electrons are shared between atoms and are represented by lines. Nonbonding valence electrons are localised on atoms and are represented by dots.

FIGURE 5.11 The Lewis structure conventions for hydrogen fluoride

1. Elemental symbols represent atoms.	H	F
2. Only valence electrons appear.	$1s \uparrow$	$2s \uparrow\downarrow \quad 2p \uparrow\downarrow \uparrow\downarrow \uparrow$
3. Lines represent bonds.	H — F	
4. Dots represent nonbonding electrons.	H — $\ddot{\text{F}}:$	

We use the following five-step procedure to draw Lewis structures.

Step 1: Count the valence electrons.

Step 2: Assemble the bonding framework using single bonds.

Step 3: Place three nonbonding pairs of electrons on each outer atom except H. (*Note:* Outer atoms are those that are bonded to only one other atom, while inner atoms are those bonded to more than one other atom.)

Step 4: Assign the remaining valence electrons to inner atoms.

Step 5: Minimise formal charges on all atoms. Negative formal charges should be on the more electronegative atoms and positive charges on the less electronegative atoms, if possible.

Building Lewis structures

Learning how to draw Lewis structures is best done through examples. We will work through the five steps using the nitrosyl chloride molecule, NOCl.

Step 1: Count the valence electrons. If the species is an ion, add or subtract one electron for each negative or positive charge, respectively. Nitrogen (group 15) has the valence electron configuration $2s^2 2p^3$, the configuration of oxygen (group 16) is $2s^2 2p^4$, while the configuration of chlorine (group 17) is $3s^2 3p^5$. Hence, there is a total of $(5 + 6 + 7) = 18$ valence electrons from the atoms themselves. The molecule is uncharged, so the total number of valence electrons is 18.

Step 2: Assemble the bonding framework using single bonds. This step is straightforward for organic molecules, which consist predominantly of C and H atoms, as there is no ambiguity as to the possible placement of atoms. However, care must be taken when drawing structures of inorganic molecules. Structures will generally consist of an inner (central) atom connected to two or more other (outer) atoms. The outer atoms will generally be either hydrogen or the most electronegative of the atoms present, and will be bonded only to the inner atom. In the case of nitrosyl chloride, oxygen and chlorine are the more electronegative elements, so nitrogen will be the inner atom. The bonding framework will therefore be as follows.

As each single bond in the framework consists of two electrons, we have used four of the original 18 valence electrons so far.

Step 3: Place three nonbonding pairs of electrons on each outer atom except H. With the exception of hydrogen, all outer atoms are associated with eight electrons (four pairs in the valence *s* and *p* orbitals), which may be bonding or nonbonding. Such a set of four pairs of electrons associated with an atom is often called an octet.

The nonbonding pairs are called **lone pairs**. Both the O and Cl atoms are associated with three lone pairs and one bonding pair and therefore have a complete octet. We used $(2 \times 6) = 12$ electrons in this step. Combined with the four used in the previous step, this means 16 of the original 18 electrons have been used.

Step 4: Assign the remaining valence electrons to inner atoms. There are two remaining valence electrons. These are placed on the inner N atom as a lone pair as follows.

We have now accounted for all the valence electrons of NOCl.

Step 5: Minimise formal charges on all atoms. At this point, we need to analyse the structure obtained and calculate the **formal charge** on each atom. We then try to minimise these by adjusting the electron distribution, since unnecessarily large formal charges do not make chemical sense. Formal charge is defined as the difference between the number of valence electrons in the free atom and the number of electrons assigned to that atom in the Lewis structure.

$$\text{formal charge} = (\text{valence electrons of free atom}) - (\text{lone pair electrons}) - \frac{1}{2} (\text{shared electrons})$$

Assume that lone pair electrons ‘belong’ to the atom on which they are located, while electrons in bonds are shared equally between the two atoms. A useful feature of formal charges is that the sum of the formal charges on all atoms equals the charge of the species. For a neutral molecule, the sum of the formal charges must be zero. For a cation or anion, the sum of the formal charges equals the charge on the ion.

The formal charges of the atoms in the structure obtained in step 4 are calculated as follows.

N	Valence electrons of free atom	5
	Lone pair electrons	2
	Shared electrons	4
	Formal charge	$5 - 2 - \frac{1}{2}(4) = +1$
O	Valence electrons of free atom	6
	Lone pair electrons	6
	Shared electrons	2
	Formal charge	$6 - 6 - \frac{1}{2}(2) = -1$
Cl	Valence electrons of free atom	7
	Lone pair electrons	6
	Shared electrons	2
	Formal charge	$7 - 6 - \frac{1}{2}(2) = 0$

We can minimise the formal charges by converting a lone pair of electrons on the O atom to a bonding pair. We can represent this process diagrammatically as follows.

If we analyse the formal charges on the right-hand structure, we find that they are all zero. Therefore, the right-hand structure is the best Lewis structural representation of the NOCl molecule.

In this structure each atom is surrounded by eight electrons, and therefore has an octet. We generally find octets surrounding atoms from the second period of the periodic table, especially C, N, O and F, as such atoms can accommodate a maximum of eight electrons in the available orbitals. The larger atoms from the third and subsequent periods may accommodate more than eight electrons, as these atoms have more than four orbitals available for valence electrons. An alternative description does not expand the octets for these larger atoms, and instead uses resonance forms that include ionic interactions.

WORKED EXAMPLE 5.1

Lewis structure of ClF₃

Chlorine trifluoride, ClF₃, is used to recover uranium from nuclear fuel rods in a high-temperature reaction that produces gaseous uranium hexafluoride.

Determine the Lewis structure of ClF₃.

Analysis

We follow the five steps outlined previously for drawing a Lewis structure.

Solution

1. All four atoms are halogens (group 17, ns^2np^5), so ClF₃ has 28 valence electrons.

2. Chlorine, with lower electronegativity than fluorine, is the inner atom. Make a single bond to each of the three fluorine atoms.

3. Add three nonbonding pairs to each fluorine atom.

4. Four electrons remain unassigned. Place two electron pairs on the chlorine atom.

5. Determine the formal charges on all the atoms and adjust the electron distribution if necessary. In this case, each atom has a formal charge of zero, and so no redistribution of electrons is required.

Is our answer reasonable?

Step 4 results in 10 electrons around the chlorine atom. However, chlorine is a third-row element and is therefore able to accommodate more than eight electrons. We have followed the rules and obtained the structure with formal charges of zero on every atom, so our answer is reasonable. As mentioned in relation to the Lewis structure of NOCl, it is also possible to include ionic interactions, which avoid the necessity to expand the octet. In the case of ClF₃, this would add a positive charge to the Cl and a negative charge to one of the F atoms (with three possible resonance forms).

PRACTICE EXERCISE 5.1

Determine the Lewis structure of sulfur tetrafluoride, SF₄.

Note that some molecules and all ions will have preferred Lewis structures in which the formal charges are not all zero. Recall that in these cases, formal charges are more plausible if positive charges are on the less electronegative atoms, while negative charges are on the more electronegative atoms (e.g. the nitrate ion, NO₃[−], in figure 5.12, where the more electronegative O atoms, rather than the N atom, have a negative formal charge). It is also important to realise that formal charges are not the same as the partial charges induced as a result of bond polarity. For example, in ClF₃, the chlorine atom would have a δ⁺ charge, despite the fact that its formal charge is zero.

FIGURE 5.12

There are three possible ways to minimise the formal charges in the nitrate ion; any of the three oxygen atoms can supply a pair of electrons.

Resonance structures

In completing step 5 of the Lewis structure procedure, there might be more than one way to minimise the formal charges on the atoms; that is, more than one Lewis structure is possible for a particular molecule or ion. This is illustrated in figure 5.12 for the nitrate anion, NO₃[−].

The anion has 24 valence electrons, and nitrogen is the inner atom. Three N—O bonds use six electrons, and assigning six electrons to each of the three outer oxygen atoms uses the remaining 18 electrons. This gives a Lewis structure in which the O atoms have formal charges of −1 and the N atom has a formal charge of +2. We can minimise the formal charges by converting the lone pair on one oxygen atom to a bonding pair. However, as figure 5.12 shows, a lone pair from any of the three oxygen atoms can be moved to form this double bond.

Which of these options is the correct Lewis structure? Actually, no single Lewis structure is an accurate representation of NO₃[−]. Any single structure of the anion shows nitrate with one N=O double bond and two N—O single bonds. Experiments, however, show that all three N—O bonds are identical (we cannot form two double bonds since nitrogen can accommodate only eight electrons in its orbitals). To show that the nitrate N—O bonds are all alike, we use a composite of the three equivalent Lewis structures, which are called **resonance structures**. Resonance structures are connected by double-headed arrows to emphasise that a complete depiction requires all of them (figure 5.13).

FIGURE 5.13 The resonance structures of the nitrate ion

It is essential to realise that electrons in the nitrate anion *do not* ‘flip’ back and forth among the three bonds, as implied by separate structures. None of these structures actually exist. The true character of the anion is a blend of the three, in which all three nitrogen–oxygen bonds are equivalent. Note also that resonance structures *differ only* in the position of the electrons; you cannot move atoms when drawing resonance structures. The need to show several equivalent structures for species such as the nitrate ion reflects the fact that Lewis structures are only approximate representations for structures with delocalised electrons. While they reveal much about how electrons are distributed in a molecule or ion, they cannot describe the entire story of chemical bonding.

WORKED EXAMPLE 5.2

Resonance structures of an oxoanion

Determine the possible resonance structures of the phosphate anion, PO_4^{3-} .

Analysis

We must first determine the Lewis structure by following the five-step procedure outlined previously. In step 5, we determine the different ways we can minimise the formal charges within the ion, thereby obtaining the resonance structures.

Solution

We have 32 electrons to be used (remember that the ion has a 3− charge). Following the rules outlined previously, we arrive at the following structure, in which all the electrons are used after step 4.

In this structure, the O atoms all have formal charges of −1, while the P atom has a formal charge of +1. Turning one lone pair from an oxygen atom into a bonding pair

makes the formal charge on the P atom zero and also makes the formal charge on the O atom involved equal to zero, thereby minimising the formal charges in the ion. We can shift electrons from any of the outer O atoms, so there are four possible resonance structures as shown below. (Note that we have omitted the 3− charge on each structure for clarity.)

Is our answer reasonable?

There are four possible ways to minimise the formal charges, so we must have four resonance structures. The four structures differ only in the position of a double bond, and therefore we can be confident that our answer is correct.

PRACTICE EXERCISE 5.2

Determine the Lewis structure of the acetate anion, CH_3COO^- .

In the examples presented so far, most of the resonance structures shown have been equivalent in energy, but resonance structures are not always equivalent. Resonance structures that are not equivalent occur when step 5 requires shifting electrons from atoms of different elements. In such cases, different possible structures may have different formal charge distributions, and the contribution of individual Lewis structures to the blend that represents reality is inverse to their stability, that is, the lower the energy the higher the contribution.

WORKED EXAMPLE 5.3

Resonance structures of N₂O

Determine the possible resonance structures of dinitrogen oxide, N₂O, a gas used as an anaesthetic, a foaming agent and a propellant for whipped cream.

Analysis

Once again, we first determine the Lewis structure, and then inspect any possible resonance structures.

Solution

We must first choose whether N or O will be the inner atom. As O is more electronegative than N, the structure will have an inner N atom bonded to an O atom and another N atom. The structure we obtain following the first four steps is as follows.

This structure has formal charges of -2 on the outer N atom, $+3$ on the inner N atom and -1 on the O atom. We can convert lone pairs on the outer N atom or the O atom into bonding pairs to reduce the formal charges, but we must ensure that the inner N atom has no more than four

electron pairs. This leaves us with the following possibilities, in which the numbers denote the formal charges.

The formal charges of the first two structures are the same, and less than those on the third structure. The third structure has a positive charge on the oxygen atom, which is not ideal, as it is the more electronegative atom. Thus, the optimal Lewis structure of the N₂O molecule is a composite of the first two structures, which are formally inequivalent, but not the third.

Is our answer reasonable?

We have chosen the two structures in which the formal charges are minimised, and so our answer should be correct. In fact, experimental studies show that the nitrogen–oxygen bond in N₂O is somewhere between an N–O single and an N=O double bond.

PRACTICE EXERCISE 5.3

Determine the Lewis structure of ozone, O₃, in which the three oxygen atoms are linked in a row.

5.4 Valence-shell-electron-pair repulsion (VSEPR) theory

LEARNING OBJECTIVE 5.4 Apply the VSEPR concept to determine the geometry of molecular compounds.

The Lewis structure of a molecule shows how the valence electrons are distributed among the atoms. It does not, however, show the three-dimensional structure, which plays an essential role in determining chemical reactivity. However, we can use the Lewis structure as a starting point to determine the shape of a molecule or ion. The **valence-shell-electron-pair repulsion (VSEPR)** theory considers that molecular shape is determined primarily by the repulsions between pairs of electrons in the molecule or molecular ion, be they bonding pairs or lone pairs. To minimise these repulsions, electron pairs around an inner atom within a molecule will be situated as far apart as possible in the preferred three-dimensional structure.

To determine the shape of a molecule using VSEPR theory, we use the following procedure.

1. Determine and draw the Lewis structure of the molecule.
2. Count the number of sets of bonding pairs and lone pairs of electrons around any inner atom, and use table 5.2 to determine the optimum geometry of these sets.

Note that VSEPR theory makes no distinction between electron pairs in single, double and triple bonds. All electron pairs in the bond are treated as being one set.

3. Modify the geometry, if necessary, to take account of the fact that the magnitudes of repulsions between sets of electron pairs depend on whether the electron pairs involved are bonding pairs (BP) or lone pairs (LP). The repulsions are in the following order.

Therefore, two neighbouring lone pairs on an inner atom will repel each other to a greater extent than will two neighbouring bonding pairs. This is because lone pairs occupy a larger volume than

bonding pairs. Note that double bonds occupy a larger volume than single bonds, and some structures may have to be modified for this.

TABLE 5.2 Optimum geometry of sets of electron pairs

Number of sets of electron pairs	Geometry of sets of electron pairs
2	linear
3	trigonal planar
4	tetrahedral
5	trigonal bipyramidal
6	octahedral

It is important to make the distinction between the geometry of the sets of electron pairs, and the shape of the molecule. The former refers to the way in which sets of electron pairs are arranged around an inner atom of the molecule, while the latter refers to the arrangement of the atoms bonded to that inner atom. As we will see, when lone pairs are present, the two are not the same.

We will now illustrate VSEPR using examples of each different geometry of sets of electron pairs.

Two sets of electron pairs: linear geometry

Beryllium hydride, BeH_2

The Lewis structure of BeH_2 is as follows.

In this case, we have two sets of electron pairs around the inner atom that we need to situate as far away from each other as possible. This is satisfied by placing the two sets in a **linear** arrangement (see table 5.2) and results in a linear shape for this molecule, with a $\text{H}-\text{Be}-\text{H}$ bond angle of 180° . Note that we do not adjust the optimum geometry of the electron pairs, since there are only two single-bonding pairs and no lone pairs.

Carbon dioxide, CO_2

The Lewis structure of CO_2 shows an inner C atom bonded to two outer O atoms.

This is similar to BeH_2 because we have two sets of electron pairs again. Even though each set comprises the two electron pairs of a double bond, the principle is still the same. We place the two sets as far apart as possible, that is, in a linear arrangement, and this leads to a linear shape. Notice that the lone pairs on the O atoms do not affect the overall shape of the molecule; only sets of electrons that are either bonded to, or lie completely on, an inner atom determine molecular shape.

Three sets of electron pairs: trigonal planar geometry

Boron trifluoride, BF_3

The Lewis structure of BF_3 shows an inner B atom singly bonded to three F atoms. We have three sets of electron pairs about the inner atom.

The optimal geometry for three sets of electron pairs is **trigonal planar** (see table 5.2). In this arrangement, the sets are oriented at 120° to each other and are coplanar. This leads to a trigonal planar shape for the BF_3 molecule, with all atoms coplanar and all F—B—F bond angles of 120° . Note that, again, as all the sets of electron pairs involved are equivalent, we do not have to adjust their optimal geometry.

The nitrite ion, NO_2^-

Two possible resonance structures can be drawn for the nitrite ion, which are as follows.

This is the first example we have encountered in which the inner atom bears a lone pair, and this has important implications when applying VSEPR theory. Note that we can choose either resonance structure and end up with the same result. There are three sets of electron pairs, two sets of bonding pairs and a lone pair. The idealised geometry is trigonal planar. However, in this case, not all the repulsions between the sets of electron pairs are the same; there are BP–BP repulsions and BP–LP repulsions. The BP–LP repulsions are stronger, which means that the two bonding pairs will be pushed slightly closer together than an exact trigonal planar arrangement. The result is that the O—N—O bond angle is about 115° , rather than 120° . This example also illustrates the difference between geometry and shape. The sets of electron pairs have an approximately trigonal planar geometry, but we would describe the shape of the NO_2^- ion as bent, because shape refers only to the positions of the atoms and not the electrons.

Four sets of electron pairs: tetrahedral geometry

Methane, CH_4

The Lewis structure of methane, CH_4 , shows that the molecule contains four C—H single covalent bonds, and therefore four sets of equivalent electron pairs.

The optimal geometry for four sets of electron pairs is **tetrahedral** (see table 5.2). This means that the methane molecule is tetrahedral in shape, with H—C—H bond angles of 109.5° , and the H atoms situated at the four vertices of a tetrahedron.

Ammonia, NH_3

The Lewis structure of ammonia, NH_3 , shows a total of four sets of electron pairs, three bonding pairs and a lone pair.

The idealised arrangement of four sets of electron pairs is tetrahedral. But we now have BP–BP and BP–LP repulsions to consider. The single lone pair on the N atom takes up more space than each of the three bonding pairs, and this distorts the idealised arrangement such that the H—N—H angles in ammonia are about 107° . Ammonia adopts a trigonal pyramidal shape, with the N atom lying out of the plane of the three H atoms.

Water, H₂O

Like methane and ammonia, water has four sets of electron pairs, as shown in its Lewis structure, and the idealised arrangement is again tetrahedral.

However, in this case we have two sets of bonding pairs and, significantly, two lone pairs. The LP–LP repulsion dominates, and there are also BP–LP repulsions to consider. The result is that the idealised tetrahedral geometry of the four sets of electron pairs is significantly distorted, such that the H—O—H bond angle in water is about 104.5°. Water adopts a bent shape.

Figure 5.14 shows the different shapes of methane, ammonia and water. The important effect of lone pairs on the shapes of the molecules is evident in these three diagrams.

FIGURE 5.14 Representations of the different shapes of methane, ammonia and water molecules, each with four sets of electron pairs

WORKED EXAMPLE 5.4

Shape of the hydronium ion

Determine the shape of the hydronium ion, H₃O⁺, using VSEPR theory. Make a sketch of the ion that shows the three-dimensional shape, including any lone pairs that may be present.

Analysis

Follow the three-step process described previously. Begin with the Lewis structure, and then use this to determine the number of sets of electron pairs and therefore the geometry of these. Finally, take into account any lone pairs to deduce the molecular shape.

Solution

1. Determine the Lewis structure. A hydronium ion has eight valence electrons. Six are used to make three O—H single bonds, and two are placed as a lone pair on the oxygen atom.

2. There are four sets of electron pairs, three bonding pairs and one lone pair. The idealised geometry is therefore tetrahedral.
3. The presence of a lone pair means that the idealised tetrahedral geometry of the sets of electron pairs will be distorted, owing to LP–BP repulsions. We would therefore expect the H—O—H bond angles to be somewhat less than the 109.5°. The shape of the hydronium ion is trigonal pyramidal, as outlined in the following diagram.

Is our answer reasonable?

The hydronium ion has the same number of electrons and atoms as the ammonia molecule, so it is reasonable for these species to have a similar shape.

PRACTICE EXERCISE 5.4

Determine the shape of chloromethane, CH_3Cl . Make a sketch of the molecule that shows its three-dimensional shape.

Five sets of electron pairs: trigonal bipyramidal geometry

Phosphorus pentachloride, PCl_5

The Lewis structure of PCl_5 shows five sets of equivalent electron pairs around a phosphorus atom.

The geometry which places these as far apart as possible is **trigonal bipyramidal** (see table 5.2). A trigonal bipyramid is so called because it can be viewed as two pyramids that share a triangular base, as shown in figure 5.15a. In contrast to the geometries encountered so far, the five positions in a trigonal bipyramid are not all equivalent. Three positions lie at the corners of an equilateral triangle around the inner atom, separated by 120° bond angles. Atoms in the trigonal plane are in *equatorial positions*. The other two positions lie along an axis above and below the trigonal plane, separated from equatorial positions by 90° bond angles. Atoms in these sites are in *axial positions*. These differences are outlined in figure 5.15b.

FIGURE 5.15

(a) Model representing the equatorial plane and opposing pyramids that make up a trigonal bipyramid. PCl_5 adopts a regular trigonal bipyramidal shape. (b) Ball-and-stick model representing a trigonal bipyramid with axial and equatorial sites labelled.

As PCl_5 contains only bonding pairs of electrons, we would expect it to adopt a regular trigonal bipyramidal shape, as shown in figure 5.15.

When lone pairs are present in molecules with five sets of electron pairs, the consequences of the inequivalence of the axial and equatorial sites become more apparent. We will illustrate this with SF_4 .

Sulfur tetrafluoride, SF_4

The Lewis structure of SF_4 (figure 5.16a) shows four S—F bonds and one lone pair of electrons on the sulfur atom. We would expect a trigonal bipyramidal geometry for these five sets of electron pairs, but the presence of the lone pair means there will be some slight distortion. In addition, because the equatorial and axial positions of a trigonal bipyramid differ, we can draw two possible structures for SF_4 with the lone pair in either axial or equatorial position. As figure 5.16 shows, placing the lone pair in an axial position gives a trigonal pyramidal shape, whereas placing the lone pair in an equatorial position gives a **seesaw shape**.

FIGURE 5.16

Representations of sulfur tetrafluoride. (a) Lewis structure. (b) Ball-and-stick model of the trigonal pyramidal shape. (c) Ball-and-stick model showing the seesaw shape.

Experiments show that SF_4 has the seesaw shape, which means that this is more stable than the trigonal pyramid. This can be explained by noting that the trigonal pyramidal structure has three LP–BP repulsions at 90° , while the seesaw structure has two at 90° and two at 120° . Minimising the number of lowest angle repulsive interactions involving lone pairs gives the lowest energy structure and consequently the seesaw shape is preferred. Note that, because of the LP–BP repulsions between the lone pair and the axial bond pairs, the axial F–S–F bond angle is slightly less than 180° .

Chlorine trifluoride, ClF_3

The Lewis structure of ClF_3 shows five sets of electron pairs: three bonding pairs and two lone pairs.

We again expect a distorted trigonal bipyramidal geometry of the five sets of electron pairs, but now we must determine whether the two lone pairs occupy axial or equatorial positions.

We can immediately discount placing one lone pair axial and the other equatorial, as this would lead to a LP–LP repulsion, the largest possible, at 90° . You might imagine that placing the lone pairs in the axial positions would be preferred, as it places them furthest away, but it also leads to a total of six LP–BP repulsions at 90° . In fact, experiments show that the two lone pairs are equatorial; this leads to four LP–BP repulsions at 90° and is energetically preferred, despite the fact that there is a LP–LP repulsion at 120° . Thus, ClF_3 is T-shaped with two equatorial lone pairs.

It is sometimes difficult to determine which of the possible structures is correct using simple VSEPR theory, and we must then resort to experimental results for definitive answers.

The triiodide ion, I_3^-

The Lewis structure for I_3^- shows five sets of electron pairs around the inner I atom (two bonding and three lone pairs).

We have seen in the previous examples that lone pairs prefer to be in equatorial positions in trigonal bipyramidal geometries, and the same principle applies here. All three lone pairs are equatorial, as this is the only way to avoid any highly destabilising LP–LP repulsions at 90° .

Figure 5.17 summarises the different possible shapes of species with five sets of electron pairs.

FIGURE 5.17 The different possible shapes of species with five sets of electron pairs

Six sets of electron pairs: octahedral geometry

Sulfur hexafluoride, SF_6

The Lewis structure of SF_6 (figure 5.18a) indicates that sulfur has six S—F bonds and no lone pairs, and therefore has six sets of electron pairs around the inner S atom. An **octahedral** geometry of the six sets (see table 5.2) places them as far apart as possible, as shown in figure 5.18b. This gives an octahedral shape; each F atom lies at one of the six vertices of an octahedron, with possible F—S—F bond angles of 90° and 180° . An octahedron has eight triangular faces, as shown in figure 5.18c.

FIGURE 5.18 Representations of sulfur hexafluoride: (a) Lewis structure, (b) ball-and-stick model and (c) ball-and-stick model emphasising the triangular faces of the octahedron

All six positions around an octahedron are equivalent, as figure 5.19 demonstrates. Replacing one fluorine atom in SF_6 with a chlorine atom gives SF_5Cl . No matter which fluorine is replaced, the SF_5Cl molecule has four fluorine atoms in a square planar arrangement, with the fifth fluorine and the chlorine atom on opposite sides, at right angles to the plane of the square.

FIGURE 5.19

Replacing any of the fluorine atoms of SF_6 with a chlorine atom gives a molecule with a square of fluorine atoms capped by one fluorine and one chlorine. This shows that all six positions of the octahedron are equivalent.

Chlorine pentafluoride, ClF_5

The Lewis structure of ClF_5 shows six sets of electron pairs (five bonding pairs and one lone pair).

We again expect an octahedral geometry of the six sets of electron pairs, and, in this case, all six possible positions of the lone pair are equivalent. Therefore, ClF_5 adopts a square pyramidal shape.

Xenon tetrafluoride, XeF_4

The Lewis structure of XeF_4 shows six sets of electron pairs (four bonding pairs and two lone pairs).

We therefore expect an octahedral geometry of the sets of electron pairs, but, as always, we must determine how to arrange the lone pairs. In XeF_4 , both lone pairs *must* be opposite each other because any other arrangement would lead to highly destabilising LP-LP repulsions at 90° . This leaves the four fluorine atoms in a square plane around xenon.

Figure 5.20 summarises the shapes of molecules with six sets of electron pairs. This completes our inventory of molecular shapes.

FIGURE 5.20

The different possible shapes of some molecules with six sets of electron pairs

The most common mistake made when determining a molecular shape using VSEPR theory is to count the number of *atoms* surrounding an inner atom, rather than the number of *sets of electron pairs*. For example, a molecule such as SF_4 may be easily mistaken as tetrahedral, by analogy with tetrahedral CH_4 , as both molecules have four outer atoms surrounding an inner atom. However, we have shown previously that SF_4 has five sets of electron pairs and its shape is based on a trigonal bipyramidal arrangement of these. While VSEPR theory often gives remarkably accurate results, it does not necessarily work for all molecules. In cases where repulsion between the electron pairs is not the dominant factor in determining molecular geometry, VSEPR theory fails. You will encounter some examples of this in the chapter on transition metal chemistry.

5.5 Properties of covalent bonds

LEARNING OBJECTIVE 5.5 Identify and explain properties of covalent bonds.

Having developed ideas about Lewis structures and shapes of molecules, we can now explore some of the important features of covalent bonds.

Dipole moments

As described in section 5.1, most covalent bonds are polar, meaning that one end of the bond is slightly negative, and the other is slightly positive. Bond polarities can lead to molecules with negative ends and positive ends. A molecule with this type of electron density distribution is said to have a **dipole moment**, μ (the lower-case Greek letter *mu*).

The dipole moment of a polar molecule can be measured by placing a sample in an electric field. For example, figure 5.21 is a schematic diagram of hydrogen fluoride, HF, molecules between a pair of metal plates. In the absence of an applied field, the molecules are oriented randomly throughout the volume of the device. When an electric potential is applied across the plates, the HF molecules align spontaneously according to the principles of electrostatic force. The positive ends of the molecules (the hydrogen atoms) point towards the negative plate, and the negative ends (the fluorine atoms) point towards the positive plate. The extent of alignment depends on the magnitude of the dipole moment. The SI unit for the dipole moment is the coulomb metre (C m). Bond dipole moments span the range from 0 to about 7×10^{-30} C m. Hydrogen fluoride has $\mu = 5.95 \times 10^{-30}$ C m, while a non-polar molecule like F_2 has no dipole moment, $\mu = 0$ C m. Experimental values are also often reported in the unit of debye, D ($1 \text{ D} = 3.34 \times 10^{-30}$ C m).

Dipole moments depend on bond polarities. For example, the trend in dipole moments for the hydrogen halides follows the trend in electronegativity differences; the more polar the bond (indicated by the difference in electronegativity, $\Delta\chi$), the larger the dipole moment, μ (figure 5.22).

Dipole moments also depend on molecular shape. Any diatomic molecule composed of atoms with different electronegativities has a dipole moment. For more complex molecules, we must evaluate dipole moments using both bond polarity and molecular shape. A molecule with polar bonds will have no dipole moment if its shape causes the dipole moments of individual bonds to cancel one another, which is more likely for small symmetrical molecules.

FIGURE 5.21

An applied electric field causes an alignment of polar HF molecules. The extent of alignment depends on the magnitude of the dipole moment.

**FIGURE 5.22**

The greater the difference in electronegativity, the larger the dipole moment, as demonstrated by the hydrogen halides.

Figure 5.23 illustrates the dramatic effect of shape on the dipole moments of triatomic molecules. Recall from section 5.1 that an arrow can be used to represent a dipole moment. The head of the arrow points to the partial positive end ($\delta+$) of the polar bond. Figure 5.23a shows that, although both bonds in linear CO_2 are polar ($\Delta\chi = 1.0$), the two arrows indicating individual bond polarities point in exactly opposite directions. Thus, the effect of one polar bond exactly cancels the effect of the other. For bent H_2O , in contrast, figure 5.23b shows that the effects of the two polar bonds do not cancel. Water has a partial negative charge on its oxygen atom and partial positive charges on its hydrogen atoms. The resulting dipole moment of the molecule is $\mu = 6.18 \times 10^{-30} \text{ C m}$, with the direction of the dipole moment shown by the coloured arrow in figure 5.23b.

FIGURE 5.23

(a) When identical polar bonds point in opposite directions, as in CO_2 , their polarity effects cancel, giving zero net dipole moment. (b) When two identical polar bonds do not point in exactly opposite directions, as in H_2O , there is a net dipole moment.

Molecules containing polar bonds whose dipole moments cancel each other do not have overall dipole moments. Such molecules tend to have highly symmetrical geometries. Phosphorus pentachloride,

for example, has $\mu = 0 \text{ C m}$. The two axial P—Cl bonds point in opposite directions, and, although three P—Cl bonds arranged in a trigonal plane have no counterparts pointing in opposite directions, trigonometric analysis shows that the polar effects of three identical bonds in a trigonal plane cancel exactly. Likewise, the bonds in a tetrahedron are arranged so that their polarities cancel exactly; that is, the tetrahedral molecule CCl_4 has no dipole moment.

The perfect symmetry of these geometric forms is disrupted when a lone pair replaces a bond, giving a molecule with a dipole moment. Examples include SF_4 (seesaw), ClF_3 (T shape), NH_3 (trigonal pyramid) and H_2O (bent), all of which have dipole moments. Replacing one or more bonds with a bond to an atom with different electronegativity might also introduce a dipole moment if the individual bond polarities no longer cancel. Thus, chloroform, CHCl_3 , has a dipole moment but CCl_4 does not. The carbon atom of chloroform has four bonds in a near-regular tetrahedron, but the four bonds are not identical. The C—Cl bonds are polar while the C—H bond is essentially non-polar, so the polarities of the four bonds do not cancel. Figure 5.24 shows the magnitude and direction of the dipole moment in chloroform ($\mu = 3.47 \times 10^{-30} \text{ C m}$).

FIGURE 5.24

Carbon tetrachloride, CCl_4 , is a symmetrical tetrahedral molecule, so the individual bond polarities cancel. Chloroform, CHCl_3 , is also a tetrahedral molecule, but the four bonds are not identical, so the bond polarities do not cancel.

In a symmetrical octahedral system such as SF_6 , each polar S—F bond has a counterpart pointing in the opposite direction. The bond polarities cancel in pairs, leaving this molecule without a dipole moment.

WORKED EXAMPLE 5.5

Predicting dipole moments

Does either ClF_5 or XeF_4 have a dipole moment?

Analysis

Molecules composed of atoms with sufficiently different electronegativities have dipole moments unless their bond polarities are cancelled by the symmetry of the arrangement. Therefore, we must examine each molecular structure and the orientation of the bonds in each molecule.

Solution

The molecular structures of chlorine pentafluoride and xenon tetrafluoride are shown in figure 5.20. Each has six sets of electron pairs around an inner atom, but these include lone pairs. As a result, ClF_5 has a square pyramidal shape, whereas XeF_4 has a square planar shape. Pictures can help us determine whether or not the bond polarities cancel.

Each molecule has four fluorine atoms at the corners of a square. The Xe—F bond polarities cancel in pairs, leaving XeF_4 without a dipole moment. Four bond polarities also

cancel in ClF_5 , but the fifth Cl—F bond has no counterpart in the opposing direction, so ClF_5 has a dipole moment that points along the axis containing the lone pair and the fifth Cl—F bond.

Is our answer reasonable?

Any molecule in which individual dipole moments do not cancel will have an overall dipole moment. It is therefore reasonable that XeF_4 will have no dipole moment while the less symmetric ClF_5 molecule will.

PRACTICE EXERCISE 5.5

Determine whether ethane, C_2H_6 , and ethanol, $\text{C}_2\text{H}_5\text{OH}$, have dipole moments.

Bond length

As we described in section 5.1, the bond length of a covalent bond is the nuclear separation distance at which the molecule is most stable. The $\text{H}-\text{H}$ bond length in molecular hydrogen is 74 pm. At this distance, attractive interactions are maximised relative to repulsive interactions (see figure 5.3). Having developed ideas about Lewis structures and molecular shapes, we can now examine bond lengths in more detail. Table 5.3 lists average bond lengths for the most common chemical bonds.

TABLE 5.3 Average bond lengths (all values in picometres, $1 \text{ pm} = 10^{-12} \text{ m}$)

$n_a^{(a)}$	$n_b^{(a)}$	Bond lengths							
H—X bonds									
1	1	H—H	74						
1	2	H—C	109	H—N	101	H—O	96	H—F	92
1	3	H—Si	148	H—P	144	H—S	134	H—Cl	127
1	4							H—Br	141
Second-row elements									
2	2	C—C	154	C—N	147	C—O	143	C—F	135
2	2			N—N	145	O—O	148	F—F	142
2	3	C—Si	185	C—P	184	C—S	182	C—Cl	177
2	3	O—Si	166	O—P	163	O—S	158	N—Cl	175
2	3	F—Si	157	F—P	157	F—S	156		
2	4, 5			F—Xe	190	C—Br	194	C—I	214
Larger elements									
3	3	Si—Si	235	P—P	221	S—S	205	Cl—Cl	199
3	3	Si—Cl	202	P—Cl	203	S—Cl	207		
4	4							Br—Br	228
5	5							I—I	267
Multiple bonds									
		C=C	133	C=N	138	C=O	120	O=O	121
		P=O	150	S=O	143				
		C≡C	120	C≡N	116	C≡O	113	N≡N	110

^(a) n_a is the principal quantum number for the first named atom and n_b is for the second named atom.

The table displays several trends. One trend is that bonds become longer as atom size increases, as shown by bond lengths of the diatomic halogens (figure 5.25).

FIGURE 5.25

Bond length becomes larger as atom size increases, as demonstrated by the diatomic halogens.

The trend is consistent with our introduction to orbital overlap. Recall that bonding involves valence orbitals, and it is the occupied valence orbitals that determine the size of an atom.

Bond polarity also contributes to bond length because partial charges generate electrostatic attraction that pulls the atoms closer together. For example, notice in table 5.3 that C—N bonds are slightly shorter than the average of C—C and N—N bonds. This is a result of the polarity of the C—N bond.

The bond lengths in table 5.3 show another feature: a multiple bond is shorter than the single bond between the same two atoms. This is because placing additional electrons between atoms decreases internuclear repulsion, leading to an increase in net attraction, thereby allowing the atoms to come closer together. Thus, triple bonds are the shortest of all bonds among second-row elements.

Because bond lengths depend on the number of electrons involved in the bond, we can use bond lengths to decide which Lewis structure best represents the actual electron distribution in a molecule. Sulfur–oxygen bonds provide a good example. Figure 5.26 shows two possible sets of Lewis structures for species that contain sulfur–oxygen bonds. One set, the ‘unoptimised structures’, places octets of electrons on the inner sulfur atom, while the other set, the optimised structures, reduces the formal charge on sulfur to zero at the expense of exceeding the octet on the S atom. As the figure shows, the two sets of structures predict different bond types.

FIGURE 5.26

‘Unoptimised structures’ and optimised structures predict different bond types for sulfur–oxygen bonds.

We can use experimental bond length values to support the optimised Lewis structures. In sulfuric acid, there are two distinctly different bond types with bond lengths of 157 pm and 142 pm. In the sulfate anion, all bond lengths are 147 pm, while the bond lengths in SO₂ and SO₃ are 143 pm and 142 pm, respectively. These values indicate that a bond length of 157 pm is consistent with an S—O single bond, and 142 pm with an S=O double bond. A bond length of 147 pm indicates an intermediate bond character (see table 5.3). These values support the optimised Lewis structures, as shown in figure 5.26, which predict double bonds only for SO₂ and SO₃, double and single bonds for H₂SO₄ and intermediate bonds for SO₄^{2−} (note that the shorter bonds might also be explained by ionic interactions without the need to expand the octet, as discussed earlier).

To summarise, generally the following factors influence bond lengths.

1. For a given pair of atoms, the more electrons in the bond between them, the shorter the bond.
2. For two atoms joined by the same type of bond (single, double or triple), the larger the electronegativity difference between the bonded atoms, the shorter the bond.

WORKED EXAMPLE 5.6

Bond lengths

What factor accounts for each of the following differences in bond length?

- I_2 has a longer bond than Br_2 .
- C—N bonds are shorter than C—C bonds.
- H—C bonds are shorter than the C≡O bond.
- The carbon–oxygen bond in formaldehyde, $H_2C=O$, is longer than the bond in carbon monoxide, $C\equiv O$.

Analysis

Bond lengths are controlled by three factors, some of which are more influential than others. To explain a difference in bond length, we need to determine the way that the factors are balanced.

Solution

- $I-I > Br-Br$. Iodine is just below bromine in the periodic table, so the valence orbitals of iodine are larger than the valence orbitals of bromine. Thus, the I_2 bond is longer than the Br_2 bond because iodine has a larger atomic radius.
- $C-N < C-C$. Carbon and nitrogen are both second-row elements. However, nitrogen has a higher effective nuclear charge than carbon, so nitrogen has the smaller radius. This makes C—N bonds shorter than

C—C bonds. In addition, a C—N bond is polar, which contributes to the shortening of the C—N bond.

- $H-C < C\equiv O$. Here, we are comparing bonds in which the atomic radii and the amount of multiple bonding influence bond length. The experimental fact that H—C bonds are shorter than the triple C≡O bond indicates that the size of the hydrogen orbital is a more important factor than the presence of multiple bonding in this case.
- $C=O > C\equiv O$. Both bonds are between carbon and oxygen, so n (the principal quantum number, which determines size), atomic number (Z) and electronegativity difference ($\Delta\chi$) are the same. However, carbon monoxide contains a triple bond, whereas formaldehyde has a double bond. The triple bond in CO is shorter than the double bond in H_2CO because more shared electrons means a shorter bond.

Is our answer reasonable?

When factors work in the same direction, such as effective nuclear charge and bond polarity in the case of $C-N < C-C$, we can make confident predictions. When factors work in the opposite direction (n value and bond multiplicity in the case of $H-C < C\equiv O$), we can explain the observed values but cannot confidently predict them.

PRACTICE EXERCISE 5.6

What factor accounts for each of the following differences in bond length?

- The C=C bond is longer than the C≡C bond.
- The C—Cl bond is shorter than the Si—Cl bond.
- The C—C bond is longer than the O—O bond.

Bond energy

Bond energies are defined as the amount of energy that must be supplied to break a particular chemical bond. Bond energies, like bond lengths, vary in ways that can be traced to atomic properties, and there are three consistent trends in bond energies.

- Bond energies increase as more electrons are shared between the atoms.* Shared electrons are the ‘glue’ of chemical bonding, so sharing more electrons strengthens the bond.
- Bond energies increase as the electronegativity difference ($\Delta\chi$) between bonded atoms increases.* Polar bonds gain stability from the electrostatic attraction between the negative and positive partial charges around the bonded atoms. Bonds between oxygen and other second-period elements exemplify this trend (note that the bond lengths also change slightly).

Bond	Difference in electronegativity ($\Delta\chi$)	Bond energy (kJ mol^{-1})
O—O	0.0	145
O—N	0.5	200
O—C	1.0	360

- Bond energies decrease as bonds become longer.* As atoms become larger, the electron density of a bond is spread over a wider region. This decreases the net attraction between the electrons and the nuclei. The following table of bond energies illustrates this effect (note that the electronegativity difference also changes, strengthening the trend).

Bond	Bond length (pm)	Bond energy (kJ mol ⁻¹)
H—F	92	565
H—Cl	127	430
H—Br	141	360
H—I	161	295

Like bond lengths, bond energies result from the interplay of several factors, including effective nuclear charge, principal quantum number, electrostatic forces and electronegativity. Thus, it is not surprising that there are numerous exceptions to these three trends in bond energies as, in most cases, more than one of the determining factors changes at the same time (see tables above) and often not with the same influence on bond energies. Although it is possible to *explain* many differences in bond energy, it frequently is not possible to *predict* differences with confidence.

CHEMICAL CONNECTIONS

Making use of the energy released when covalent bonds are formed

Australian industries use large amounts of explosives, estimated at about 2.5 million tonnes each year. Most explosives are used in the mining and quarrying industries, but they are also used in the manufacturing and construction industries, the demolition industry and, to a smaller extent, in the entertainment industry for fireworks and special effects (figure 5.27).

FIGURE 5.27

Australian industry uses approximately 2.5 million tonnes of explosives a year. A portion is used by the entertainment industry, such as in the annual Riverfire fireworks display held in Brisbane, Queensland.

The difference in the strengths of chemical bonds between the starting material and the products is responsible for the characteristics of an explosive. Ideally, the explosive is a compound that has weak chemical bonds with the reaction producing molecules with strong chemical bonds, thereby ensuring that the reaction releases a lot of

energy. However, of course the explosive must be stable enough so that it can be handled safely. The products of the explosive reaction should be gaseous, so that a large pressure is created accompanying the explosion, and the reaction must also be very fast.

One of the best-known explosives is liquid nitroglycerin (figure 5.28), also known as tri-nitroglycerine (with the systematic IUPAC name propane-1,2,3-triyl trinitrate). Nitroglycerine is very unsafe to handle — merely shaking it can lead to an explosion. Alfred Nobel (1833–1896) discovered that nitroglycerine can be stabilised by cellulose, and it was this discovery that has allowed the compound to play an important role in the explosives industry. Nobel's accidental discovery has had a major impact on society, albeit not all good, and — along with the many other serendipitous scientific discoveries — exemplifies the great value of fundamental scientific research. The fortune Nobel made from his discovery eventually found its way into the funding of the Nobel Prize in chemistry, amongst others, thereby creating an ongoing connection between Alfred Nobel and scientific discovery.

Summary of molecular shapes

Table 5.4 summarises the relationships between number of sets of electron pairs, the geometry of the sets of electron pairs and molecular shape. If you remember the geometry associated with each number of sets of electron pairs, you can deduce molecular shapes, bond angles and the existence of dipole moments.

TABLE 5.4 Features of molecular geometries

Number of sets of electron pairs	Number of outer atoms	Lone pairs	Geometry of sets of electron pairs	Molecular shape	Bond angles	Dipole moment ^(a)	Example
2	2	0	linear	linear	180°	no	 CO ₂
3	3	0	trigonal planar	trigonal planar	120°	no	 BF ₃
	2	1	trigonal planar	bent	< 120°	yes	 NO ₂ ⁻ (plus other resonance structures)
4	4	0	tetrahedral	tetrahedral	109.5°	no	 CH ₄
	3	1	tetrahedral	trigonal pyramidal	< 109.5°	yes	 NH ₃
	2	2	tetrahedral	bent	< 109.5°	yes	 H ₂ O
5	5	0	trigonal bipyramidal	trigonal bipyramidal	90°, 120°	no	 PCl ₅
	4	1	trigonal bipyramidal	seesaw	< 90°, < 120°	yes	 SF ₄
	3	2	trigonal bipyramidal	T-shaped	< 90°, < 120°	yes	 ClF ₃
	2	3	trigonal bipyramidal	linear	180°	no	 I ₃ ⁻
6	6	0	octahedral	octahedral	90°	no	 SF ₆
	5	1	octahedral	square pyramidal	< 90°	yes	 ClF ₅
	4	2	octahedral	square planar	90°	no	 XeF ₄

^(a)This column refers to molecules with identical outer atoms.

This relatively small catalogue of molecular shapes accounts for a remarkable number of molecules. Even complicated molecules such as proteins and other polymers have shapes that can be traced back to these relatively simple templates. The overall shape of a large molecule is a composite of the shapes associated with its inner atoms, with the shape around each inner atom determined by the number of sets of surrounding bonding electron pairs and the number of lone pairs.

5.6 Valence bond theory

LEARNING OBJECTIVE 5.6 Analyse bonding in molecules using valence bond theory.

Lewis structures are blueprints that show the distribution of valence electrons in molecules. However, the dots and lines of a Lewis structure do not show how bonds form, how molecules react or the shape of a molecule. In this respect, a Lewis structure is like the electron configuration of an atom; both tell us about electron distributions, but neither provides detailed descriptions. Just as we need atomic orbitals to understand how electrons are distributed in an atom, we need an orbital view to understand how electrons are distributed in a molecule.

In the remainder of this chapter, we describe two ways to think about covalent bonding: valence bond theory, which uses **localised bonds**, and molecular orbital theory, which uses **delocalised bonds**. The valence bond approach to molecules assumes that electrons are either localised in bonds between two atoms or localised on a single atom, usually in pairs. Accordingly, the localised bonding model develops orbitals of two types. One type is a bonding orbital that has high electron density between two atoms. The other type is an orbital located on a single atom. In other words, any electron is restricted to the region around a single atom, either in a bond to another atom or in a nonbonding orbital.

Localised bonds are easy to apply, even to very complex molecules, and they do an excellent job of explaining much chemical behaviour. In many instances, however, localised bonds are insufficient to explain molecular properties and chemical reactivity. We therefore also show how to construct delocalised bonds that spread over several atoms using molecular orbital theory. Delocalisation requires a more complicated analysis, but it explains chemical properties that localised bonds cannot.

Orbital overlap

As described earlier in this chapter, the electrons in a hydrogen molecule are located between the two nuclei in a way that maximises electron–nucleus attraction. To understand chemical bonding, we must develop a new orbital model that accounts for shared electrons. In other words, we need to develop a set of **bonding orbitals**.

The model of bonding used by most chemists is an extension of the atomic theory that incorporates a number of important ideas from the chapters on the atom and atomic energy levels. Bonding orbitals are created by combining atomic orbitals. Remember that orbitals have wave-like properties. Waves interact, resulting in addition of their amplitudes. Two waves that occupy the same region of space will be superimposed, generating a new wave that is a composite of the original waves. In regions where the amplitudes of the superimposed waves have the same phase, addition of the amplitudes of the waves leads to constructive overlap. This gives a new wave amplitude that is larger than either original wave in that region, as figure 5.29a shows. In regions where the amplitudes have opposite phases, addition of the amplitudes of the waves leads to destructive overlap, giving a new wave amplitude that is smaller than either of the original waves, as illustrated in figure 5.29b.

Because electrons have wave-like properties, orbital interactions involve similar addition or subtraction of wavefunctions. When two orbitals of the same phase are superimposed, the result is a new orbital that is a composite of the originals, as shown for molecular hydrogen in figure 5.30. This interaction is called **orbital overlap**, and is the foundation of the bonding models we will describe.

Conventions of the orbital overlap model

Orbital overlap models proceed from the following assumptions.

1. Each electron in a molecule is assigned to a specific orbital.
2. No two electrons in a molecule have identical descriptions because the Pauli exclusion principle (see the chapter on atomic energy levels) applies to electrons in molecules as well as in atoms.
3. The electrons in molecules obey the Aufbau principle (see the chapter on atomic energy levels), meaning that, in the ground state, they occupy the lowest energy orbitals available to them.
4. Only the valence orbitals are needed to describe bonding.

FIGURE 5.29

(a) When two waves (dashed lines) have amplitudes of the same phase, addition gives a new wave (solid line) with an increased amplitude in the overlap region. (b) When two waves (dashed lines) have amplitudes of opposite phases, addition gives a new wave (solid line) with a reduced amplitude and a phase change in the overlap region. (Note that the curves have been slightly offset so both curves can be seen.)

**FIGURE 5.30**

As two hydrogen atoms approach each other, the overlap of their 1s atomic orbitals increases. The wave amplitudes add to generate a new orbital with high electron density between the nuclei.

Bonding involves the valence orbitals exclusively in this model, because these orbitals have the appropriate sizes and energies to interact strongly. We have already seen examples of the overlap of valence atomic orbitals in the H_2 and F_2 molecules earlier in this chapter, and this simple approach is adequate for these small diatomic molecules. There are, however, instances where this simple model does not reproduce the experimentally determined structures of certain molecules. For example, if we consider the bonding in a water molecule to arise from overlap of the valence atomic orbitals on O and H, we find that we cannot reproduce the 104.5° $\text{H}-\text{O}-\text{H}$ bond angle. The two singly occupied p orbitals on oxygen lie at 90° to each other, and overlap of these with the H 1s orbitals should give a bond angle of 90° .

Valence bond theory recognises this problem, and attempts to solve it by constructing hybrid orbitals from valence atomic orbitals. This approach gives much better agreement with experiments, and we will outline it in detail, with particular emphasis on the tetrahedral molecule methane.

Hybridisation of atomic orbitals

The experimentally determined structure of methane is shown in figure 5.31. Methane adopts a tetrahedral molecular geometry with $\text{H}-\text{C}-\text{H}$ bond angles of 109.5° and the H atoms situated at the vertices of a tetrahedron. If we consider the bonding in methane solely in terms of the overlap of atomic valence orbitals, we quickly come to the conclusion that such a model could not reproduce these bond angles; the three $2p$ orbitals on C are at 90° to each other, while the $2s$ orbital has no directional preference, and we would therefore expect a structure with three of the four C—H bonds at 90° to each other. Obviously, this simple model is inadequate to describe the bonding in methane. We can, however, use the individual valence

FIGURE 5.31

The experimentally determined structure of methane. The molecule has a tetrahedral geometry with 109.5° bond angles.

atomic orbitals as a starting point to construct **hybrid orbitals**. These are combinations of atomic orbitals and the process by which we combine them is called hybridisation. We illustrate this with methane.

Methane: sp^3 hybrid orbitals

To construct hybrid orbitals, we first need to identify the valence atomic orbitals that we will use. Carbon has the electron configuration $1s^2 2s^2 2p^2$, which means that the valence orbitals of interest are the one $2s$ and three $2p$ orbitals. We then ‘mix’ these four atomic orbitals to form four new hybrid orbitals that are called **sp^3 hybrid orbitals**. Recall from the chapter on atomic energy levels that a p orbital has two lobes of opposite phase (indicated in figure 5.32a as pink and blue lobes). If we can imagine placing an s and a p orbital such that their centres coincide, one of these lobes will interact constructively with the s orbital and will therefore be enhanced, while the other will interact destructively and be diminished. The name sp^3 refers to the fact that the four hybrid orbitals are constructed from one s and three p atomic orbitals. Equally, and possibly more instructively, it can also be interpreted as each individual sp^3 hybrid orbital having $\frac{1}{4}s$ character and $\frac{3}{4}p$ character. Figure 5.32a shows the shape of sp^3 hybrid orbitals, and also shows diagrammatically the process by which they are formed.

FIGURE 5.32

(a) The formation of four sp^3 hybrid orbitals from one s orbital and three p orbitals. (b) The tetrahedral arrangement of the four sp^3 hybrid orbitals. *Note:* The lobes of the sp^3 orbitals shown in (b) are the same as the blue lobe in the sp^3 orbital in (a). Different colours have been used to help distinguish the hybrid orbitals from non-hybridised atomic orbitals in the diagrams in the rest of this section. The smaller lobes of opposite phase for the sp^3 hybrid orbitals have been omitted for clarity as they are not significantly involved in any major bonding interactions.

The energy level diagram for this process is shown in figure 5.33.

FIGURE 5.33

Energy level diagram for the formation of four sp^3 hybrid orbitals from one $2s$ and three $2p$ atomic valence orbitals

Because we can neither create nor destroy energy, the total energy of the four atomic orbitals must equal the total energy of the four hybrid orbitals. This means that the energy of the sp^3 hybrid orbitals must lie between the energies of the $2s$ and $2p$ atomic orbitals. Specifically, the energy of each sp^3 hybrid orbital must be $\frac{1}{4}E_{2s} + \frac{3}{4}E_{2p}$. As the four hybrid orbitals are degenerate, each of them accommodates one valence electron.

The four sp^3 hybrid orbitals are arranged such that their electrons undergo the minimum repulsion. This results in a tetrahedral arrangement in which each hybrid orbital points towards a different corner

of a tetrahedron. Every hybrid orbital is directional, with a lobe of high electron density pointing in one specific direction, as shown in figure 5.32b.

We can now complete our model of methane. We overlap each singly occupied sp^3 hybrid orbital with one singly occupied $1s$ orbital of a H atom. This leads to the formation of four identical σ bonds and a regular tetrahedral shape for the molecule, as shown in figure 5.34.

FIGURE 5.34

Methane forms from orbital overlap between the hydrogen $1s$ orbitals and the sp^3 hybrid orbitals of the carbon atom. *Note:* The large lobes of the sp^3 orbitals and the hydrogen s orbitals shown are of the same phase, and the different colours have been used for clarity only. Diminished lobes of opposite phase for the sp^3 hybrid orbitals have been omitted.

Note that sp^3 hybridisation is not limited to C atoms. In fact, any atom which exhibits a tetrahedral (or nearly so) arrangement of electron pairs can be considered to be sp^3 hybridised. This is illustrated in worked example 5.7 for the hydronium ion in which the O atom is sp^3 hybridised.

WORKED EXAMPLE 5.7

Bonding in the hydronium ion

Describe the bonding of the hydronium ion, H_3O^+ , in terms of hybrid orbitals.

Analysis

Determine the Lewis structure to confirm that the inner O atom is surrounded by four sets of electron pairs, which will adopt a nearly tetrahedral geometry. This suggests sp^3 hybridisation of the O atom. Then construct the four sp^3 hybrid orbitals from the appropriate atomic orbitals on the O atom.

Solution

We have determined the Lewis structure of the hydronium ion before (worked example 5.4).

As the inner atom is O, we use the $2s$ and $2p$ atomic orbitals to construct the sp^3 hybrid orbitals. These will contain a total of six electrons.

We have two half-occupied sp^3 hybrid orbitals that can overlap with two half-occupied $1s$ orbitals on H to form two O—H σ bonds. We form the third bond by overlapping one of the *full* sp^3 orbitals with an empty $1s$ orbital on an H^+ ion. Although both electrons in this bond derive formally from the O atom, the bond is identical to the other two O—H bonds. This leaves an sp^3 hybrid orbital not involved in bonding, which contains two electrons. These electrons constitute a lone pair on the O atom. We can visualise the bonding situation as follows.

PRACTICE EXERCISE 5.7

Describe the bonding in a water molecule in terms of hybrid orbitals.

Note that, in methane, the number of hybridised valence atomic orbitals equals the number of valence atomic orbitals participating in hybridisation. This is always the case, regardless of the nature of the hybridisation. For example, as we will see later, hybridisation of three atomic orbitals gives three sp^2 hybrid orbitals, while hybridisation of two atomic orbitals gives two sp hybrid orbitals.

To this point, we have considered only molecules in which hybrid orbitals on the inner atom overlap with H $1s$ atomic orbitals. In cases where the outer atoms are not hydrogen, we also hybridise these atoms to obtain a better description of the geometry of any lone pairs present. We can illustrate this with reference to the dichloromethane molecule, CH_2Cl_2 , the Lewis structure of which is as follows.

We hybridise the inner C atom to generate four singly occupied sp^3 hybrid orbitals, and we can generate two C—H σ bonds by overlapping these with two singly occupied H $1s$ orbitals. We could also form the C—Cl σ bonds by overlapping the remaining two hybrid orbitals with the singly occupied p orbital on each of two Cl atoms. However, the problem with this approach is the same as that which led us to hybridise atomic orbitals in the first place — it leads to an incorrect geometry of electron pairs (in this case, the three lone pairs on each Cl atom). We can hybridise the valence orbitals on Cl in the same way as we have done previously for C, as shown in figure 5.35.

FIGURE 5.35

Energy level diagram for the formation of sp^3 hybrid orbitals on Cl from the $3s$ and $3p$ valence atomic orbitals

This hybridisation gives one singly occupied sp^3 hybrid orbital on each Cl atom, which can overlap with the sp^3 hybrid orbitals on the carbon atom to form two C—Cl σ bonds. Given that the sp^3 hybrid orbitals on the chlorine atom are tetrahedrally arranged, the three lone pairs will be at approximately 109.5° to each other.

sp^2 hybrid orbitals

Boron trifluoride appears in section 5.4 as an example of a molecule where the inner atom has three sets of electron pairs in a trigonal planar geometry, with 120° angles separating the three B—F bonds. If we were to treat the bonding in BF_3 solely in terms of overlap of atomic valence orbitals, we would predict bond angles close to 90° . A set of sp^3 hybrids is also not appropriate, because these would give F—B—F bond angles of 109.5° rather than 120° . We need a different set of hybrid orbitals to represent an atom with trigonal planar geometry. In this case we can generate a set of three sp^2 hybrid orbitals by mixing the $2s$ orbital with two $2p$ orbitals on the boron atom. We represent this process in figure 5.36, in which each resulting sp^2 hybrid orbital has $\frac{1}{3}s$ and $\frac{2}{3}p$ character.

FIGURE 5.36

(a) The formation of three sp^2 hybrid orbitals from one s orbital and two p orbitals. (b) The orientation of the three sp^2 hybrid orbitals. They lie in the same plane at an angle of 120° to each other. *Note:* The large lobes of the sp^2 orbitals are the same phase as the s orbital. The smaller lobes of opposite phase have been omitted for clarity as they are not involved in the major bonding interaction.

Although an individual sp^2 hybrid orbital looks very much like its sp^3 counterpart, the energetics of the hybridisation process are quite different, as shown in figure 5.37.

The three sp^2 hybrid orbitals are coplanar, and are positioned at angles of 120° to each other around the B atom. As we use only two of the three $2p$ orbitals in constructing the sp^2 hybrid orbitals, this leaves one orbital (by convention, the p_z) unhybridised. Figure 5.38 shows the arrangement of all the orbitals.

We also hybridise the F atoms. Each F atom is surrounded by four electron pairs, which means the atoms will be sp^3 hybridised, and the process is entirely analogous to that used previously for the Cl atoms in CH_2Cl_2 . We now overlap each of the three singly occupied sp^2 hybrid orbitals with a singly occupied sp^3 hybrid orbital on a fluorine atom to form the three identical σ B—F bonds.

The presence of the unoccupied p_z orbital on the B atom has significant consequences for the reactivity of BF_3 . BF_3 often reacts very easily with molecules that have a lone pair of electrons, such as NH_3 .

FIGURE 5.37

Energy level diagram for the formation of sp^2 hybrid orbitals from the 2s and 2p valence atomic orbitals on a B atom

FIGURE 5.38

An sp^2 hybridised atom has three coplanar hybrid orbitals separated by 120° angles. One unchanged p orbital is perpendicular to the plane of the hybrid orbitals. *Note:* Apart from one half (pink or blue) of the unhybridised p_z atomic orbital, all orbitals are of the same phase. The different colours are used for clarity only. Diminished lobes of opposite phase have been omitted for the sp^2 hybrid orbitals.

The p_z orbital serves to accept the pair of electrons from such molecules, thereby giving the B atom an octet and converting it to sp^3 hybridisation in the process.

sp hybrid orbitals

Beryllium hydride appears in section 5.4 as an example of a molecule with linear geometry. There are two bonds to the beryllium atom and a $\text{H}-\text{Be}-\text{H}$ bond angle of 180° . To describe linear orbital geometry, we need a hybridisation scheme that generates two orbitals pointing in opposite directions. We do this by hybridising the 2s orbital of Be with one of the 2p orbitals to generate a pair of **sp hybrid orbitals**. We represent this process in figure 5.39, in which each sp hybrid orbital has $\frac{1}{2}s$ character and $\frac{1}{2}p$ character.

Figure 5.40 shows the energetics of the hybridisation process. In this case, we use only one of the p orbitals, which leaves two of them unhybridised.

The two sp hybrid orbitals are oriented at 180° from each other, which leads to a linear shape for the molecule. We form two identical $\text{Be}-\text{H}$ σ bonds by overlapping each half-filled hybrid orbital with one half-filled 1s orbital on a H atom. Note that we cannot hybridise the outer H atoms, as they have only a 1s orbital each. Figure 5.41 shows a diagram of the bonding for BeH_2 . Note that the two unoccupied

and unhybridised p orbitals lie perpendicular to each other. We will see how such orbitals can participate in bonding when we consider triply bonded molecules later in this chapter. Table 5.5 summarises the hybridisation schemes we have encountered so far.

FIGURE 5.39

(a) The formation of two sp hybrid orbitals from one s orbital and one p orbital. (b) The orientation of the two sp hybrid orbitals. They lie at an angle of 180° to each other. *Note:* The larger lobes of the sp orbitals are the same phase as the s orbital. The smaller lobes have been omitted for clarity as they are not involved in the major bonding interaction.

FIGURE 5.40

Energy level diagram for the formation of sp hybrid orbitals from the $2s$ and $2p$ valence atomic orbitals on Be

FIGURE 5.41

The bonding in BeH_2 . *Note:* The large lobes of the sp orbitals and the hydrogen s orbitals shown are of the same phase. The different colours are used for clarity only. Diminished lobes of opposite phase in the sp hybrid orbitals have been omitted.

While other hybridisation schemes are required to describe the bonding in molecules with coordination numbers higher than 4, sp , sp^2 and sp^3 are by far the most useful, particularly to describe the bonding in organic molecules. Multiple bonding is one of the features of many organic molecules. We will now look at this phenomenon from a valence bond point of view.

Multiple bonds

Many of the Lewis structures in this text represent molecules that contain double and triple bonds. From simple molecules (e.g. ethene and ethyne) to complex compounds such as chlorophyll and vitamin B_{12} , multiple bonds are abundant in chemistry. Double and triple bonds can be described by extending the valence bond model. We begin with ethene, a simple hydrocarbon with the formula C_2H_4 .

Bonding in ethene

Ethene (ethylene) is a colourless, flammable gas with a boiling point of -104°C that is predominantly used in the manufacture of plastics such as polyethylene. Because ethene stimulates the breakdown of cell walls, it is used commercially to speed up the ripening of fruit, particularly bananas.

TABLE 5.5 A summary of valence orbital hybridisation

Number of sets of electron pairs	Electron group geometry	Hybridisation	Number of hybrid orbitals	Number of unused <i>p</i> orbitals	Diagram(a) ⁰
2	linear	<i>sp</i>	2	2	
3	trigonal planar	<i>sp</i> ²	3	1	
4	tetrahedral	<i>sp</i> ³	4	0	

(a) Apart from one half (pink or blue) of the unhybridised atomic orbitals, all orbitals are of the same phase. The different colours are used for clarity only. Diminished lobes of opposite phase have also been omitted.

Every description of bonding starts with a Lewis structure. Ethene has 12 valence electrons. The bond framework of the molecule has one C—C bond and four C—H bonds, requiring 10 of these electrons. If we place the final two electrons as a lone pair on one of the carbon atoms, this gives a formal charge of -1 on one carbon atom and $+1$ on the other. These charges can be minimised by forming a double bond between the carbon atoms, leaving them both with an octet of electrons.

Each carbon atom is thus surrounded by three sets of electron pairs, which implies that the carbon atoms are *sp*² hybridised, with a trigonal planar geometry. (Recall that in VSEPR theory double bonds and triple bonds are treated as being a single set of electron pairs.)

To develop a bonding picture for molecules with multiple bonds, we start by considering *only* the singly bonded σ framework of the molecule, which we construct using hybrid orbitals. The orbital diagram for an *sp*² hybridised C atom is shown in figure 5.42 and the σ framework is shown in figure 5.43. Note that the electron configuration on the right-hand side of figure 5.42 violates the Aufbau principle. This is justified as the energy difference between the *sp*² orbitals and the *p*_z orbital is small, and therefore the energy required to populate the *p*_z orbital is smaller than the spin-pairing energy that would otherwise be required to occupy one of the hybrid orbitals with two electrons. Such an electron configuration provides us with results that agree with experiments.

FIGURE 5.42 Energy level diagram for the formation of *sp*² hybrid orbitals from the 2s and 2*p* valence atomic orbitals on C**FIGURE 5.43** The σ framework of the ethene molecule

For the σ framework, we must form four C—H bonds and one C—C bond. We can do this, as shown in figure 5.44, by using two sp^2 hybrid orbitals on each carbon to form two C—H σ bonds, with the C—C bond formed by overlap of the remaining sp^2 hybrid orbital on each C atom.

Having constructed the σ framework, we are left with one half-occupied p_z orbital on each C atom, which is used to construct the double bond. As we have seen earlier, a σ bond has its maximum electron density along the internuclear axis between the two nuclei. To construct the double bond, we overlap the two p_z orbitals in a side-by-side fashion to form a **pi (π) bond**, as shown in figure 5.45. A π bond has its maximum electron density above and below the plane of the nuclei, and has zero electron density along the internuclear axis between the nuclei. A double bond always consists of one σ bond and one π bond. The σ bond forms from the end-on overlap of the two hybrid orbitals, and the π bond forms from the side-by-side overlap of the two atomic p orbitals. As the side-by-side overlap is not as efficient as the end-on overlap, double bonds are not twice as strong as single bonds between the same atoms. Figure 5.45 shows the complete orbital picture of the bonding in ethene. Ethene is the simplest of a class of molecules, the alkenes, which contain C=C double bonds (see the chapter on the chemistry of carbon).

FIGURE 5.44

Orbital overlaps used to form the σ framework of ethene. Note that all orbitals shown are of the same phase and colours are used for clarity only. Diminished lobes of opposite phase in the sp^2 hybrid orbitals have been omitted.

FIGURE 5.45

Orbital pictures of the bonding in ethene from three perspectives: (a) view of the p_z atomic orbitals which overlap to form the π bond, (b) view of the π bond formed from the overlap of the p_z atomic orbitals and (c) the π bond superimposed on the σ framework. Note that the pink and blue lobes together represent a single π bond, which is occupied by two electrons. Diminished lobes of opposite phase have been omitted.

The availability of an unhybridised valence p orbital to form π bonds is characteristic of sp^2 hybridisation and is not restricted to carbon atoms. Many organic molecules contain C=N and C=O double bonds and we can describe the bonding in such compounds in a similar fashion to the above description of a C=C double bond.

To summarise, we can construct the valence bond description of any double bond using the following four-step procedure.

1. Determine the Lewis structure.
2. Use the Lewis structure to determine the type of hybridisation.
3. Construct the σ bond framework.
4. Add the π bonds.

Bonding in ethyne

The ethyne molecule may be familiar to you by its more common name acetylene, the gas used in oxyacetylene welding torches. Ethyne has 10 valence electrons, and we use six of these to form one C—C bond and two C—H bonds. This leaves each C atom in the molecule with a share of only four electrons. We can complete the octet of one of the C atoms by allocating the remaining four electrons to it in the form of two lone pairs. However, this leads to a -2 charge on this and a formal charge of $+2$ on the other C atom. Converting the two lone pairs on the C atom to two bonding pairs situated between the two C atoms, we obtain formal charges of zero for all atoms in the molecule. This produces the following Lewis structure in which the carbon atoms are joined by a triple bond.

Each carbon atom is surrounded by two sets of electron pairs, and we would predict a linear geometry for this molecule. We can therefore use sp hybrid orbitals to describe the bonding in ethyne.

As we did for ethene, we first construct the singly bonded σ framework using the hybrid orbitals. The orbital diagram for an sp hybridised C atom is shown in figure 5.46, and the σ framework of ethyne is shown in figure 5.47.

FIGURE 5.46 Energy level diagram for the formation of sp hybrid orbitals from the $2s$ and $2p$ valence atomic orbitals on C

We form the σ framework by forming two C—H bonds and one C—C bond using the sp hybrid orbitals, as shown in figure 5.48.

FIGURE 5.47 The σ framework of the ethyne molecule

FIGURE 5.48 Orbital overlaps used to form the σ framework of ethyne. All orbitals are in the same phase; different colours are used for clarity only. Diminished lobes of opposite phase in the sp hybrid orbitals have been omitted.

This then leaves two singly occupied p orbitals on each C atom. We can form two π bonds by overlapping the p_y orbital on one C atom with the p_y orbital on the other C atom, and overlapping the p_z orbital on one C atom with the p_z orbital on the other C atom, as shown in figure 5.49.

FIGURE 5.49 Overlapping non-hybridised p orbitals form the π framework of ethyne.

Thus, each triple bond has one C—C σ bond and two C—C π bonds perpendicular to each other, which is always the case in any alkyne. Worked example 5.8 treats another molecule with bonding that can be described by sp hybrid orbitals.

WORKED EXAMPLE 5.8

Orbital overlap in triple bonds

Hydrogen cyanide, HCN, is an extremely poisonous gas. Approximately half a million tonnes of HCN is produced each year, most of which is used to prepare starting materials for polymers. Construct a complete bonding picture for HCN and sketch the various orbitals.

Analysis

Use the four-step procedure described previously. Begin with the Lewis structure for the molecule, and then identify the appropriate hybrid orbitals. Construct a σ bond framework, and complete the bonding picture by assembling the π bonds from the unhybridised p orbitals.

Solution

The five steps of our procedure for writing Lewis structures lead to a triple bond between carbon and nitrogen.

The inner C atom is surrounded by two sets of electron pairs, as is the N atom. These atoms can therefore be considered to be sp hybridised. We have derived the orbital diagram for an sp hybridised C atom previously, while that for an sp N atom is shown below.

We form the linear singly bonded σ framework shown below by overlapping one of the sp hybrid orbitals on C with the 1s orbital on the H atom to give a C—H σ bond. Similarly, we form a C—N σ bond by overlapping the other sp hybrid orbital on the C atom with the singly occupied sp hybrid orbital on the N atom.

This leaves two singly occupied p orbitals on C and two singly occupied p orbitals on the N atom with which we can construct the C $\equiv$ N triple bond, in the same way as described previously for ethyne. We are then left with an sp hybrid orbital containing two electrons situated on the N atom. This is a nonbonding lone pair and is shown in the diagram below in gold, for clarity.

Is our answer reasonable?

We have already shown that a triple bond consists of one σ and two π bonds, which is what we have derived. Our bonding scheme also accounts for the presence of a lone pair on the N atom, so it is consistent with the experimentally determined structure.

PRACTICE EXERCISE 5.8

Describe the bonding in the but-2-yne molecule, $\text{CH}_3\text{C}\equiv\text{CCH}_3$, using valence bond theory, and sketch the orbitals involved.

5.7 Molecular orbital theory: diatomic molecules

LEARNING OBJECTIVE 5.7 Analyse bonding in molecules using molecular orbital theory.

Hybrid orbitals and localised bonds provide a model of bonding that can be easily applied to a wide range of molecules. Using this model we do an excellent job of rationalising and predicting chemical structures, but localised bonds cannot predict or interpret all aspects of bonding and reactivity. For example, it fails to explain why there are unpaired electrons in a molecule of O_2 . In this section we introduce **molecular orbital theory**, a powerful theory of bonding that is more successful than valence bond theory in predicting and explaining molecular properties. Molecular orbital theory differs fundamentally from valence bond theory in that the electrons within a molecule are not localised either on one atom or between two atoms; instead, they occupy **molecular orbitals (MOs)** that can cover the entire molecule.

Although molecular orbital theory is more complex than the hybrid orbital approach, we can illustrate the fundamentals of the theory with reference to simple diatomic molecules.

Molecular orbitals of H_2 and He_2

Molecular orbital theory considers the formation of molecular orbitals from the overlap of atomic orbitals on all of the individual atoms in the molecule. The overlap of N atomic orbitals will always lead to the formation of N molecular orbitals. Because of the large number of possible overlaps in even quite small molecules, we will restrict our discussion to diatomic molecules, and will first consider the molecular orbital treatment of the H_2 molecule.

We can consider the MOs of H_2 to be formed from the overlap of the $1s$ orbitals on the H atoms. As each atomic orbital can have either a positive or negative phase, there are two possible ways in which these atomic orbitals can overlap — both orbitals can have the same phase (in-phase overlap) or they can have opposite phases (out-of-phase overlap). In-phase overlap is constructive and results in the formation of a molecular orbital with a large amplitude, and consequently high electron density, between the nuclei. Out-of-phase overlap is destructive and gives a molecular orbital with zero amplitude, and therefore zero electron density, exactly halfway between the nuclei. As for atomic orbitals, this position where the amplitude changes phase is called a **node**. These overlaps and the resulting molecular orbitals are shown in figures 5.29 and 5.50.

FIGURE 5.50

When two hydrogen $1s$ atomic orbitals interact, they generate two molecular orbitals, one bonding (σ_{1s}) and one antibonding (σ_{1s}^*).

Constructive overlap gives a **bonding molecular orbital**, in which electron density is maximised between the two nuclei. Such an arrangement of electrons minimises internuclear repulsions. The orbital is completely symmetric with respect to rotation around the internuclear axis and is therefore a σ orbital. We use a $1s$ subscript to show that it derives from the overlap of two $1s$ atomic orbitals, and the complete description of this orbital is therefore σ_{1s} .

Destructive overlap gives an **antibonding molecular orbital** in which electron density is minimised between the nuclei and is zero at the node between the nuclei. (All antibonding orbitals have more nodes than the corresponding bonding orbitals and are therefore of higher energy.) Internuclear repulsions are therefore significant as they are not mediated by the electrons. As the orbital is completely symmetric with respect to rotation about the internuclear axis, it is a σ orbital. We use a superscript asterisk (*) to denote its antibonding nature and again use a subscript $1s$ to show that it is derived from two $1s$ atomic orbitals. The complete description of this orbital is therefore σ_{1s}^* .

The relative energies of atomic orbitals and the molecular orbitals they form are shown in a **molecular orbital diagram**. Figure 5.51 shows the molecular orbital diagram for H_2 . It shows that the bonding orbital is of lower energy than the orbitals from which it is formed, whereas the antibonding orbital is of higher energy. When a hydrogen molecule forms, its two electrons obey the same principles for distributing electrons as described in the chapter on atomic energy levels. The lowest energy arrangement of electrons requires adherence to the Aufbau principle, the Pauli exclusion principle and Hund's rule, no matter what types of orbitals they occupy. The two valence electrons of molecular hydrogen therefore fill the lowest energy orbital, the σ_{1s} orbital, with their spins paired, leaving the σ_{1s}^* orbital empty.

The molecular orbital diagram shown in figure 5.51 applies to all diatomic species from the first row of the periodic table, except that the electron occupancy and the absolute energies involved are different. We can, for instance, use molecular orbital theory to rationalise why two helium atoms do not combine to form a molecule of He_2 . The electron configuration of He is $1s^2$ and therefore the hypothetical He_2 molecule would have four electrons. Two of these would populate the bonding σ_{1s} orbital, while the remaining two electrons would have to occupy the antibonding σ_{1s}^* orbital, as shown in figure 5.52. The total electronic

FIGURE 5.51

Molecular orbital diagram for H₂

FIGURE 5.52

Diatomic He₂ does not exist because the stability imparted by the electrons in bonding orbitals is offset by the destabilisation due to the electrons in antibonding orbitals.

energy of the He₂ molecule would therefore be exactly the same as that of two isolated He atoms, as the destabilising effect of the electrons in the antibonding orbital cancels out any stabilisation due to the electrons in the bonding orbital. As there is no energetic advantage, a molecule is not formed (see the discussion of entropy in the chapter on chemical thermodynamics for an explanation). A convenient way to summarise this argument is by calculating the **bond order**, which represents the net amount of bonding between two atoms.

$$\text{Bond order} = \frac{1}{2}(\text{number of electrons in bonding molecular orbitals} - \text{number of electrons in antibonding molecular orbitals})$$

Bond orders usually have integer or half-integer values: the larger the bond order, the stronger the bond (for the same type of atom).

For molecular hydrogen, with two bonding electrons and no electrons in the antibonding orbitals, the bond order is $\frac{1}{2}(2 - 0) = 1$. A bond order of 1 corresponds to a single bond, consistent with the Lewis structure of H₂. For the hypothetical He₂ molecule, two bonding and two antibonding electrons give a bond order of $\frac{1}{2}(2 - 2) = 0$, so no bond forms and helium does not form stable diatomic molecules.

WORKED EXAMPLE 5.9

Does He₂⁺ exist?

Use a molecular orbital diagram to predict if it is possible to form the He₂⁺ cation.

Analysis

The schematic MO diagram shown in figure 5.51 can be applied to any of the possible diatomic molecules or ions formed from the first-row elements, hydrogen and helium. Count the electrons of He₂⁺, place the electrons in the molecular orbital diagram and calculate the bond order. If the bond order is greater than zero, the species can potentially form under the right conditions.

Solution

One He atom has two electrons, so a He₂⁺ cation has three electrons. Following the Aufbau principle, two electrons fill

the lower-energy σ_{1s} orbital, so the third must be placed in the antibonding σ_{1s}^* orbital in either spin orientation.

The bond order of the cation is therefore $\frac{1}{2}(2 - 1) = \frac{1}{2}$. Although a bond order of $\frac{1}{2}$ might sound unusual, it is greater than zero and therefore we predict that He_2^+ , with a net bond order of $\frac{1}{2}$, can be prepared in the laboratory under appropriate conditions.

Is our answer reasonable?

Until this point, we have discussed only single, double and triple bonds, and have not encountered bonds with non-

integer orders. In fact, such bonds are quite common in chemistry. He_2^+ can be prepared by passing an electrical discharge through a sample of helium gas. The He_2^+ ion is unstable but survives long enough to allow its study. The bond dissociation energy of He_2^+ is 250 kJ mol^{-1} , approximately 60% as strong as the bond in the H_2 molecule, which has a bond order of 1.

PRACTICE EXERCISE 5.9

Which species has the stronger bond, H_2 or H_2^- ? Use a molecular orbital diagram to support your answer.

Molecular orbitals of O_2

The next step in the development of molecular orbital theory is to consider the molecular orbitals formed by constructive and destructive overlap of atomic p orbitals. We use molecular oxygen, O_2 , as a case study.

The Lewis structure of O_2 shows the two atoms connected by a double bond, with two nonbonding electron pairs on each atom. Note that there are no unpaired electrons in the Lewis structure.

We derive the molecular orbital diagram for the O_2 molecule by considering overlap of only the valence atomic orbitals on the two oxygen atoms; an exact treatment would also include the core $1s$ orbitals, but we will ignore these in the interests of clarity. Each oxygen atom has four valence orbitals, so the molecular orbital diagram for O_2 will contain eight molecular orbitals. The first interaction involves the $2s$ atomic orbitals. This pair interacts in exactly the same way as the $1s$ orbitals described previously for H_2 . The constructive overlap generates a bonding σ_s orbital, and the destructive overlap forms an antibonding σ_s^* orbital. Because of the larger size of the $2s$ atomic orbitals, these two molecular orbitals are larger than their hydrogen σ_{1s} and σ_{1s}^* counterparts, but their overall appearances are similar.

Figure 5.53 shows the construction of the $2p$ -based molecular orbitals. One pair of molecular orbitals forms from end-on constructive and destructive overlap of the p_z orbitals that point towards each other along the bond axis. (By convention, the bond axis is chosen to be the z -axis.) These end-on overlaps give a pair of σ orbitals, the bonding σ_p and the antibonding σ_p^* , as shown in figure 5.53a. (Note that here we have simply labelled the molecular orbitals as σ_p and σ_p^* , rather than σ_{2p} and σ_{2p}^* for reasons we will explain a little further on.) The remaining sets of p orbitals undergo constructive and destructive overlap in a side-by-side fashion to form pairs of molecular orbitals with electron density located primarily above and below the internuclear axis. Such molecular orbitals are called π orbitals. Constructive overlap gives a bonding π orbital, while destructive overlap gives an antibonding π^* orbital. One of these pairs comes from overlap of the p_y orbitals, while the other comes from overlap of the p_x orbitals. Figure 5.53b shows only the p_y pair of π orbitals, which we label π_y — the π_x pair of orbitals derived from the p_x atomic orbitals has the same appearance, but is perpendicular to the π_y orbitals. Note that the antibonding π^* orbital contains a node between the two O atoms.

To draw the molecular orbital diagram for O_2 , we must first determine the relative energies of the molecular orbitals. We can do this with the following rules.

1. The core σ_s and σ_s^* orbitals derived from the overlap of the $1s$ atomic orbitals are of lowest energy and contribute little to bonding. For this reason, they are not shown explicitly.
2. The bonding σ_s and antibonding σ_s^* orbitals derived from the overlap of the $2s$ orbitals are of lower energy than any of the six molecular orbitals derived from the $2p$ orbitals. This is because the $2s$ orbitals that generate the σ_s and σ_s^* orbitals are of lower energy than the $2p$ atomic orbitals.

FIGURE 5.53

Constructive and destructive overlap of p orbitals lead to bonding and antibonding orbitals. (a) End-on overlap of the p_z orbitals gives σ orbitals. (b) Side-by-side overlap of the p_y atomic orbitals gives π_y and π_y^* molecular orbitals. Similar combinations of p_x orbitals would give π_x and π_x^* MOs.

3. The π_x and π_y bonding orbitals are degenerate, because the corresponding atomic p orbitals from which they are derived are degenerate. The π_x^* and π_y^* orbitals are degenerate for the same reason.
4. The antibonding orbitals formed from the atomic $2p$ orbitals are highest in energy, with the σ_p^* orbital higher than the degenerate π_x^* and π_y^* pair of orbitals.

After applying these features, we are left with the bonding σ_p and π molecular orbitals. These must be placed between σ_s^* and π^* , but which of them is lower in energy? It can be shown mathematically that end-on overlap is more efficient than side-by-side overlap, which suggests that the σ_p orbital should be of lower energy than the π orbitals. This is the case for the O_2 molecule and figure 5.54 shows the complete diagram. To obtain the ground-state electron configuration, we place the 12 valence electrons in the molecular orbitals in accordance with the Pauli and Aufbau principles and Hund's rule. We can describe the resulting electron configuration by naming the orbitals (σ_s , π_x etc.), and using superscripts to show how many electrons each orbital contains. Therefore, the configuration for the ground state of O_2 is as follows.

$$(\sigma_s)^2(\sigma_s^*)^2(\sigma_p)^2(\pi_x)^2(\pi_y)^2(\pi_x^*)^1(\pi_y^*)^1$$

Note that, to satisfy Hund's rule, we must place one electron in each of the two π^* orbitals with parallel spins. Therefore, this model of bonding predicts that O_2 should contain two unpaired electrons, in contrast to both the Lewis structure and the valence bond theory. Which model agrees with experiment?

FIGURE 5.54

The molecular orbital diagram for O_2 . The energy ordering of the MOs applies to second-row diatomic molecules with $Z > 7$.

Figure 5.55 shows that liquid oxygen adheres to the poles of a magnet. Attraction to a magnetic field shows that molecular oxygen is paramagnetic. Recall from the chapter on atomic energy levels that paramagnetism arises when the electron configuration includes unpaired electrons. Neither the Lewis structure of O_2 nor the valence bond model predicts the presence of unpaired electrons. However, the molecular orbital description shows that the two highest energy electrons of the oxygen molecule occupy the two degenerate π_x^* and π_y^* antibonding orbitals (figure 5.54). So, molecular orbital theory gives us a more appropriate model of the bonding in O_2 than either the Lewis or the valence bond theories. This does not necessarily mean that the molecular orbital theory is ‘correct’, just that it gives better agreement with experiment than the other models.

FIGURE 5.55

Molecular oxygen clings to the poles of a magnet, showing that it is paramagnetic.

Bond length and bond energy measurements on oxygen and its cation provide evidence that the π^* orbitals are indeed antibonding. The bond order of the O_2 molecule is $\frac{1}{2}(8 - 4) = 2$. If we remove an electron from O_2 , we form the O_2^+ cation. Experimental measurements show that this species has a larger bond energy and shorter bond length than O_2 , both observations consistent with an increased bond order. This indicates that the electron removed must be antibonding in character, as its removal has strengthened rather than weakened the bond.

Molecular orbital theory predicts the observed increase in bond order, with the calculated bond order of O_2^+ being $\frac{1}{2}(8 - 3) = 2.5$. The experimental data indicating that the highest energy orbital of O_2 is antibonding in character are in good agreement with theoretical molecular orbital predictions.

Species	Bond length	Bond energy	Configuration	Bond order
O_2	121 pm	496 kJ mol ⁻¹	$\dots(\sigma_p)^2(\pi_x)^2(\pi_x^*)^1(\pi_y^*)^1$	2
O_2^+	112 pm	643 kJ mol ⁻¹	$\dots(\sigma_p)^2(\pi_x)^2(\pi_y)^2(\pi_{xy}^*)^1$	2.5

Our treatment of O_2 shows that the extra complexity of the molecular orbital approach explains features that a simpler description of bonding cannot. The Lewis structure of O_2 does not reveal its two unpaired electrons, but a molecular orbital approach does. The simple σ - π description of the double bond in O_2 does not predict that the bond in O_2^+ is stronger than that in O_2 , but a molecular orbital approach does. We now extend our discussion to include all of the homonuclear diatomic molecules formed by elements in the second row of the periodic table.

Homonuclear diatomic molecules

We saw previously that very similar molecular orbital diagrams can describe the bonding in H_2 , He_2^+ and He_2 . Can we use the molecular orbital diagram for O_2 to explain the bonding in all of the second-row diatomic molecules (Li_2 , Be_2 , B_2 , C_2 , N_2 , O_2 , F_2 and Ne_2)? Consider the B_2 molecule, which can be formed in the gas phase by strong heating of solid boron. If we use the molecular orbital diagram for O_2 and insert the six valence electrons of B_2 , we would predict the electron configuration $(\sigma_s)^2(\sigma_s^*)^2(\sigma_p)^2$ for this molecule. With all its electrons paired, B_2 should be diamagnetic. However, experiments show that B_2 molecules are paramagnetic, with two unpaired electrons. When theory and experiment conflict, theory must be revised. The molecular orbital diagram we used for O_2 must be revised to account for the paramagnetism of B_2 .

The view of molecular orbital theory that leads to the molecular orbital diagram in figure 5.54 assumes that the $2s$ and $2p$ orbitals act independently. A more refined treatment considers interactions between the $2s$ and $2p$ orbitals. Recall from the chapter on atomic energy levels that the $2s$ and $2p$ orbitals have similar radii. Consequently, when two atoms approach each other, the $2s$ orbital on one atom will overlap not only with the $2s$ orbital, but also with the $2p_z$ orbital of the other atom. This mixed interaction of $2s$ and $2p_z$ stabilises the σ_s molecular orbital and destabilises the σ_p molecular orbital. In other words, **orbital mixing** causes the σ_s and σ_p molecular orbitals to move further apart in energy. In this more refined treatment, the resulting molecular orbitals are therefore not derived solely from two atomic orbitals, and hence we do not use specific labels, such as σ_{1s} , as we did for the hydrogen and helium cases. Labels of the type σ_s and π_y show the *predominant* type of overlap that contributes to the molecular orbital. The amount of mixing depends on the difference in energy between the $2s$ and $2p$ atomic orbitals. Mixing is largest when the energies of the orbitals are nearly the same. As figure 5.56 shows, the energies of the $2s$ and $2p$ atomic orbitals diverge as Z increases across the second row, so mixing is large for B_2 but small for F_2 . Figure 5.57 shows how mixing affects the energies of the σ_s and σ_p molecular orbitals.

The main effect of mixing is to make the σ_p molecular orbital of higher energy than the degenerate π orbitals for the B_2 , C_2 and N_2 molecules. Therefore, according to the Aufbau principle, we first fill the π orbitals and then the σ_p orbital for these molecules. Following Hund's rule, this means that B_2 is paramagnetic, as it has the electron configuration $(\sigma_s)^2(\sigma_s^*)^2(\pi_x)^1(\pi_y)^1$, in agreement with experiment. Notice that crossover of the σ_p and π energy levels takes place from molecular nitrogen to molecular oxygen. Because of orbital mixing, we therefore require two generalised molecular orbital diagrams for diatomic molecules, one for B_2 , C_2 and N_2 , and the other for O_2 and F_2 . Figure 5.57 shows both diagrams.

These molecular orbital diagrams help to rationalise experimental observations about molecules.

FIGURE 5.56

Energies of the $n = 2$ valence orbitals as a function of Z

FIGURE 5.57

Mixing of the $2s$ and $2p_z$ orbitals causes the σ_s MOs to become lower in energy and the σ_p MOs to increase in energy. (a) For B_2 , C_2 and N_2 , the π MOs are of lower energy than the σ_p orbitals. (b) For O_2 and F_2 , the opposite is true.

WORKED EXAMPLE 5.10

Trends in bond energy

Use molecular orbital diagrams to explain the trend in the following bond energies. $B_2 = 290 \text{ kJ mol}^{-1}$, $C_2 = 600 \text{ kJ mol}^{-1}$ and $N_2 = 942 \text{ kJ mol}^{-1}$.

Analysis

The data show that bond energies for these three diatomic molecules increase as we move across the second row of the periodic table. We must construct molecular orbital diagrams for the three molecules and use the results to interpret the trend.

Solution

The crossover for the σ_p/π energy levels is from N_2 to O_2 , so the general diagram for $Z \leq 7$ in figure 5.57a applies to all three molecules. The valence electron counts are $B_2 = 6e^-$, $C_2 = 8e^-$ and $N_2 = 10e^-$. Place these electrons in the MO diagram following the Pauli exclusion and Aufbau principles and Hund's rule. The results are shown below.

The diagrams show that the increasing electron counts as we progress from boron to carbon to nitrogen result in the filling of bonding molecular orbitals. This is revealed most clearly by calculating the bond orders for the three molecules: $B_2 = \frac{1}{2}(4 - 2) = 1$, $C_2 = \frac{1}{2}(6 - 2) = 2$ and $N_2 = \frac{1}{2}(8 - 2) = 3$. Increasing bond order corresponds to stronger bonding between the atoms and therefore larger bond energies.

Is our answer reasonable?

Our predicted bond orders correlate perfectly with the experimental bond energies, and therefore our answer is reasonable. Of these three diatomic molecules, only N_2 exists under normal conditions. Boron and carbon form nonmolecular solids rather than isolated diatomic molecules. However, molecular orbital theory predicts that B_2 and C_2 may exist under the right conditions, and in fact both molecules can be generated in the gas phase by vaporising solid boron or solid carbon.

PRACTICE EXERCISE 5.10

Use molecular orbital diagrams to explain the trend in bond energies for the following diatomic molecules: $\text{N}_2 = 942 \text{ kJ mol}^{-1}$, $\text{O}_2 = 495 \text{ kJ mol}^{-1}$ and $\text{F}_2 = 155 \text{ kJ mol}^{-1}$.

Heteronuclear diatomic molecules

Nitrogen oxide (NO) is an example of a heteronuclear diatomic molecule. This interesting molecule has been in the news in recent years because of important discoveries about the role of NO as a biological messenger. A molecular orbital diagram of NO is shown in figure 5.58.

Because the qualitative features of orbital overlap do not depend on the identity of the atoms, the bonding in NO can be described by the same sets of orbitals that describe homonuclear diatomic molecules. Which of the two general molecular orbital diagrams for diatomic molecules applies to nitrogen oxide? The crossover for the energy rankings of the σ_p and π molecular orbitals is from N to O, so we expect the orbital energies to be nearly equal. Experiments have shown that the σ_p molecular orbital is slightly more stable than the π molecular orbital. Consequently, the molecular orbital configuration for the 11 valence electrons of NO mirrors that for the 12 valence electrons of O_2 , except that there is a single electron in the π^* orbital.

FIGURE 5.58

Molecular orbital diagram of NO

$$(\sigma_s)^2 (\sigma_s^*)^2 (\sigma_p)^2 (\pi_x)^2 (\pi_y)^2 (\pi_x^*)^1$$

There are eight bonding electrons and three antibonding electrons, so the bond order of NO is 2.5. This bond is stronger and shorter than the double bond of O_2 but weaker and longer than the triple bond of N_2 .

Species	Bond length	Bond energy	Configuration	Bond order
O_2	121 pm	495 kJ mol^{-1}	$\dots(\sigma_p)^2 (\pi_x)^2 (\pi_y)^2 (\pi_x^*)^1 (\pi_y^*)^1$	2
NO	115 pm	605 kJ mol^{-1}	$\dots(\sigma_p)^2 (\pi_x)^2 (\pi_y)^2 (\pi_{xy}^*)^1$	2.5
N_2	110 pm	945 kJ mol^{-1}	$\dots(\pi_x)^2 (\pi_y)^2 (\sigma_p)^2$	3

Electron configurations for these molecules lead to a guideline for molecular orbital configurations based on average nuclear charge, Z_{average} .

For second-row diatomic molecules and ions:

- σ_p is lower in energy than π_x , π_y when $Z_{\text{average}} > 7$
- π_x , π_y is lower in energy than σ_p when $Z_{\text{average}} \leq 7$.

Worked example 5.11 compares the ionisation energies of three diatomic molecules and uses MO theory to explain the differences.

WORKED EXAMPLE 5.11

Comparing ionisation energies

The first ionisation energy of NO is 891 kJ mol^{-1} , that of N_2 is 1500 kJ mol^{-1} , and that of CO is 1350 kJ mol^{-1} . Use electron configurations to explain why NO ionises more easily than either N_2 or CO.

Analysis

Recall from the chapter on atomic energy levels that ionisation energy refers to the removal of an electron from an atom, or, in this case, from a molecule. We must count the valence electrons, choose the correct MO diagram, follow

the Aufbau principle in placing the electrons, and then use the configurations to explain the ionisation energy data.

Solution

Begin with a summary of the important information for each molecule: NO has 11 valence electrons and $Z_{\text{average}} = 7.5$; N_2 has 10 valence electrons and $Z_{\text{average}} = 7$; CO has 10 valence electrons and $Z_{\text{average}} = 7$. Applying the general diatomic MO diagrams of figure 5.57 gives the following configurations.

CO and N_2 are isoelectronic species, meaning they have the same number of electrons, and each has a bond order of 3. It makes sense that these two molecules have comparable ionisation energies. NO has one electron more than N_2 and CO, and this electron occupies one of the antibonding π^* orbitals. It is much easier to remove this antibonding electron from NO than it is to remove a bonding electron from either of the other two species.

π^* orbitals. It is much easier to remove this antibonding electron from NO than it is to remove a bonding electron from either of the other two species.

$$\text{NO} = (\sigma_s)^2 (\sigma_s^*)^2 (\pi_x)^2 (\pi_y)^2 (\sigma_p)^2 (\pi_{x,y}^*)^1$$

$$\text{N}_2 = (\sigma_s)^2 (\sigma_s^*)^2 (\sigma_p)^2 (\pi_x)^2 (\pi_y)^2 (\sigma_p)^2$$

$$\text{CO} = (\sigma_s)^2 (\sigma_s^*)^2 (\pi_x)^2 (\pi_y)^2 (\sigma_p)^2$$

CO and N_2 are isoelectronic species, meaning they have the same number of electrons, and each has a bond order of 3. It makes sense that these two molecules have comparable ionisation energies. NO has one electron more than N_2 and CO, and this electron occupies one of the antibonding π^* orbitals. It is much easier to remove this antibonding electron from NO than it is to remove a bonding electron from either of the other two species.

PRACTICE EXERCISE 5.11

Use electron configurations to predict which of the following is the most stable diatomic combination of carbon and nitrogen: CN^- , CN or CN^+ .

For diatomic molecules composed of atoms that have very different energies of their atomic orbitals, the MO diagram becomes slightly more complicated. We will use HF as an example. The energy levels for both atomic orbitals and molecular orbitals are shown in figure 5.59.

Molecular orbitals can form only when there is net overlap between the constituent atomic orbitals and when the atomic orbitals are relatively close in energy. Generally, orbitals are of lower energy in a more electronegative atom and orbitals with the same designation are lower in energy if the nuclear charge is larger.

Armed with these rules, we can understand that the $2s$ orbital in the F atom is much lower in energy than the $1s$ orbital of H. While overlap of the hydrogen $1s$ and fluorine $2s$ orbitals can, in theory, occur, the energies of the orbitals are too different to permit effective overlap, and for this reason, the fluorine $2s$ orbital remains essentially nonbonding (see figure 5.59). Note, the numbers in the MO labels give the energy order with, for example, 2σ being the second-lowest σ orbital and 1π being the lowest energy π orbital. These numbers do not relate to the principal quantum number of the atomic orbitals.

FIGURE 5.59 The molecular orbital diagram of HF

The $1s$ orbital of hydrogen and the $2p$ orbitals of fluorine are much closer in energy, and hence are able to interact with each other. The $1s$ orbital of hydrogen and the $2p_z$ orbital of fluorine overlap effectively and form two MOs. The 3σ orbital is much closer in energy to the $2p_z$ orbital of fluorine and therefore has more $2p_z$ character and is closer to the fluorine nucleus, while the antibonding $4\sigma^*$ orbital has more hydrogen $1s$ character.

In contrast, the interaction of the hydrogen $1s$ orbital with either the $2p_x$ or $2p_y$ orbital of the fluorine atom leads to nonbonding MOs. As the orbitals approach each other in a 'side-on' manner, there will be constructive interference, and hence a bonding interaction, between the s orbital and the same phased lobe of the p orbital, but there will be an equal and opposite destructive interference, and hence an antibonding interaction, between the s orbital and the opposite phased lobe of the p orbital (see figure 5.60). Therefore, there is no net overlap between an s orbital and a p_x or p_y orbital when they approach in this manner, and no molecular orbitals are formed. Instead, the $2p_x$ and $2p_y$ orbitals are located primarily on the fluorine atom as essentially nonbonding molecular orbitals.

The CO molecule is another heteronuclear diatomic molecule that can serve to illustrate features of MO theory. Both C and O have $2s$ and $2p$ valence orbitals and therefore can form π bonds. Given that O is more electronegative than C, the valence orbitals on O will be of lower energy than the corresponding orbitals on C.

Figure 5.61 shows the energy level diagram for CO. The $2s$ and the $2p_z$ orbitals on both C and O overlap to form four σ molecular orbitals, while the other two p orbitals on C and O overlap to form two bonding and two antibonding π orbitals. The bonding π orbitals are lower in energy than the σ bonding orbital with mainly p character due to s - p mixing, which is significant in second-row heteronuclear diatomic molecules with average $Z \leq 7$.

FIGURE 5.60

As the H $1s$ orbital and either the F $2p_x$ or $2p_y$ orbital approach each other in a 'side-on' manner, there are equal and opposite bonding and antibonding interactions between the s orbital and the opposite phased lobe of the p orbital. Therefore, there is no net overlap and no molecular orbitals are formed.

FIGURE 5.61

The molecular orbital diagram of CO

We have barely scratched the surface of molecular orbital theory. More complicated systems (three or more atoms) require the use of powerful computers to adequately treat the bonding. Indeed, even the simple diatomic systems we have discussed have involved huge simplifications; it is, in fact, currently impossible to exactly describe a molecule containing more than one electron, as the mathematics of such a system have so far defied solution. We have discussed a number of ways to describe the bonding in molecules; each of them has particular strengths and, if applied appropriately, we can use them to satisfactorily explain the bonding in virtually all chemical systems.

SUMMARY

5.1 Describe qualitatively the bonding in molecules.

Covalent bonds are formed as a result of the sharing of electrons between nuclei in a way that balances attractive and repulsive forces. In the hydrogen molecule, H_2 , this leads to a lowest energy internuclear separation of 74 pm. This distance is called the bond length, and the energy difference between the molecule at this distance and the separated atoms is called the bond energy. The single bond in H_2 is an example of a σ bond, a bond that is totally symmetric with respect to rotation about the internuclear axis. In simple diatomic molecules such as H_2 and F_2 we can describe bonding in terms of overlap of atomic orbitals containing single electrons. When the two atoms in a diatomic molecule are different, the electron pair will tend to be attracted more to one atom, resulting in unequal sharing of the electrons and a polar covalent bond. The unequal sharing is a consequence of the different electronegativity values of the atoms in the molecule; the greater the electronegativity difference between the atoms, the more polar the bond. Electronegativities generally increase across a period and decrease down a group in the periodic table.

5.2 Describe qualitatively the bonding in ionic compounds.

Compounds formed between elements with very different electronegativities are often ionic in character. Ionic compounds generally consist of alternating positively and negatively charged ions that are held together by attractive electrostatic forces between the oppositely charged ions. The magnitude of the attractive forces is dependent on the charge of the ions and the separation between them, as well as a number of other factors. The total energy that must be supplied to break the crystal lattice into its gaseous ions is called the lattice energy. Trends in lattice energy values for ionic compounds can be explained in terms of ionic charge and separation.

5.3 Determine Lewis structures for molecular compounds.

Lewis structures show the distribution of valence electrons within a molecule. Bonding electrons are found in single bonds (1 electron pair), double bonds (2 electron pairs) or triple bonds (3 electron pairs) and these are represented as 1, 2 and 3 lines respectively between the bonded atoms.

Nonbonding electrons, called lone pairs, are indicated as dots next to the elemental symbol for the atom on which they are located. Lewis structures may be determined using the following five-step procedure.

Step 1: Count the valence electrons.

Step 2: Assemble the bonding framework using single bonds.

Step 3: Place three nonbonding pairs of electrons on each outer atom, except H.

Step 4: Assign the remaining valence electrons to inner atoms.

Step 5: Minimise formal charges on all atoms.

An atom has an octet if it is surrounded by four pairs of electrons. This arrangement is often found for elements in the second period of the periodic table. When there is a choice of electron arrangement, the one which minimises the formal charge on all atoms will be preferred.

In some cases, two or more energetically equivalent Lewis structures for a molecule can be drawn which differ only in the position of one electron pair. Such structures are called resonance structures. We can also have energetically inequivalent resonance structures; different possible structures may have different formal charge distributions, and the contribution of the individual Lewis structures to the blended structure that represents reality is inverse to their stability (i.e. the lower the energy, the higher the contribution).

5.4 Apply the VSEPR concept to determine the geometry of molecular compounds.

VSEPR theory states that a molecule will adopt a shape in which electron-pair repulsions are minimised. This is achieved by placing electron pairs as far apart as possible.

We can predict the structure of a molecule by using the following three-step procedure.

1. Draw the Lewis structure of the molecule.
2. Count the number of sets of bonding pairs and lone pairs of electrons around any inner atom, and use the following table to determine the optimum geometry of these sets.

Number of sets of electron pairs	Geometry of sets of electron pairs
2	linear
3	trigonal planar
4	tetrahedral
5	trigonal bipyramidal
6	octahedral

3. Modify the geometry, if necessary, to take account of the fact that the magnitudes of repulsions between sets of electron pairs depend on whether the electron pairs involved are bonding pairs (BP) or lone pairs (LP). The repulsions are in the following order.

$$LP-LP > BP-LP > BP-BP$$

The idealised electron pair geometries will be slightly distorted whenever lone pairs are present, because lone pairs occupy more space than bonding pairs.

5.5 Identify and explain properties of covalent bonds.

Molecules where the centres of partial negative and partial positive charges do not coincide have a dipole moment. The magnitudes of dipole moments are measured in C m (coulomb metres). Molecules containing polar bonds do not necessarily have a dipole moment, as the polarities of such bonds may cancel each other. Carbon dioxide provides such an example.

Bond lengths in molecules are dependent on the atomic radii of the bonded atoms, which themselves are dependent on effective nuclear charge. A multiple bond between two atoms is shorter than a single bond between the same atoms. Bond energies increase as the number of electrons in the bond increases, and also as the electronegativity difference between the bonded atoms increases. The length of a bond is inversely proportional to its bond energy — as a bond lengthens, its energy becomes less.

5.6 Analyse bonding in molecules using valence bond theory.

Valence bond theory describes bonding in molecules using localised bonds formed from orbital overlap of hybrid orbitals. As the name suggests, valence bond theory considers only valence orbitals in the formation of bonds. Valence atomic orbitals undergo hybridisation to form hybrid orbitals, with the orbitals involved depending on the type of hybrid orbital required. Hybridisation of one s and three p orbitals gives four sp^3 hybrid orbitals, hybridising one s and two p orbitals gives three sp^2 hybrid orbitals, and hybridising one s and one p orbital gives two sp hybrid orbitals. These processes leave zero, one

and two p orbitals, respectively, unhybridised. The sp^3 hybrid orbitals are positioned tetrahedrally, sp^2 hybrid orbitals are arranged in a trigonal plane, and sp hybrid orbitals adopt a linear arrangement. The hybrid orbitals form σ bonds by overlapping with either atomic orbitals or hybrid orbitals on adjacent atoms. Multiple bonds can be described in terms of one σ bond plus one π bond (double bond) or one σ bond plus two π bonds (triple bond); π bonds are formed by overlap of the unhybridised p orbitals on adjacent sp^2 or sp hybridised atoms.

5.7 Analyse bonding in molecules using molecular orbital theory.

Molecular orbital theory considers all possible overlaps between atomic orbitals in a molecule and describes bonding in terms of delocalised bonds. Overlap of two atomic orbitals gives the formation of molecular orbitals that can cover the entire molecule. Atomic orbitals can overlap in phase (constructive overlap) to give a low energy bonding molecular orbital, or out of phase (destructive overlap) to give a high energy antibonding

molecular orbital. Electron density is maximised between the nuclei in bonding MOs, while antibonding MOs contain a node, a position where the amplitude changes sign, between the nuclei. The relative energies of the resulting orbitals are shown on a molecular orbital diagram. Electrons are placed into a molecular orbital diagram following the same rules as used in an atomic energy level diagram. The bond order of a simple diatomic molecule can be calculated from the following expression.

$$\text{bond order} = \frac{1}{2} \left(\begin{array}{l} \text{number of electrons in bonding molecular} \\ \text{orbitals} - \text{number of electrons in antibonding} \\ \text{molecular orbitals} \end{array} \right)$$

While bond orders are generally 1, 2 or 3, it is possible to have non-integer bond orders. Molecular orbital theory can account for the observed paramagnetism of O_2 while valence bond theory cannot. However, to account for the observed properties of other diatomic molecules, orbital mixing, the overlap of s atomic orbitals with p_z atomic orbitals, must be considered.

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation												
Periodic trends in electronegativity	5.1	These trends allow us to use the positions of elements in the periodic table to estimate the degree of bond polarity and to estimate which atom in a bond is the more electronegative.												
Method for drawing Lewis structures	5.3	Lewis structures show the distribution of valence electrons in a molecule or ion and are drawn according to the following conventions. 1. Each atom is represented by its elemental symbol. 2. Only the valence electrons appear in a Lewis structure. 3. A line joining two elemental symbols represents one pair of electrons shared between two atoms. 4. Dots placed next to an elemental symbol represent nonbonding electrons on that atom.												
Formal charges	5.3	By assigning formal charges, we can select the best Lewis structure for a molecule or polyatomic ion.												
Method for determining resonance structures	5.3	By distributing multiple bonds over atoms in a molecule, we obtain a better description of the bonding.												
VSEPR theory	5.4	This theory enables us to predict the shape of a molecule or polyatomic ion when its Lewis structure is known. 1. Draw the Lewis structure of the molecule. 2. Count the number of sets of bonding pairs and lone pairs of electrons around any inner atom, and use the following table to determine the optimum geometry of these sets. <table><tr><th>Number of sets of electron pairs</th><th>Geometry of sets of electron pairs</th></tr><tr><td>2</td><td>linear</td></tr><tr><td>3</td><td>trigonal planar</td></tr><tr><td>4</td><td>tetrahedral</td></tr><tr><td>5</td><td>trigonal bipyramidal</td></tr><tr><td>6</td><td>octahedral</td></tr></table> 3. Modify the geometry, if necessary, to take account of the fact that the magnitudes of repulsions between sets of electron pairs depend on whether the electron pairs involved are bonding pairs (BP) or lone pairs (LP). The repulsions are in the following order. $\text{LP-LP} > \text{BP-LP} > \text{BP-BP}$	Number of sets of electron pairs	Geometry of sets of electron pairs	2	linear	3	trigonal planar	4	tetrahedral	5	trigonal bipyramidal	6	octahedral
Number of sets of electron pairs	Geometry of sets of electron pairs													
2	linear													
3	trigonal planar													
4	tetrahedral													
5	trigonal bipyramidal													
6	octahedral													
Hybrid orbitals	5.6	Hybrid orbitals help to explain the bonding in molecules, and in particular can be used to rationalise the shapes of molecules.												
Molecular orbital diagrams	5.7	By placing electrons in molecular orbital diagrams we are able to obtain bond orders that agree with experiments for simple diatomic molecules.												

KEY TERMS

antibonding molecular orbital A molecular orbital that has electron density concentrated outside the bonding region, making it less stable than the atomic orbitals from which it forms.

bond energy The energy required to break a bond between two atoms to form infinitely separated atoms.

bond length The separation distance between two atoms that gives the maximum possible energetic advantage over infinitely separated atoms.

bond order $\frac{1}{2}$ (number of electrons in bonding molecular orbitals – number of electrons in antibonding molecular orbitals)

bonding molecular orbital An orbital formed from atomic orbitals in which electron density is maximised between the bonded atoms.

bonding orbital An orbital with high electron density between atoms, formed by constructive interaction between atomic orbitals.

covalent bond A chemical bond in which two atoms share one or more pairs of electrons.

delocalised bond A bond in which electron density is distributed over more than two atoms.

dipole moment The net electrical character arising from an asymmetric charge distribution.

double bond A chemical bond containing two pairs of bonding electrons.

electronegativity A measure of the ability of an atom in a molecule to attract the shared electrons in a chemical bond.

formal charge The difference between the number of valence electrons in the neutral atom and the sum of nonbonding electrons plus half the bonding electrons for an atom in a molecule.

hybrid orbital An atomic orbital obtained by mixing of two or more valence orbitals on the same atom.

ionic compound A compound formed between two elements with large electronegativity differences.

lattice energy The energy required to convert 1 mol of an ionic solid into its constituent gaseous ions.

Lewis structure A representation of covalent bonding that uses symbols for the elements, dots for nonbonding valence electrons, and lines for pairs of bonding valence electrons.

linear Lying along a straight line.

localised bond A chemical bond in which the bonding electrons are shared by only two atoms.

lone pair A pair of valence electrons that is localised on an atom rather than involved in bonding.

molecular orbital (MO) A three-dimensional wave that encompasses an entire molecule and describes a bound electron.

molecular orbital diagram A diagram displaying the energy levels for molecular orbitals of a particular molecule.

molecular orbital theory A bonding theory that considers all possible overlaps between atomic orbitals in a molecule. The

overlap of two atomic orbitals leads to the formation of one bonding molecular orbital and one antibonding molecular orbital. Molecular orbitals are generally delocalised and can be spread over the entire molecule.

node A point, line or surface where the electron density of an orbital is zero.

octahedral Describes a geometry in which a central atom is surrounded by six atoms located at the vertices of an imaginary octahedron.

orbital mixing Interactions among *s* and *p* atomic orbitals that change the relative energies of the molecular orbitals resulting from these atomic orbitals.

orbital overlap The extent to which two orbitals on different atoms interact.

pi (π) bond A chemical bond formed by side-by-side orbital overlap so that electron density is concentrated above and below the bond axis.

polar covalent bond A bond that possesses an asymmetric distribution of electrons.

resonance structure One of two or more Lewis structures that are equivalent to one another.

seesaw shape The molecular shape that resembles a seesaw.

sigma (σ) bond A bond that is totally symmetrical with respect to rotation about the internuclear axis.

single bond A chemical bond formed by one pair of electrons shared between two atoms.

***sp* hybrid orbitals** Two atomic orbitals constructed by the interaction between an *s* orbital and a *p* orbital on the same atom.

***sp*² hybrid orbitals** Three atomic orbitals constructed by the interactions between an *s* orbital and two *p* orbitals on the same atom.

***sp*³ hybrid orbitals** Four atomic orbitals constructed by the interactions between an *s* orbital and three *p* orbitals on the same atom.

tetrahedral Describes a geometry in which a central atom is surrounded by four atoms located at the vertices of an imaginary tetrahedron.

trigonal bipyramidal Describes a geometry in which a central atom is surrounded by five atoms located at the corners of a trigonal bipyramid.

trigonal planar Describes a geometry in which a central atom is surrounded by three atoms lying in a plane at 120° angles to one another.

triple bond A bond between two atoms consisting of three pairs of bonding electrons.

valence-shell-electron-pair repulsion (VSEPR) The principle of minimising electron–electron repulsion by placing electron pairs as far apart as possible.

REVIEW QUESTIONS

Fundamentals of bonding

LO1

5.1 For the following atoms, write the complete electron configuration and identify which of the electrons will be involved in bond formation.

- (a) O
- (b) P
- (c) Be
- (d) Br

5.2 Describe bond formation between a hydrogen atom and a chlorine atom to form a molecule of HCl. Include a diagram of the overlapping orbitals.

5.3 Give the group number and the number of valence electrons for the following elements.

- (a) nitrogen
- (b) aluminium
- (c) iodine
- (d) germanium

5.4 For each of the following pairs, identify which element tends to attract electron density from the other in a covalent bond.

- (a) O and H
- (b) O and N
- (c) K and H
- (d) P and Ga

5.5 Show the direction of bond polarity for the following bonds using δ^+/δ^- notation.

- (a) Al—N
- (b) O—C
- (c) Br—Cl
- (d) C—P

5.6 Arrange the following molecules in order of increasing bond polarity: H_2Se , AsH_3 , NH_3 and H_2S .

Ionic bonding

LO2

5.7 From the following list, select the elements that form ionic compounds: Sr, B, Ag, K, Cl and V. Indicate whether each forms a stable cation or a stable anion.

5.8 From the following list, select the elements that form ionic compounds: C, Ca, Rb, Sb and Br. Indicate whether each forms a stable cation or a stable anion.

5.9 Consider three possible ionic compounds formed by magnesium and oxygen: Mg^+O^- , $\text{Mg}^{2+}\text{O}^{2-}$ and $\text{Mg}^{3+}\text{O}^{3-}$.

- (a) Which would have the greatest lattice energy?
- (b) Which would require the least energy to form the ions?
- (c) Which compound actually exists, and why?

Lewis structures

LO3

5.10 Count the total number of valence electrons in the following species.

- (a) HPO_4^{2-}
- (b) $(\text{C}_6\text{H}_5)_3\text{CCl}$
- (c) $(\text{NH}_2)_2\text{CO}$
- (d) HSO_4^-

5.11 Convert the following formulae into molecular frameworks. For each molecule, calculate how many valence electrons are required to construct the framework.

- (a) $(\text{CH}_3\text{CH}_2)_3\text{CBr}$
- (b) $(\text{CH}_3\text{CH}_2)\text{NH}_2$
- (c) HBrO_4
- (d) $\text{OP}(\text{OCH}_3)_3$

5.12 Determine the Lewis structures of the following.

- (a) NH_3
- (b) NH_4^+
- (c) H_2N^-

5.13 Determine the Lewis structures of the following.

- (a) PBr_3
- (b) SiF_4
- (c) BF_4^-

5.14 Use the standard procedures to determine the Lewis structures of the following.

- (a) H_3CNH_2
- (b) CF_3Cl
- (c) O_2F_2

5.15 Determine the Lewis structures of the following.

- (a) IF_5
- (b) SO_3
- (c) OPCl_3
- (d) XeF_2

5.16 Determine the Lewis structure of each of the following polyatomic ions. Include all resonance structures and formal charges where appropriate.

- (a) NO_3^-
- (b) HSO_4^-
- (c) CO_3^{2-}
- (d) ClO_2^-

Valence-shell-electron-pair repulsion (VSEPR) theory

LO4

5.17 Sketch the following molecular shapes and give the various bond angles in the structures.

- (a) trigonal bipyramidal
- (b) tetrahedral
- (c) octahedral

5.18 Sketch and name the shapes of the following molecules.

- (a) CCl_4
- (b) BH_4^-
- (c) AsF_3

5.19 Draw a ball-and-stick model that shows the geometry of 1,2-dichloroethane, $\text{ClH}_2\text{CCH}_2\text{Cl}$.

5.20 Write the Lewis structure of dimethylamine, $(\text{CH}_3)_2\text{NH}$. Determine its geometry.

5.21 Iodine forms three compounds with fluorine: (a) IF , (b) IF_3 and (c) IF_5 . Determine the Lewis structure, describe the shape and draw a ball-and-stick model of each compound.

5.22 Determine the molecular shape and the ideal bond angles for each of the following.

- (a) SO_2
- (b) SbF_5
- (c) ClF_4^+
- (d) ICl_4^-

Properties of covalent bonds

LO5

5.23 Determine the Lewis structures of the following compounds, and determine which have dipole moments. For each molecule that has a dipole moment, draw a ball-and-stick model and include an arrow to indicate the direction of the dipole moment.

- (a) SiF_4
- (b) H_2Se
- (c) XeF_2
- (d) GaCl_3
- (e) NH_3

5.24 Carbon dioxide has no dipole moment, but sulfur dioxide has $\mu = 5.44 \times 10^{-30} \text{ C m}$. Use Lewis structures to account for this difference in dipole moments.

5.25 Which of the following molecules would you expect to have bond angles that deviate from the ideal VSEPR values? For the molecules that do, make sketches that illustrate the deviations.

- (a) PCl_5
- (b) CH_3I
- (c) ICl_5

5.26 Use table 5.3 to arrange the following bonds in order of increasing bond strength (weakest first): $\text{C}=\text{C}$, $\text{H}-\text{O}$, $\text{C}\equiv\text{N}$, $\text{N}\equiv\text{N}$ and $\text{C}-\text{C}$. List the single most important factor for each successive increase in strength.

Valence bond theory

LO6

5.27 Describe the bonding between iodine and chlorine atoms in the mixed halogen ICl .

5.28 Describe the bonding between hydrogen and fluorine atoms in HF and include a picture of the overlapping orbitals.

5.29 The bond angles in antimony trifluoride are 87° . Describe the bonding in SbF_3 , including a picture of the orbital overlap interaction that creates the $\text{Sb}-\text{F}$ bonds.

5.30 Determine the hybridisation of an inner atom in a molecule with each of the following characteristics.

- (a) 2 lone pairs and 2 ligands
- (b) 3 ligands and 1 lone pair
- (c) 3 ligands and no lone pairs

5.31 Name the hybrid orbitals formed by combining each of the following sets of atomic orbitals.

- (a) one $2s$ and two $2p$ orbitals
- (b) one $3s$ and three $3p$ orbitals

5.32 Identify the hybridisation of the bolded atom in each of the following species.

- (a) $(\text{CH}_3)_2\text{NH}$ (b) SO_2 (c) CO_2

5.33 Describe the bonding in the dichloromethane molecule, CH_2Cl_2 . Sketch an orbital overlap diagram of the molecule.

5.34 Describe the bonding in the hydrogen peroxide molecule, HOOH . Sketch an orbital overlap diagram of the molecule.

5.35 Describe the bonding in the common solvent acetone, $(\text{CH}_3)_2\text{CO}$, and include sketches of all the bonding orbitals.

5.36 The carbon compounds penta-1,4-diene, pent-1-yne and cyclopentene all have the molecular formula C_5H_8 . Use the number of sets of electron pairs and hybridisation to develop bonding pictures of these three molecules.

5.37 Decide if the following pairs of orbitals overlap to form a σ bond, π bond, or no bond at all. Explain your reasoning in each case, including a sketch of the orbitals. Assume the bond lies along the z -axis.

- (a) $2p_z$ and $2p_z$ (b) $2p_y$ and $2p_x$
(c) sp^3 and $2p_z$ (d) $2p_y$ and $2p_y$

Molecular orbital theory: diatomic molecules **L07**

5.38 Use molecular orbital diagrams to rank the bond energies of the following diatomic species from weakest to strongest: Li_2 , Li_2^- and Li_2^+ .

5.39 Which of O_2 or O_2^+ has the stronger bond? Use orbital configurations to justify your selection.

5.40 For each of the following interactions between orbitals of two different atoms, sketch the resulting molecular orbitals. Assume that the nuclei lie along the z -axis, and include at least two coordinate axes in your drawing. Label each MO as bonding or antibonding and σ or π .

- (a) $2s$ and $2p_z$
(b) $2p_y$ and $2p_y$
(c) $2s$ and $2p_x$

5.41 The diagram below shows two $3d$ orbitals about to overlap. The drawing also shows the algebraic signs of the wavefunctions for both orbitals in this combination. Will this combination of orbitals produce a bonding or an antibonding MO?

REVIEW PROBLEMS

5.42 List the following $X\text{—H}$ bonds from smallest bond polarity to largest bond polarity. C—H , F—H , N—H , O—H and Si—H

L01

5.43 Using information in table 5.1, determine the average difference in lattice energy between group 1 fluorides and group 1 chlorides. Determine the average difference in lattice energy between group 1 bromides and group 1 iodides. Is there a trend in the individual values? If so, describe and explain it.

L02

5.44 Determine the molecular geometries of each of the following molecules.

L04

- (a) SiF_4 (b) SeF_4 (c) CF_4

5.48 Species with the general chemical formula XY_4 can have the shapes shown below. For each, name the molecular geometry, identify the ideal VSEPR bond angles, give the number of lone pairs present in the structure and provide a specific example.

L04

5.49 Species with the general chemical formula XY_3 can have the shapes shown below. For each, name the molecular geometry, identify the ideal VSEPR bond angles, give the number of lone pairs present in the structure and provide a specific example.

L04

- 5.50** In the lower atmosphere, NO_2 participates in a series of reactions in air that is also contaminated with unburned hydrocarbons. One product of these reactions is peroxyacetyl nitrate (PAN). The skeletal arrangement of the atoms in PAN appears below. **LO4**

- (a) Complete the Lewis structure of this compound.
 (b) Determine the geometry around each atom marked with an asterisk.
 (c) Give the approximate values of the bond angles indicated with arrows.
- 5.51** The $\text{H}-\text{O}-\text{H}$ bond angle in a water molecule is 104.5° . The $\text{H}-\text{S}-\text{H}$ bond angle in hydrogen sulfide is only 92.2° . Explain these variations in bond angles using orbital sizes and electron–electron repulsion arguments. Draw space-filling models to illustrate your explanation. **LO4**
- 5.52** Sulfur forms two stable oxides, SO_2 and SO_3 . Describe the bonding and geometry of these two compounds. **LO4**
- 5.53** Capsaicin is the molecule responsible for the hot spiciness of chillies. **LO4**

- (a) How many π bonds does capsaicin have?
 (b) Which orbitals are used for bonding by each of the labelled atoms?
 (c) What are the bond angles around each of the labelled atoms?
 (d) Redraw the structure of capsaicin adding the lone pairs.
- 5.54** Determine the Lewis structures for the two possible arrangements of the N_2O molecule: $\text{N}-\text{N}-\text{O}$ and $\text{N}-\text{O}-\text{N}$. Experiments show that the molecule is linear and has a dipole moment. What is the arrangement of atoms? Justify your choice. **LO4**
- 5.55** The inner atom of a triatomic molecule can have any of four different geometries for the surrounding sets of electron pairs. Identify the four geometries, describe the shape associated with each and give a specific example of each. **LO4**

ADDITIONAL EXERCISES

- 5.56** Phosphonic acid, H_3PO_3 , is an exception to the rule that hydrogen always bonds to oxygen in oxoacids. In this compound, one of the hydrogen atoms bonds to phosphorus. Determine the Lewis structure of phosphonic acid and determine the geometry around the phosphorus atom. Draw a ball-and-stick model of the molecule. **LO4**
- 5.57** When an oxalate anion, $\text{C}_2\text{O}_4^{2-}$, adds two protons to form oxalic acid, two $\text{C}-\text{O}$ bonds become longer and two become shorter than the bonds in oxalate anions. Which bonds get longer and which shorter? Use bonding principles to explain the changes. **LO5**
- 5.58** Determine the type of orbitals (atomic, sp^3 or sp^2) used by each atom in the molecules shown below. **LO6**
- (a) (b) H_3CNH_2 (c)
- 5.59** Both PF_3 and PF_5 are known compounds. NF_3 also exists, but NF_5 does not. Why is there no molecule with the formula NF_5 ? **LO6**
- 5.60** Chlorine forms the neutral oxide ClO_2 . Describe the bonding in this unusual compound. Explain why it is considered unusual. **LO6**
- 5.61** Use electron configurations to decide if the following species are paramagnetic or diamagnetic. **LO7**
- (a) NO^+
 (b) O_2^+
- 5.62** Nitrogen molecules can absorb photons to generate excited-state molecules. Construct an energy level diagram and place the valence electrons so that it describes the most stable excited state of an N_2 molecule. Is the $\text{N}-\text{N}$ bond in this excited-state N_2 molecule stronger or weaker than the $\text{N}-\text{N}$ bond in ground-state nitrogen? Explain your answer. **LO7**
- 5.63** Dilithium molecules can be generated by vaporising lithium metal at very low pressure. Do you think it is possible to prepare diberyllium? Explain your reasoning using MO diagrams for Li_2 and Be_2 . **LO7**
- 5.64** Consider the bond lengths of the following diatomic molecules: N_2 , 110 pm; O_2 , 121 pm; F_2 , 143 pm. Explain the variation in length in terms of the molecular orbital descriptions of these molecules. **LO7**

Gases

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 6.1** list the three common states of matter
 - 6.2** describe qualitatively the macroscopic characteristics of gases
 - 6.3** outline and apply the molecular description of gases
 - 6.4** describe the behaviour of gas mixtures
 - 6.5** apply the ideal gas equation to pure gases and mixtures
 - 6.6** complete stoichiometric calculations involving gases
 - 6.7** extend the description of gases to those that deviate from ideal behaviour
 - 6.8** identify and explain intermolecular forces.
-

If you take a look over all the elements on the periodic table you will find that only a few occur naturally as gases. This is mirrored in the fact that overall not many compounds occur as gases under ambient conditions. However, we should not underestimate the importance of gases, since we spend almost all of our time immersed in them and depend on them for our survival.

The Earth's atmosphere is mainly comprised of nitrogen, N_2 , ($\approx 78\%$) and oxygen, O_2 , ($\approx 21\%$) with some other species in trace amounts. The precise composition and temperature of this mixture of gases is responsible for our weather. Figure 6.1 shows a hot-air balloon drifting over Melbourne and reminds us that balloonists exploit the fact that hot air rises.

We begin this chapter with a discussion of the variables that characterise gases. Then we develop a molecular description that explains gas behaviour. Next, we explore additional gas properties and show how to carry out stoichiometric calculations for reactions involving gas-phase species. We then explore the kinds of attractions that exist between molecules and how these forces affect the physical properties of gases.

FIGURE 6.1

Hot-air balloons, such as this one floating over Melbourne, can fly because hot air rises. The air inside the balloons is heated by propane gas burners, making it less dense than the outside air.

6.1 The states of matter

LEARNING OBJECTIVE 6.1 List the three common states of matter.

It is remarkable that essentially all of the matter in the universe exists in only three states: solid, liquid or gas. A fourth state of matter, plasma, exists only under extreme conditions such as those found in the interiors of stars, while the Bose–Einstein condensate, a recently discovered state of matter, is found only at temperatures approaching absolute zero. We will also encounter supercritical fluids, which have properties of both liquids and gases, in the chapter on condensed phases.

It is also interesting that most substances can exist in any of these three states, and that we can change the state that a particular substance is in by varying the temperature and/or pressure; for example, cooling liquid water to below 0 °C at ambient pressure will produce solid water (ice).

Why, at 25 °C and atmospheric pressure, does water exist as a liquid, while oxygen is a gas and gold is a solid? The answer lies in the forces that occur between individual atoms, molecules or ions in a substance. Solids are held together by relatively strong forces between their components, while the corresponding forces in gases are relatively weak. This chapter and the chapter on condensed phases focus on the different possible states of matter. In this chapter, we concentrate on the gaseous state of matter, and investigate the different types of forces that can occur between atoms, ions and molecules. The chapter on condensed phases is primarily concerned with liquids and solids, and also looks at the processes involved when substances change from one state to another.

6.2 Describing gases

LEARNING OBJECTIVE 6.2 Describe qualitatively the macroscopic characteristics of gases.

Gases are characterised by the fact that, in contrast to liquids and solids, they expand to occupy all the space of their container. For example, gaseous water (water vapour) will be found in all parts of any flask it is in, but, if the temperature is lowered, the resulting liquid water occupies only the bottom of the flask. Lowering the temperature further to below the freezing point produces ice, which also occupies only the bottom of the flask. The fact that gases fill all available space implies that the individual gas atoms or molecules are free to move anywhere within their container (figure 6.2), and therefore the forces between them must be very weak. One of the defining characteristics of gases is the pressure they exert. This results from the rapid motion of individual gas atoms or molecules and their collisions with the walls of the container. The pressure (p) exerted by a gas is dependent on the amount of gas present (n), the volume in which it is contained (V) and its temperature (T). We can derive a relationship relating all of these variables.

FIGURE 6.2

Molecules or atoms of a gas move freely throughout the entire volume of a container, changing direction whenever they collide with other molecules or atoms or with a wall. The line traces a possible path of a single molecule or atom.

Pressure (p)

Any object that strikes a surface exerts a force against that surface. In the same way that a ball exerts a force against the ground when it strikes it, the gas molecules inside the ball also exert pressure through collisions with the walls of the ball. At any temperature above absolute zero, atoms and molecules are always in motion. At the molecular level, atoms and molecules exert forces through never-ending collisions with each other and with the walls of their container (e.g. the inside surface of the ball). The collective result of these collisions is what we call **pressure**. We experience pressure as a macroscopic property.

We can get a feel for the macroscopic characteristics of gas pressure by examining the Earth's atmosphere. The atmosphere is a huge reservoir of gas that, due to Earth's gravity, exerts pressure on the

Earth's surface. The pressure of the atmosphere can be measured with an instrument called a **barometer**. Figure 6.3 shows a schematic view of a simple mercury barometer. A long glass tube, closed at one end, is filled with liquid mercury. The filled tube is inverted carefully into a dish that is partially filled with more mercury. The force of gravity pulls downwards on the mercury in the tube. With no opposing force, all the mercury would run out of the tube and mix with the mercury in the dish. The mercury does fall, but the flow stops at a certain height. The column of mercury stops falling because the atmosphere exerts pressure on the mercury in the dish, pushing the column up the tube. When the height of the mercury column generates a downward force on the inside of the tube that exactly balances the force exerted by the atmosphere on the outside of the tube, the column of mercury will remain steady.

At sea level, atmospheric pressure supports a mercury column approximately 760 mm high. Changes in altitude and weather cause fluctuations in atmospheric pressure. At sea level the height of the mercury column seldom varies by more than 10 mm, except under extreme conditions, such as in the eye of a cyclone, when it may fall below 740 mm.

A **manometer** is similar to a barometer, but in a manometer gases exert pressure on both liquid surfaces. Consequently, a manometer measures the difference in pressures exerted by two gases. A simple manometer, shown in figure 6.4, is a U-shaped glass tube containing mercury. One side of the tube is exposed to the atmosphere and the other to a gas whose pressure we want to measure. In figure 6.4, the pressure exerted by the atmosphere (p_{atm}) is less than the pressure exerted by the gas in the bulb (p_{gas}). The difference in heights of mercury between the two sides of the manometer depends on the difference in the pressures exerted by the gas and the atmosphere (equal to p_{Hg}).

FIGURE 6.3

A mercury barometer. The pressure of the atmosphere on the surface of the mercury balances the pressure of the column of mercury.

FIGURE 6.4

The difference in heights of liquid on the two sides of a manometer is a measure of the difference in gas pressures applied to the two sides.

As we learned in the chapter on the language of chemistry, the SI unit for pressure is the **pascal (Pa)**. Pressure is defined as force per unit area, so the pascal is expressed by combining the SI units for these two variables. The SI unit of force is the newton (N), and the unit of area is square metres (m^2). Thus, $1 \text{ Pa} = 1 \text{ N m}^{-2} = 1 \text{ kg m}^{-1} \text{ s}^{-2} = 1 \text{ J m}^{-3}$ (with $1 \text{ N} = 1 \text{ kg m s}^{-2}$ and $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$).

A number of non-SI units for pressure are also commonly used.

- One standard atmosphere (1 atm) is the pressure that will support a column of mercury 760 mm in height (i.e. average atmospheric pressure at sea level); $1 \text{ atm} = 1.013\,25 \times 10^5 \text{ Pa}$.
- One torr is the pressure exerted by a column of mercury 1 mm in height; $1 \text{ atm} = 760 \text{ torr}$.
- $1 \text{ bar} = 1 \times 10^5 \text{ Pa}$.

In this text, we will always express pressure in the SI unit: the pascal (Pa). Standard pressure, p° is defined as $1 \times 10^5 \text{ Pa}$, and we will encounter that in the chapter on chemical thermodynamics.

The gas laws

The volume occupied by a gas changes in response to changes in pressure, temperature and amount of gas. The relationships among these variables are known as the gas laws.

Boyle's Law: the relationship between volume and pressure

Figure 6.5a illustrates experiments conducted at constant temperature by the English scientist Robert Boyle in about 1660. Boyle added liquid mercury to the open end of a J-shaped glass tube, trapping a fixed amount of air on the closed side. When Boyle added additional mercury to the open end of the tube, the pressure exerted by the weight of the additional mercury compressed the trapped gas into a smaller volume.

FIGURE 6.5

(a) Schematic illustration of Boyle's experiments on air trapped in J-shaped tubes. The pressure on the enclosed gas in the right-hand tube is twice that in the left-hand tube, and the volume of the enclosed gas is halved. (b) Graph showing the linear variation of V versus $\frac{1}{p}$.

For example, as shown in figure 6.5a, Boyle found that doubling the total pressure on the trapped air by the addition of mercury halved its volume. In more general terms, Boyle's experiments showed that the volume of the trapped air was inversely proportional to the total pressure applied by the mercury plus the atmosphere.

$$V_{\text{gas}} \propto \frac{1}{p_{\text{gas}}} \quad (\text{fixed temperature and amount of gas})$$

This is shown graphically in figure 6.5b. Alternatively:

$$p_{\text{gas}} V_{\text{gas}} = k \quad (\text{fixed temperature and amount of gas})$$

where k is a constant.

Charles' Law: the relationship between volume and temperature

Boyle also observed that heating a gas causes it to expand in volume, but more than a century passed before Jacques-Alexandre-César Charles reported the first quantitative studies of gas volume as a function of temperature. Charles found that, for a fixed amount of gas, a graph of gas volume versus temperature gives a straight line, as shown in figure 6.6. In other words, the volume of a gas is directly proportional to its temperature.

$$V_{\text{gas}} \propto T_{\text{gas}} \quad (\text{fixed pressure and amount of gas})$$

Alternatively:

$$V_{\text{gas}} = k' T_{\text{gas}} \quad (\text{fixed pressure and amount of gas})$$

where k' is a constant.

FIGURE 6.6

Plots of volume versus temperature for 1 mol of air at three constant pressures. The dots represent experimental data, with dashed lines of best fit extrapolated to 0 K.

Avogadro's Law: the relationship between volume and amount

The volume of a gas also changes when the amount of the gas changes. If we double the amount of a gas while keeping the temperature and pressure fixed, the gas volume doubles. In other words, gas volume is proportional to the amount of gas.

$$V_{\text{gas}} \propto n_{\text{gas}} \quad (\text{fixed pressure and temperature of gas})$$

Alternatively:

$$V_{\text{gas}} = k'' n_{\text{gas}} \quad (\text{fixed pressure and temperature of gas})$$

where k'' is a constant.

The ideal gas equation

The work of Boyle, Charles, Avogadro and other early scientists showed that the volume of any gas is proportional to the temperature and amount of the gas, and inversely proportional to the pressure of the gas. Combining these observations, we find the following.

$$V \propto \frac{nT}{p}$$

This proportionality is converted into an equality by introducing the **gas constant**, represented by the symbol R . Introducing R and multiplying both sides of the equation by p gives the following.

$$pV = nRT$$

This is known as the **ideal gas equation**, because it describes the behaviour of an **ideal gas**. While no gas is truly ideal, the ideal gas equation is adequate to describe most real gases provided that their pressure is relatively low.

The temperature in the ideal gas equation is expressed in kelvin, with $T(\text{K}) = T(^{\circ}\text{C}) + 273.15$. The gas constant is defined in SI units as $R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1}$. Pressure is expressed in Pa, volume is expressed in m^3 ($1 \text{ m}^3 = 1 \times 10^3 \text{ L}$) and amount (n) is expressed in mol. There is a second version of the gas constant that is expressed in non-SI units: $R = 0.08206 \text{ L atm K}^{-1} \text{ mol}^{-1}$. This is still in use, so it is important to always confirm that the value and units of the gas constant are chosen appropriately for a given problem. Worked example 6.1 shows the calculations for both gas constants.

It follows naturally from the ideal gas equation that all ideal gases have the same molar volume under a given set of standard conditions. For example, at 0°C and $1 \times 10^5 \text{ Pa}$, 1 mol of an ideal gas occupies 22.71 L.

WORKED EXAMPLE 6.1**Calculation of gas pressure**

A 1.000×10^3 L steel storage tank contains 88.5 kg of methane, CH_4 . If the temperature is 25°C , what is the pressure inside the tank?

Analysis

The problem asks for the pressure exerted by a gas. The gas is stored in a steel tank, so the volume of the gas cannot change. No chemical changes are described in the problem. We can therefore solve this problem using the ideal gas equation.

Solution

We are given the following data.

$$V = 1.000 \times 10^3 \text{ L} = 1.000 \text{ m}^3 \quad T = 25^\circ\text{C}$$

$$m = 88.5 \text{ kg of methane}$$

We can calculate the pressure of the gas using the ideal gas equation, but we need to make sure all the variables are expressed in appropriate units. Temperature must be in kelvin, amount of methane in mol and volume in m^3 .

We rearrange the ideal gas equation by dividing both sides by V , thus making pressure the subject of the equation.

$$pV = nRT$$

$$p = \frac{nRT}{V}$$

Add 273.15 to the temperature in $^\circ\text{C}$ to convert to kelvin.

$$T = 25 + 273.15 = 298 \text{ K}$$

Note that, when we add numbers, the result has the same number of decimal places as the number with the fewest decimal places (zero in this example).

Use the molar mass of methane to calculate the amount of gas.

$$n_{\text{CH}_4} = \frac{88.5 \times 10^3 \text{ g}}{16.04 \text{ g mol}^{-1}} = 5.52 \times 10^3 \text{ mol}$$

Now substitute this into the rearranged ideal gas equation and calculate the pressure.

$$p = \frac{(5.52 \times 10^3 \text{ mol})(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K})}{1.000 \text{ m}^3}$$

$$= 1.37 \times 10^7 \text{ Pa}$$

If we use the non-SI version of the gas constant, $0.08206 \text{ L atm K}^{-1} \text{ mol}^{-1}$, we need to express the volume in litres (L).

Is our answer reasonable?

It is important to check that the units cancel properly, giving a result in pressure units (recall that $1 \text{ Pa} = 1 \text{ J m}^{-3}$). The problem describes a large amount of methane in a relatively small volume, so a high pressure (over 100 times atmospheric pressure) is reasonable. This high value indicates why gases must be stored in tanks made of materials such as steel that can withstand high pressures.

PRACTICE EXERCISE 6.1

Determine the new pressure if the tank described in worked example 6.1 is stored in a hot shed where the temperature reaches 45°C .

During chemical and physical transformations, any of the four variables in the ideal gas equation (p , V , n , T) may change, and any of them may remain constant. The ideal gas equation can be rearranged as follows.

$$R = \frac{pV}{nT}$$

Then, for different initial and final conditions, we have the following.

$$\frac{p_i V_i}{n_i T_i} = \frac{p_f V_f}{n_f T_f}$$

WORKED EXAMPLE 6.2

Pressure–volume variations

A sample of helium gas is held at constant temperature inside a cylinder with a volume of 0.80 L when a piston exerts a pressure of 1.5×10^5 Pa. If the external pressure on the piston is increased to 2.1×10^5 Pa, what will the new volume be?

Analysis

We can visualise the conditions by drawing a schematic diagram of the initial and final conditions.

p_i = initial pressure
 p_f = final pressure
 V_i = initial volume
 V_f = final volume

Solution

Gas behaviour is involved, so the equation that applies is the ideal gas equation, $pV = nRT$. Rearranging the gas equation to solve for V will not help because we do not know n , the amount of He present, or T , the temperature of the gas. We do know, however, that n and T remain unchanged as the pressure increases.

To determine the final volume of the helium gas, apply the ideal gas equation to the initial and final conditions (shown with subscripts i and f , respectively).

$$p_i V_i = n_i R T_i \quad \text{and} \quad p_f V_f = n_f R T_f$$

In this problem, the quantity of He inside the cylinder and the temperature of the gas are constant.

$$n_i = n_f \quad \text{and} \quad T_i = T_f \quad \text{so} \quad n_i R T_i = n_f R T_f$$

Therefore:

$$p_i V_i = p_f V_f \quad (\text{constant } n \text{ and } T)$$

Notice that we can solve this for V_f without knowing the values of n and T .

Now we rearrange the above equation, substitute the appropriate values and calculate the final volume.

$$\begin{aligned} V_f &= \frac{p_i V_i}{p_f} = \frac{(1.5 \times 10^5 \text{ Pa})(0.80 \times 10^{-3} \text{ m}^3)}{2.1 \times 10^5 \text{ Pa}} \\ &= 0.57 \times 10^{-3} \text{ m}^3 = 0.57 \text{ L} \end{aligned}$$

Is our answer reasonable?

This answer is reasonable because an external pressure increase has caused a volume decrease.

PRACTICE EXERCISE 6.2

The piston in worked example 6.2 is withdrawn until the gas volume is 2.75 L. Calculate the final pressure of the gas.

In worked example 6.2, the quantities on the right-hand side of the ideal gas equation ($pV = nRT$) are fixed, whereas the quantities on the left are changing. A useful strategy for organising gas calculations is to rearrange the gas equation to place all variables that do not change on one side.

6.3 Molecular view of gases

LEARNING OBJECTIVE 6.3 Outline and apply the molecular description of gases.

To understand why all gases can be described by a single equation, we need to explore how gases behave at the molecular level. As gases are characterised by rapid motion of their constituent atoms or molecules, the most important energy component to consider is their kinetic energy, E_{kinetic} . The kinetic energy of an object is given by the equation below where m is the mass of the object (in this case an individual gas atom or molecule) and u is its speed.

$$E_{\text{kinetic}} = \frac{1}{2} m u^2$$

We can easily obtain the mass of a single atom or molecule from the molar mass of the gas, but in order to calculate E_{kinetic} we must measure the speed with which an atom or molecule is moving. As the atoms or molecules in any sample of gas are constantly undergoing collisions with other atoms or molecules and with the walls of the container, they are not all moving at the same speed.

Molecular speeds

The speeds of molecules in a gas can be measured using a molecular beam apparatus, which is shown schematically in figure 6.7a. Gas molecules in an oven escape through a small hole into a chamber with very low molecular density; that is, high vacuum. A set of slits blocks the passage of all molecules except those moving in the forward direction. The result is a beam of molecules, all moving in the same direction. A rotating disc blocks the beam path except for a small slit that allows a packet of molecules to pass through. Each molecule moves down the beam axis at its own speed undergoing minimal collisions with other molecules in the packet. The faster a molecule moves, the less time it takes to travel the length of the chamber. A detector at the end of the chamber measures the number of molecules arriving as a function of time, giving a profile of speeds.

When the speed profile of a gas is measured in this way, the results give a distribution like the one shown in figure 6.7b. If all the molecules travelled at the same speed, they would all reach the detector at the same time, in a single clump. Instead, faster molecules move ahead of the main packet, and slower molecules fall behind. This experiment shows that molecules in a gas have a distribution of speeds.

A pattern emerges when this molecular beam experiment is repeated for various gases at a common temperature; molecules with small masses usually move faster than those with large masses. Figure 6.8 shows this for H_2 , CH_4 and CO_2 . Of these molecules, H_2 has the smallest mass and CO_2 the largest. The vertical line drawn for each gas shows the speed at which there is the largest number of molecules. More molecules have this speed than any other, so this is the most probable speed for molecules of that gas. Figure 6.8 shows that the most probable speed for a molecule of hydrogen at 300 K is $1.57 \times 10^3 \text{ m s}^{-1}$ or $5.65 \times 10^3 \text{ km h}^{-1}$.

FIGURE 6.7

(a) Schematic diagram of a molecular beam apparatus designed to measure the speeds of gas molecules. (b) Distribution of molecules observed by the detector as a function of the time after a packet of molecules passes the slit in the disc.

FIGURE 6.8

Graph showing molecular speed distributions for CO_2 , CH_4 and H_2 at a temperature of 300 K

WORKED EXAMPLE 6.3

A molecular beam experiment

The figures below represent mixtures of neon atoms and hydrogen molecules. (Refer back to figure 2.16 to remind yourself of the colours we use in this text to represent atoms of the various elements in space-filling and ball-and-stick models.)

One of the gas mixtures was used in a molecular beam experiment. The result of the experiment is shown below. Which of the two gas samples, A or B, was used for this experiment?

Analysis

Examine the two samples, and then decide how each of them would behave in a beam experiment.

Solution

Sample A contains twice as many H_2 molecules as Ne atoms, and sample B contains half as many H_2 molecules as Ne atoms. In a molecular beam experiment, both samples would give two peaks in relative areas of 2 : 1. Atoms or molecules with a small mass move faster than those with a large mass, so we expect H_2 ($M = 2.02 \text{ g mol}^{-1}$) to reach the detector before Ne ($M = 20.2 \text{ g mol}^{-1}$). The data show that the first substance to reach the detector is present in the smaller amount. Consequently, the sample used in the beam experiment is the one with the smaller amount of hydrogen molecules: that is, sample B.

Is our answer reasonable?

H_2 moves faster than other, heavier substances, so it makes sense that the H_2 molecules, which are lighter than Ne atoms, get to the detector faster. H_2 molecules are present in a smaller amount than Ne atoms, and the experimental data are consistent with that.

PRACTICE EXERCISE 6.3

Suppose that, in worked example 6.3, sample A is used and that the second gas is helium instead of neon. Sketch

a graph, similar to the graph shown in worked example 6.3, showing the number of molecules/atoms versus time.

Speed and energy

As described above, the energy of any moving object, including a molecule, is related to its mass and speed by the following equation.

$$E_{\text{kinetic}} = \frac{1}{2}mu^2$$

Since atoms or molecules in a gas sample have a distribution of speeds, they will also have a distribution of kinetic energy. If we are interested in the most probable kinetic energy, then we must use the most probable speed in the equation above.

The most probable speed of hydrogen molecules at 300 K is $1.57 \times 10^3 \text{ m s}^{-1}$. We need the mass of one H_2 molecule to be able to calculate its most probable kinetic energy. The SI unit of energy is the joule (J), which equals $1 \text{ kg m}^2 \text{ s}^{-2}$. Thus, we need the mass (m) in kilograms. The molar mass gives the mass of 1 mol of molecules, so dividing molar mass by the Avogadro constant (N_A) gives the mass of 1 molecule.

$$\begin{aligned} m &= \frac{M}{N_A} = \frac{2.016 \text{ g mol}^{-1}}{6.022 \times 10^{23} \text{ mol}^{-1}} \\ &= 3.348 \times 10^{-24} \text{ g} \\ &= 3.348 \times 10^{-27} \text{ kg} \end{aligned}$$

Now apply:

$$\begin{aligned} E_{\text{kinetic}} &= \frac{1}{2} m u^2 \\ E_{\text{kinetic}} (\text{most probable}) &= \frac{1}{2} (3.348 \times 10^{-27} \text{ kg}) (1.57 \times 10^3 \text{ m s}^{-1})^2 \\ &= 4.13 \times 10^{-21} \text{ kg m}^2 \text{ s}^{-2} = 4.13 \times 10^{-21} \text{ J} \end{aligned}$$

The most probable speeds of methane and carbon dioxide are slower than the most probable speed of hydrogen (see figure 6.8), but CH_4 and CO_2 molecules have larger masses than H_2 . When kinetic energy calculations are repeated for these gases, they show that the most probable kinetic energy is the same for all three gases.

For a CH_4 molecule ($m = 2.664 \times 10^{-26} \text{ kg}$):

$$E_{\text{kinetic}} = \frac{1}{2} \times 2.664 \times 10^{-26} \text{ kg} \times (5.57 \times 10^2 \text{ m s}^{-1})^2 = 4.13 \times 10^{-21} \text{ J}$$

For a CO_2 molecule ($m = 7.308 \times 10^{-26} \text{ kg}$):

$$E_{\text{kinetic}} = \frac{1}{2} \times 7.308 \times 10^{-26} \text{ kg} \times (3.36 \times 10^2 \text{ m s}^{-1})^2 = 4.13 \times 10^{-21} \text{ J}$$

Even though the speed distributions for these three gases peak at different values, the most probable kinetic energies are identical. We can also show that, *at a given temperature, all gases have the same molecular kinetic energy distribution.*

Molecular beam experiments show that molecules move faster as the temperature increases. Molecules escaping from the oven at 900 K take less time to reach the detector than molecules escaping at 300 K. As the molecular speed increases, so does the kinetic energy. Figure 6.9 shows the molecular kinetic energy distributions at 300 K and 900 K. By comparing this figure with figure 6.8, we see that the molecular energies show a wide distribution that is similar to the distribution in molecular speeds. Unlike speeds, however, the molecular energy distributions are the same for all gases at any particular temperature. The distributions shown in figure 6.9 apply to any gas.

FIGURE 6.9

Graph of distribution of molecular energies for any gas at 300 K and 900 K

Average kinetic energy and temperature

The most probable kinetic energy is not the same as the average kinetic energy. To find the average kinetic energy per molecule ($\overline{E}_{\text{kinetic}}$; the bar over a variable indicates that it is an average value), we must add all the individual molecular energies and divide by the total number of molecules. The result describes how the average kinetic energy of gas molecules is related to the temperature of the gas.

$$\overline{E}_{\text{kinetic}} = \frac{3RT}{2N_A}$$

In this equation for average kinetic energy per molecule, T is the temperature in kelvin, N_A is the Avogadro constant and R is the gas constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$).

The average kinetic energy expressed by the equation is kinetic energy per molecule. We find the total kinetic energy of 1 mol ($E_{\text{kinetic, molar}}$) of gas molecules by multiplying by the Avogadro constant.

$$E_{\text{kinetic, molar}} = N_A \frac{3RT}{2N_A} = \frac{3}{2}RT$$

Thus, 1 mol of a gas has a total molecular kinetic energy of $\frac{3}{2}RT$ independent of the nature of that gas. While the equation is usually stated in this way, it is worthwhile to note that it is the temperature that is a measure of average kinetic energy.

WORKED EXAMPLE 6.4

Molecular kinetic energies

Determine the average molecular kinetic energy and molar kinetic energy of gaseous sulfur hexafluoride, SF_6 , at 150°C .

Analysis

The problem asks for a calculation of kinetic energies and provides a temperature. We have two equations for the kinetic energy of a gas.

$$\bar{E}_{\text{kinetic}} = \frac{3RT}{2N_A} \quad \text{and} \quad E_{\text{kinetic, molar}} = \frac{3}{2}RT$$

To carry out the calculations, we need to know the gas constant R ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$) and the Avogadro constant N_A ($6.022 \times 10^{23} \text{ mol}^{-1}$) as well as T in kelvin.

Solution

Convert the temperature from $^\circ\text{C}$ to K by adding 273.15.

$$T = 150^\circ\text{C} + 273.15 = 423 \text{ K}$$

Now substitute this into the kinetic energy equation and calculate.

For a single molecule:

$$\begin{aligned} \bar{E}_{\text{kinetic}} &= \frac{3(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(423 \text{ K})}{2(6.022 \times 10^{23} \text{ mol}^{-1})} \\ &= 8.76 \times 10^{-21} \text{ J} \end{aligned}$$

For 1 mol of molecules:

$$\begin{aligned} \bar{E}_{\text{kinetic, molar}} &= \frac{3}{2}(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(423 \text{ K}) \\ &= 5.28 \times 10^3 \text{ J mol}^{-1} \end{aligned}$$

Is our answer reasonable?

We have shown that the average kinetic energy is independent of the nature of the gas. Figure 6.9 shows the molecular energy distributions for a temperature of 300 K and 900 K. The temperature of 423 K is in between these and the molecular energy that we calculated is also between the values at 300 K and 900 K. This answer therefore seems reasonable.

PRACTICE EXERCISE 6.4

The atmospheric temperature at the altitudes at which commercial jets fly is around -53°C . Calculate the aver-

age molecular and molar kinetic energies of N_2 at this temperature.

Rates of gas movement

The average speed of the molecules in a gas determines its temperature. To state this dependence quantitatively, we start with the following two equations.

$$\bar{E}_{\text{kinetic}} = \frac{1}{2}m\bar{u}^2$$

$$\bar{E}_{\text{kinetic}} = \frac{3RT}{2N_A}$$

We set the two expressions for kinetic energy equal to each other.

$$\frac{1}{2}m\bar{u}^2 = \frac{3RT}{2N_A}$$

Now we solve this equality for u , noting that the product mN_A is equal to the molar mass of the gas in kg mol^{-1} .

$$\bar{u}^2 = \frac{3RT}{mN_A} = \frac{3RT}{M} \quad \text{so} \quad \bar{u}_{\text{rms}} = \left(\frac{3RT}{M} \right)^{\frac{1}{2}}$$

This speed is called the **root-mean-square speed** because it is found by taking the square root of $\bar{u}^2$. The average speed of gas molecules is directly proportional to the square root of the temperature and is inversely proportional to the square root of the molar mass of the gas in kg mol^{-1} . This equation can be applied directly to the movement of molecules escaping from a container into a vacuum. This process is one example of **effusion** (more generally, effusion is the flow of molecules through a very small opening that does not allow for collisions between molecules). Effusion is exemplified by the escape of molecules from the oven shown in figure 6.7a.

A second type of gas movement is **diffusion**, the movement of one type of molecule through molecules of the same or another type. Diffusion is exemplified by petrol vapour diffusing from the nozzle of petrol pumps or from small spills at a service station, so you can smell the petrol even from some distance away. The escaping molecules must diffuse among the molecules already present in the atmosphere. Diffusing molecules undergo frequent collisions, so their paths are similar to that shown in figure 6.2. Nevertheless, their average rate of movement depends on temperature and molar mass.

An example of diffusion is shown in figure 6.10, in which concentrated aqueous solutions of hydrochloric acid, HCl, and ammonia, NH_3 , are placed at opposite ends of a glass tube. Molecules of HCl gas and NH_3 gas escape from the solutions and diffuse through the air in the tube. When the two gases meet, they undergo a reaction that produces ammonium chloride, a white solid salt.

The lighter NH_3 molecules diffuse more rapidly than the heavier HCl molecules, so the white band of salt forms closer to the HCl end of the tube, as can be seen in figure 6.10.

FIGURE 6.10

NH_3 diffuses through a glass tube faster than HCl. When the two gases meet, they form solid ammonium chloride, $\text{NH}_4\text{Cl(s)}$, which appears as a white band closer to the end of the tube that contains HCl.

From the discussion of root-mean-square speed, it follows that the ratio of distances that HCl and NH₃ travel, respectively, is inversely related to the square root of the molar masses.

$$\frac{d_{\text{NH}_3}}{d_{\text{HCl}}} = \sqrt{\frac{M_{\text{HCl}}}{M_{\text{NH}_3}}}$$

Rates of molecular motion are directly proportional to molecular speeds, so, for any gas, rates of effusion and diffusion increase with the square root of the temperature in kelvin. Also, at any particular temperature, ratios of effusion and diffusion are faster for molecules with small molar masses.

Ideal gases

As we have seen in this chapter, gases can consist of either atoms or molecules. In what follows, we will use the term ‘molecules’ exclusively for brevity’s sake, but you must remember that everything said about molecules in this section applies equally to atoms.

The behaviour of gases suggests that gas molecules have little effect on one another. Gases are easy to compress, showing that there is lots of empty space between molecules. Gases also escape easily through any opening, indicating that their molecules are not strongly attracted to one another. An ideal gas is defined as a gas for which the ideal gas equation holds. This requires that both the volume of molecules and the forces between the molecules are so small that they have no effect on the behaviour of the gas. We can assume that this is the case when molecular sizes are negligible compared with the volume of the container, and the energies generated by forces between molecules are negligible compared with molecular kinetic energies.

As we describe later in this chapter, small molecules usually have small attractive forces with respect to their kinetic energies, or with respect to RT , often called the *thermal energy*. Table 6.1 lists substances that exist as gases under ambient conditions (note that a binary gas is one that contains molecules formed from two elements). These gases are mostly small molecules with molar masses less than 50 g mol⁻¹. There are some notable exceptions to this; for example, tungsten hexafluoride, WF₆ ($M = 297.8$ g mol⁻¹), and the element radon, Rn ($M = 222$ g mol⁻¹), are gases with much larger molar masses.

TABLE 6.1 Molar masses of some gaseous substances (at 298 K and 1.013×10^5 Pa)

Elemental gases			Binary gases		
Substance	Formula	M (g mol ⁻¹)	Substance	Formula	M (g mol ⁻¹)
hydrogen	H ₂	2.016	methane	CH ₄	16.04
helium	He	4.003	ammonia	NH ₃	17.03
neon	Ne	20.18	carbon monoxide	CO	28.01
nitrogen	N ₂	28.02	nitrogen oxide	NO	30.01
oxygen	O ₂	32.00	ethane	C ₂ H ₆	30.07
fluorine	F ₂	38.00	hydrogen sulfide	H ₂ S	34.09

chlorine	Cl ₂	70.90	nitrogen dioxide	NO ₂	46.01

How does an ideal gas behave? We can answer this question by considering, for example, how changes in V , T or n affect the pressure, p . Each time a molecule strikes a wall, it exerts a force on the wall. During each second, many collisions exert many such forces. Pressure is the sum of all these forces per unit area and unit time. In an ideal gas, each molecule is independent of all others. This independence means that the total pressure is the sum of the pressure created by each individual molecule.

To see how pressure depends on V , T or n , we consider the effect of changing one property while holding the other properties constant. We analyse what happens to the molecular collisions as each property changes.

First, consider increasing the amount of gas while keeping the temperature and volume fixed. Doubling the amount of gas in a fixed volume (figure 6.11) doubles the number of collisions with the walls. Thus, as pressure is essentially a measure of the number of collisions of the molecules with the walls of the container, pressure is directly proportional to the amount of gas. This agrees with the ideal gas equation.

Next, consider keeping the temperature and amount fixed and changing the volume of the gas. Figure 6.12 shows that compressing a gas into a smaller volume has the same effect as adding more molecules. The result is more collisions with the walls. If the molecules act independently, cutting the volume in half will double the pressure. In other words, pressure is inversely proportional to volume, again in agreement with the ideal gas equation.

FIGURE 6.11

Schematic view of the effect of doubling the number of gas molecules in a fixed volume.

(b) represents a container with twice as many molecules as the container in (a). Consequently, the molecular density is twice as large in (b), with twice as many collisions per second with the walls.

FIGURE 6.12

Schematic view of the effect of compressing a fixed quantity of gas into a smaller volume at constant T . Decreasing the volume increases the molecular density, which increases the number of collisions per second with the walls.

To complete our analysis, we must determine the effect of a change in temperature, keeping volume and amount fixed. Recall that kinetic energy is proportional to the square of the molecular speed (a microscopic variable), and temperature (a macroscopic variable) is a measure of average molecular kinetic energy. Thus, the square of the molecular speed is proportional to temperature. We can summarise these relationships by:

$$T \propto E_{\text{kinetic}} \quad \text{and} \quad E_{\text{kinetic}} = \frac{1}{2}mu^2 \quad \text{so} \quad T \propto u^2$$

Molecular speed affects pressure in two ways, which are illustrated in figure 6.13. First, faster moving molecules hit the walls more often than slower moving molecules. The number of collisions each molecule makes with the wall is proportional to the molecule's speed. Second, the force exerted when a molecule strikes the wall also depends on the molecule's speed. A fast-moving molecule exerts a larger force than the same molecule moving more slowly. Force per collision and number of collisions increase with speed, so the total effect of a single molecule on the pressure of a gas is proportional to the square of its speed.

FIGURE 6.13

Schematic view of the effect of increasing molecular speeds (as measured by an increase in temperature), resulting in more wall collisions and more force per collision, and therefore an increase in pressure.

Pressure is proportional to molecular speed squared, which in turn is proportional to temperature. For an ideal gas, then, the pressure is directly proportional to temperature, and a plot of p versus T yields a straight line. Again, this agrees with the ideal gas equation.

The behaviour of any real gas departs somewhat from ideality because real molecules occupy volume and exert forces on one another. Nevertheless, departures from ideality are small enough to neglect under many circumstances, and real gases approximate ideal behaviour under conditions of low pressure and high temperature. We consider departures from ideal gas behaviour later in this chapter.

6.4 Gas mixtures

LEARNING OBJECTIVE 6.4 Describe the behaviour of gas mixtures.

The atmosphere, which contains nitrogen, oxygen and various trace gases, is one obvious example of a gas mixture. Another example is the gas used by deep-sea divers, which contains a mixture of helium and oxygen (figure 6.14). The ideal gas model provides guidance as to how to describe mixtures of gases.

All constituents of an ideal gas, whether atoms or molecules, act independently. This notion applies to gas mixtures as well as to pure gases. Gas behaviour depends on the *number* of gas atoms or molecules but not on their *identity*. The ideal gas equation applies to each gas in the mixture, as well as to the entire collection of atoms or molecules.

Suppose we introduce 0.1 mol of helium into an evacuated 20 L flask. If we add another 0.1 mol of He, the container now contains 0.2 mol of gas. The pressure can be calculated using the ideal gas equation, with $n = 0.1 \text{ mol} + 0.1 \text{ mol} = 0.2 \text{ mol}$. Suppose that we add 0.1 mol of molecular oxygen. Now the container holds a total of 0.3 mol of gas. According to the ideal gas model, it does not matter whether we add the same gas or a different gas because all atoms or molecules in a sample of an ideal gas behave independently. The pressure increases in proportion to the increase in the total amount of gas. Thus, we can calculate the total pressure from the ideal gas equation, using $n = 0.2 \text{ mol} + 0.1 \text{ mol} = 0.3 \text{ mol}$.

How does a 1 : 2 mixture of O_2 and He appear on the molecular level? As O_2 is added to the container, its molecules move throughout the volume and become distributed uniformly. Diffusion causes gas mixtures to become homogeneous. Figure 6.15 illustrates this.

FIGURE 6.14

Deep-sea divers use mixtures of helium and molecular oxygen in their breathing tanks.

FIGURE 6.15

(a) 0.2 mol of He is added to a container. (b) The atoms quickly become distributed uniformly throughout the container. (c) 0.1 mol of O₂ is added to this container. (d) The molecules move about independently of the He atoms, causing the gases to mix uniformly.

Dalton's law of partial pressures

The pressure exerted by an ideal gas mixture is determined by the total amount (n_{total}) of gas.

$$p = \frac{n_{\text{total}}RT}{V}$$

We can express the total amount of gas as the sum of the amounts of the individual gases. For the He and O₂ mixture:

$$n_{\text{total}} = n_{\text{He}} + n_{\text{O}_2}$$

Substitution gives a two-term equation for the total pressure.

$$p = \frac{(n_{\text{He}} + n_{\text{O}_2})RT}{V} = \frac{n_{\text{He}}RT}{V} + \frac{n_{\text{O}_2}RT}{V}$$

Each term on the right resembles the ideal gas equation rearranged to express pressure. Each term therefore represents the **partial pressure** of one of the gases. As figure 6.16 illustrates, partial pressure is the pressure that would be present in a gas container if one gas were present by itself.

$$p_{\text{He}} = \frac{n_{\text{He}}RT}{V} \quad \text{and} \quad p_{\text{O}_2} = \frac{n_{\text{O}_2}RT}{V}$$

The total pressure in the container is the sum of the partial pressures.

$$p_{\text{total}} = p_{\text{He}} + p_{\text{O}_2}$$

We have used He and O₂ to illustrate the behaviour of a mixture of ideal gases. This relationship can be extended to mixtures with three or more substances behaving as ideal gases. **Dalton's law of partial pressures** states in a mixture of gases in which no chemical reaction occurs, each gas contributes to the total pressure the amount that it would exert if the gas were present in the container by itself, so we simply add the contributions from all gases present.

$$p_{\text{total}} = p_1 + p_2 + p_3 + \dots + p_i$$

When working with mixtures of gases, we can apply the ideal gas equation to each component to find its partial pressure (p_i). Alternatively, we can treat the entire gas as a unit, using the total amount of gases present to determine the total pressure of the mixture (p).

FIGURE 6.16

Schematic representation of a sample of O₂, a sample of He and a mixture of the two gases. Both components are distributed uniformly throughout the gas volume. Each gas exerts the same pressure, whether it is pure or part of a mixture.

Describing gas mixtures

There are several ways to describe the chemical composition of a mixture of gases. The simplest method is to list each component with its partial pressure or amount. Two other descriptions, mole fractions and parts per million (ppm), are also used frequently.

Chemists often express chemical composition in fractional terms, stating the amount of a substance as a fraction of the amount of all substances in the mixture. This way of stating composition is the **mole fraction** (x).

$$\text{mole fraction of A} = x_{\text{A}} = \frac{n_{\text{A}}}{n_{\text{total}}}$$

Mole fractions provide a simple way to relate the partial pressure of one component to the total pressure of the gas mixture.

$$p_{\text{A}} = \frac{n_{\text{A}}RT}{V} \quad \text{and} \quad p_{\text{total}} = \frac{n_{\text{total}}RT}{V}$$

Dividing p_{A} by p_{total} gives the following.

$$\frac{p_{\text{A}}}{p_{\text{total}}} = \frac{\left(\frac{n_{\text{A}}RT}{V}\right)}{\left(\frac{n_{\text{total}}RT}{V}\right)} = \frac{n_{\text{A}}}{n_{\text{total}}} = x_{\text{A}}$$

or:

$$p_{\text{A}} = x_{\text{A}} p_{\text{total}}$$

The partial pressure of a component in a gas mixture is its mole fraction multiplied by the total pressure.

WORKED EXAMPLE 6.5

Gas mixtures

Exactly 8.00 g of O₂ and 2.00 g of He was placed in a 5.00 L tank at 298 K. Determine the total pressure of the mixture, and find the partial pressures and mole fractions of the two gases.

Analysis

We have a mixture of two gases in a container with known volume and temperature. The problem asks for pressures and mole fractions. Assuming that molecular interactions

are negligible, each gas can be described independently by the ideal gas equation. As usual, we need molar amounts for the calculations.

Solution

Begin with the data provided.

$$\begin{array}{ll} V = 5.00 \text{ L} = 5.00 \times 10^{-3} \text{ m}^3 & T = 298 \text{ K} \\ m_{\text{He}} = 2.00 \text{ g} & m_{\text{O}_2} = 8.00 \text{ g} \end{array}$$

Convert the mass of each gas into an amount.

$$n = \frac{m}{M} \quad n_{\text{He}} = 0.500 \text{ mol} \quad n_{\text{O}_2} = 0.250 \text{ mol}$$

Next, use the ideal gas equation to calculate the partial pressure of each gas.

$$\begin{aligned} p_{\text{He}} &= \frac{(0.500 \text{ mol})(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K})}{5.00 \times 10^{-3} \text{ m}^3} \\ &= 2.48 \times 10^5 \text{ Pa} \end{aligned}$$

The same calculation for O_2 gives $p_{\text{O}_2} = 1.24 \times 10^5 \text{ Pa}$. The total pressure is the sum of the partial pressures.

$$\begin{aligned} p_{\text{total}} &= p_{\text{He}} + p_{\text{O}_2} = (2.48 \times 10^5 \text{ Pa}) + (1.24 \times 10^5 \text{ Pa}) \\ &= 3.72 \times 10^5 \text{ Pa} \end{aligned}$$

Mole fractions can be calculated from amounts or partial pressures.

$$\begin{aligned} x_{\text{He}} &= \frac{n_{\text{He}}}{n_{\text{total}}} = \frac{0.500 \text{ mol}}{0.750 \text{ mol}} = 0.667 \\ x_{\text{O}_2} &= \frac{p_{\text{O}_2}}{p_{\text{total}}} = \frac{1.24 \times 10^5 \text{ Pa}}{3.72 \times 10^5 \text{ Pa}} = 0.333 \end{aligned}$$

Is our answer reasonable?

The mole fractions calculated from the partial pressures must sum to 1.00. They do in this case, suggesting that our answer is reasonable.

PRACTICE EXERCISE 6.5

A 5.00 L tank is charged with 7.50 g of O_2 and 2.50 g of He. Calculate the mole fractions and the partial pressures of the gases at 25°C .

When referring to lower concentrations in a gas mixture, we typically use **parts per million (ppm)** or **parts per billion (ppb)**. Mole fractions, parts per million and parts per billion can all describe ratios of amount of a particular substance to total amount of a sample. Mole fraction is moles per total moles, ppm is moles per million moles and ppb is moles per billion moles. A concentration of 1 ppm is a mole fraction of 1×10^{-6} , and 1 ppb is a mole fraction of 1×10^{-9} .

WORKED EXAMPLE 6.6

Working with ppm

The exhaust gas from an average car contains 206 ppm of the pollutant nitrogen oxide, NO. If a car emits 0.125 m^3 of exhaust gas at $1.00 \times 10^5 \text{ Pa}$ and 345 K , what mass of NO has been added to the atmosphere?

Analysis

The question asks for the mass of NO. Information about concentration in ppm tells us the amount of NO present in 1 mol of exhaust gas. We can use the ideal gas equation to determine the total amount of gas emitted, then use the concentration information to find the amount of NO, and use the molar mass of NO to obtain the required mass.

Solution

$$\begin{aligned} [\text{NO}] &= 206 \text{ ppm} & V &= 0.125 \text{ m}^3 & p &= 1.00 \times 10^5 \text{ Pa} \\ T &= 345 \text{ K} \end{aligned}$$

$$n_{\text{gas}} = \frac{pV}{RT} = \frac{(1.00 \times 10^5 \text{ Pa})(0.125 \text{ m}^3)}{(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(345 \text{ K})} = 4.36 \text{ mol}$$

$$x_{\text{NO}} = 206 \text{ ppm} = 206 \times 10^{-6} = 2.06 \times 10^{-4}$$

$$\begin{aligned} x_{\text{NO}} &= (x_{\text{NO}})(x_{\text{gas}}) = (2.06 \times 10^{-4})(4.36 \text{ mol}) \\ &= 8.98 \times 10^{-4} \text{ mol} \end{aligned}$$

$$\begin{aligned} m &= nM = (8.98 \times 10^{-4} \text{ mol})(30.01 \text{ g mol}^{-1}) \\ &= 2.69 \times 10^{-2} \text{ g} \end{aligned}$$

Is our answer reasonable?

The mass of NO is rather small, only 27 mg, but the mole fraction is also small, so this result is reasonable.

PRACTICE EXERCISE 6.6

If the maximum NO emission allowed in worked example 6.6 is 762 ppm, what mass of NO is allowed per litre of exhaust gas emitted at a temperature of 55°C ?

The description presented in this section applies to a gas mixture that is not undergoing chemical reactions. As long as reactions do not occur, the amount of each gas is determined by the amount of that substance initially present. When reactions occur, the amounts of reactants and products change as predicted by the principles of stoichiometry. Changes in composition must be taken into account before the properties of the gas mixture can be calculated. Gas stoichiometry is described in section 6.6.

6.5 Applications of the ideal gas equation

LEARNING OBJECTIVE 6.5 Apply the ideal gas equation to pure gases and mixtures.

The ideal gas equation and the molecular view of gases lead to several useful applications. We have already described how to carry out calculations involving p – V – n – T relationships. In this section, we examine the use of the ideal gas equation to determine molar masses and gas density.

Determination of molar mass

The ideal gas equation can be combined with the equation $n = \frac{m}{M}$ (from the chapter on chemical reactions and stoichiometry) to find the molar mass of an unknown gas.

$$pV = nRT \quad \text{and} \quad n = \frac{m}{M}$$

If we know the pressure, volume and temperature of a gas sample, we can use this information to calculate the amount of the ideal unknown gas in the sample.

$$n = \frac{pV}{RT}$$

If we also know the mass of the gas sample, we can use that information to determine the molar mass of the gas.

$$M = \frac{m}{n}$$

WORKED EXAMPLE 6.7

Molar mass determination

Pure calcium carbide, CaC_2 , is a hard, colourless solid that was used in caving lamps. It has a melting point of 2160°C , and it reacts vigorously with water to produce a gas and a solution containing OH^- ions.

A 12.8 g sample of CaC_2 was treated with excess water and the resulting gas was collected in an evacuated 5.00 L glass bulb with a mass of 1054.49 g. The filled bulb had a mass of 1059.70 g and the pressure of the gas inside was 1.00×10^5 Pa when the temperature was 26.8°C . Calculate the molar mass of the gas and determine its formula. Assume that the product gas is insoluble in water and that the vapour pressure of water is negligible in relation to the pressure of the product gas.

Analysis

We can use the ideal gas equation to calculate the molar mass. Then we can use the molar mass to identify the correct molecular formula from a group of possible candidates, as the products may contain only the same elements as the reactants. The problem involves a chemical reaction, so we must make a connection between the gas measurements and the chemistry that takes place. Because the reactants and one product are known, we can write a partial equation that describes the chemical reaction.

In any chemical reaction, atoms must be conserved, so the gas molecules can contain only H, O, C and Ca atoms. To determine the chemical formula of the gas, we must find the combination of these elements that gives the observed molar mass.

Solution

Use the data given to determine the molar mass of the unknown gas.

$$V_{\text{bulb}} = V_{\text{gas}} = 5.00 \text{ L} = 5.00 \times 10^{-3} \text{ m}^3$$

$$T = 26.8^\circ\text{C} = 300.0 \text{ K}$$

$$p = 1.00 \times 10^5 \text{ Pa}$$

$$m_{\text{O}_2} = 8.00 \text{ g}$$

$$m_{\text{bulb+gas}} = 1059.70 \text{ g} \quad m_{\text{bulb}} = 1054.49 \text{ g}$$

$$m_{\text{gas}} = m_{\text{bulb+gas}} - m_{\text{bulb}} = 5.21 \text{ g}$$

We use V , T , p and the ideal gas equation to find the amount of gas. Then, with the mass of the gas sample, we can determine the molar mass.

$$n_{\text{gas}} = \frac{pV}{RT} = \frac{m_{\text{gas}}}{M}$$

We could rearrange this expression and solve the equality for M directly, but to reduce the likelihood of introducing

errors, it is often better to carry out each step explicitly. Therefore, we will first determine n and then solve for M .

$$n_{\text{gas}} = \frac{pV}{RT} = \frac{(1.00 \times 10^5 \text{ Pa})(5.00 \times 10^{-3} \text{ m}^3)}{(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(300.0 \text{ K})} = 2.00 \times 10^{-1} \text{ mol}$$

$$M = \frac{m_{\text{gas}}}{n_{\text{gas}}} = \frac{5.21 \text{ g}}{2.00 \times 10^{-1} \text{ mol}} = 26.0 \text{ g mol}^{-1}$$

To identify the gas, we examine the formulae and molar masses of known compounds that contain only H, O, C or Ca.

Formula	M	Comment
Ca	40	A gas with $M = 26.0 \text{ g mol}^{-1}$ cannot contain Ca.
CO	28	This is too high.
O ₂	32	This is too high.

H ₂ O	18	This is too low, and H ₂ O is a reactant not a product.
CH ₄	16	This is too low.
C ₂ H ₂	26	This substance has the observed molar mass.

Consideration of these possibilities leads to the molecular formula C₂H₂, ethyne (commonly known as acetylene).

Is our answer reasonable?

Knowing the formula of the gaseous product and that OH[−] is another product, we can write a balanced equation for the generation of ethyne.

The balanced equation suggests that the result is reasonable. A systematic evaluation of all possible gases from the reagents that involve only one or two atoms other than hydrogen shows that there are no other possibilities for molar mass 26 g mol^{-1} .

PRACTICE EXERCISE 6.7

The glass bulb in worked example 6.7 is filled with an unknown gas until the pressure is $1.03 \times 10^5 \text{ Pa}$ at a tem-

perature of 24.5°C . The mass of the bulb plus contents is 1260.33 g . Determine the molar mass of the unknown gas.

Determination of gas density

One characteristic of gases is that the density of a gas varies significantly with the conditions. To see this, we combine the ideal gas equation and $n = \frac{m}{M}$ and rearrange to obtain an equation for density ($\rho = \frac{m}{V}$).

$$n = \frac{pV}{RT} \quad \text{and} \quad n = \frac{m}{M}$$

Set the two expressions for n equal to each other.

$$\frac{m}{M} = \frac{pV}{RT}$$

Now, multiply both sides of the equality by M and divide both sides by V .

$$\rho_{\text{gas}} = \frac{m}{V} = \frac{pM}{RT}$$

This equation reveals three features of gas density.

1. The density of an ideal gas increases linearly with increasing pressure at fixed temperature. The reason is that increasing the pressure compresses the gas into a smaller volume without changing its mass.

$$\rho_{\text{gas}} \propto p$$

2. The density of an ideal gas decreases linearly with increasing temperature at fixed pressure. The reason is that increasing the temperature causes the gas to expand without changing its mass.

$$\rho_{\text{gas}} \propto \frac{1}{T}$$

3. The density of ideal gases increases linearly with increasing molar mass at a given temperature and pressure. The reason is that equal amounts of different gases occupy equal volumes at a given temperature and pressure.

$$\rho_{\text{gas}} \propto M$$

There are practical examples of all these features.

- SCUBA divers use high-pressure cylinders, where the high density of the gas gives them more dive time per volume.
- Balloons inflated with helium (figure 6.17) rise in the atmosphere because the molar mass of helium is much lower than the average molar mass of air. Consequently, the density of a helium-filled balloon is less than the density of air, and the balloon rises.
- When the air within a hot-air balloon is heated, its density decreases below that of the outside air. With sufficient heating, the balloon rises and floats. In contrast, cold air is denser than warm air, so cold air sinks. For this reason, valleys often are colder than the surrounding hillsides.

When a gas is released into the atmosphere, whether it rises or sinks depends on its molar mass. If the molar mass of the gas is greater than the average molar mass of air, the gas remains near the ground. Carbon dioxide fire extinguishers are effective for certain fires because of this feature. The molar mass of CO_2 (44.0 g mol^{-1}) is greater than that of N_2 (28.0 g mol^{-1}) or O_2 (32.0 g mol^{-1}), and so a CO_2 fire extinguisher lays down a blanket of this gas that excludes oxygen from the fire.

FIGURE 6.17

Helium-filled balloons float because helium is less dense than air. While they are popular at celebrations, there are growing calls to ban these balloons. They pose a risk to fauna once they deflate and return to the environment. In addition, helium is scarce — and the helium from balloons is lost to the atmosphere and eventually to space.

WORKED EXAMPLE 6.8

Gas density

A certain hot-air balloon will rise when the density of its air is 15.0% lower than that of the surrounding atmospheric air. Calculate the density of air at 295 K and $1.00 \times 10^5 \text{ Pa}$ (assume that dry air is 78.0% N_2 and 22.0% O_2), and determine the minimum temperature of air inside the balloon that will cause the balloon to rise.

Analysis

The problem has two parts. First, we must calculate the density of atmospheric air. To do this, we need to determine the molar mass of dry air, which is the weighted average of the molar masses of its components. Then we must calculate the temperature needed to reduce the density by 15.0%. For both calculations, we use the ideal gas equation as rearranged to give gas density.

$$\rho_{\text{gas}} = \frac{pM}{RT}$$

Solution

Begin by calculating the molar mass of dry air. Multiply the fraction of each component by its molar mass.

$$\begin{aligned} M_{\text{air}} &= \left(\frac{0.78}{1.00} \right) (28.02 \text{ g mol}^{-1}) + \left(\frac{0.22}{1.00} \right) (32.00 \text{ g mol}^{-1}) \\ &= 28.9 \text{ g mol}^{-1} \end{aligned}$$

The other conditions are stated in the problem.

$$T = 295 \text{ K} \quad p = 1.00 \times 10^5 \text{ Pa}$$

Recall that, because the unit Pa is defined in terms of Nm^{-2} , and that $1 \text{ N} = 1 \text{ kg m s}^{-2}$, we must use a molar mass in kg mol^{-1} in this equation. Substituting these into the equation for gas density gives:

$$\begin{aligned} \rho_{\text{gas}} &= \frac{pM}{RT} = \frac{(1.00 \times 10^5 \text{ Pa})(28.9 \times 10^{-3} \text{ kg mol}^{-1})}{(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(295 \text{ K})} \\ &= 1.18 \text{ kg m}^{-3} \end{aligned}$$

The balloon will rise when the density of its contents is 15% less than the density of the surrounding air.

$$\rho_{\text{gas}} = 1.18 \text{ kg m}^{-3} - \left(\frac{0.15}{1.00} \right) (1.18 \text{ kg m}^{-3}) = 1.00 \text{ kg m}^{-3}$$

Rearrange the density equation to solve for temperature, then substitute and calculate.

$$\rho_{\text{gas}} = \frac{pM}{RT} \quad \text{so} \quad T = \frac{pM}{R\rho}$$

$$T = \frac{(1.00 \times 10^5 \text{ Pa})(28.9 \times 10^{-3} \text{ kg mol}^{-1})}{(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(1.00 \text{ kg m}^{-3})} = 348 \text{ K}$$

Is our answer reasonable?

A resultant temperature of 348 K or 75 °C is reasonable as it is higher than the temperature of the surrounding air. Notice that the molar mass and gas constant appear in both calculations, so we can also find the temperature requirement by simple proportions (comparing the air inside and outside the balloon).

$$T_{\text{inside}} = T_{\text{outside}} \left(\frac{\rho_{\text{outside}}}{\rho_{\text{inside}}} \right) = \frac{(295 \text{ K})(1.18 \text{ kg m}^{-3})}{1.00 \text{ kg m}^{-3}} = 348 \text{ K (which rounds to 350 K)}$$

PRACTICE EXERCISE 6.8

Helium is used for lighter-than-air blimps, whereas argon is used to exclude air from flasks in which air-sensitive syntheses are performed. Calculate the densities of these

two group 18 gases at 295 K and $1.00 \times 10^5 \text{ Pa}$, and explain why the two gases have different uses.

Gas density has a significant effect on the interactions between molecules of a gas. As molecules move about, they collide regularly with one another and with the walls of their container. Figure 6.18 shows that the frequency of collisions depends on the density of the gas. At low density, a molecule may move a significant distance before it encounters another molecule. At high density, a molecule travels only a short distance before it collides with another molecule.

FIGURE 6.18

As the molecular density decreases, the average distance travelled between molecular collisions increases.

6.6 Gas stoichiometry

LEARNING OBJECTIVE 6.6 Complete stoichiometric calculations involving gases.

The principles of stoichiometry apply equally to solids, liquids and gases. The ideal gas equation relates the amount of gas to the physical properties of that gas. When a chemical reaction involves a gas, the ideal gas equation provides the link between p – V – T data and amounts.

$$n_i = \frac{p_i V}{RT}$$

Stoichiometric calculations always require amounts and, for gases, these are usually calculated from the ideal gas equation.

WORKED EXAMPLE 6.9

Gas stoichiometry

Worked example 6.7 described the formation of ethyne, C_2H_2 , from calcium carbide, CaC_2 . Modern industrial production of ethyne is based on a reaction of methane, CH_4 , under carefully controlled conditions. At temperatures greater than 1600 K, hydrogen and ethyne are produced in accordance with the following equation.

A 50.0 L steel vessel, filled with CH_4 to a pressure of 10.0×10^5 Pa at 298 K, is heated to exactly 1600 K to convert CH_4 into C_2H_2 . What is the maximum possible mass of C_2H_2 that can be produced? What pressure does the reactor reach at 1600 K? Assume that both CH_4 and C_2H_2 behave as ideal gases under the conditions of the reaction.

Analysis

This is a stoichiometry problem involving gases. The mass of a product and the final pressure must be calculated. We can draw a diagram representing the process and listing the data.

Solution

In any stoichiometry problem, we work with amounts. This problem involves gases, so we use the ideal gas equation to obtain amounts from the p - V - T information. Use the ideal gas equation to calculate the amount of CH_4 present initially.

$$n = \frac{p_i V}{RT_i} = \frac{(10.0 \times 10^5\text{ Pa})(0.0500\text{ m}^3)}{(8.314\text{ J mol}^{-1}\text{ K}^{-1})(298\text{ K})} = 20.18\text{ mol CH}_4$$

From the stoichiometry of the balanced chemical equation, we can determine that complete conversion of 20.18 mol of CH_4 into C_2H_2 and H_2 will give $\left(\frac{1}{2} \times 20.18\right) = 10.09\text{ mol C}_2\text{H}_2$ and $\left(\frac{3}{2} \times 20.18\right) = 30.27\text{ mol H}_2$.

Now we determine the mass of ethyne formed.

$$m = nM = (10.09\text{ mol})(26.04\text{ g mol}^{-1}) = 263\text{ g C}_2\text{H}_2$$

Using the ideal gas equation and the total amount present at the end of the reaction, and assuming all the CH_4 has reacted, we can calculate the final pressure.

$$\begin{aligned} n_{\text{total}} &= 10.09 + 30.27 = 40.36\text{ mol} \\ pV &= nRT \quad \text{and so} \quad p = \frac{nRT}{V} \\ p &= \frac{(40.36\text{ mol})(8.314\text{ J mol}^{-1}\text{ K}^{-1})(1600\text{ K})}{0.0500\text{ m}^3} \\ &= 1.07 \times 10^7\text{ Pa} \end{aligned}$$

Is our answer reasonable?

From the initial amount of methane, we can calculate the initial mass of methane, which is 323 g. The mass of ethyne, 263 g, is less than this, a reasonable result given that H_2 is also produced. The final pressure, 1.07×10^7 Pa, seems high, but the temperature of the reactor has increased substantially and the amount of products is twice the amount of reactants, so a large pressure increase is to be expected.

PRACTICE EXERCISE 6.9

Calculate the volume of hydrogen gas generated when 1.52 g of Mg reacts with an excess of aqueous HCl, if the gas is collected at 1.00×10^5 Pa and 22.5 °C. The balanced

chemical equation for the reaction is as follows.

Any of the types of problems discussed in the chapter on chemical reactions and stoichiometry can involve gases. The strategy for doing stoichiometric calculations is the same whether the species involved are solids, liquids or gases. In this chapter, we add the ideal gas equation to our equations for relating measured quantities to amounts.

WORKED EXAMPLE 6.10

Limiting reagents in a gas mixture

Margarine can be made from natural oils such as coconut oil by hydrogenation.

A hydrogenator (figure 6.19) with a volume of 2.50×10^2 L is charged with 12.0 kg of oil. The remaining volume is then filled with 7.00×10^5 Pa of hydrogen, H_2 , at 473 K. The reaction produces the maximum amount of margarine. What is the final pressure of H_2 , and what mass of margarine will be produced? Assume that H_2 does not dissolve in coconut

oil or margarine, that it behaves as an ideal gas under the reaction conditions and that the coconut oil and margarine occupy a negligible volume in the hydrogenator.

Analysis

We have data from which we can calculate the amounts of both starting materials. Given the chemical equation, the first step in a stoichiometry problem is to determine the initial amount of each starting material. Next, calculate ratios of amounts to identify the limiting reagent. After that, use the ideal gas equation and the stoichiometric principles we learned in the chapter on chemical reactions and stoichiometry to obtain the final answers.

FIGURE 6.19

A hydrogenator available commercially for small-scale use, such as in a research laboratory

Source: Image courtesy Armfield Ltd. FT67 Hydrogenation Unit.

Solution

The ideal gas equation is used for the gaseous starting material.

$$n_{\text{H}_2} = \frac{pV}{RT} = \frac{(7.00 \times 10^5 \text{ Pa})(2.50 \times 10^{-1} \text{ m}^3)}{(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(473 \text{ K})} = 44.5 \text{ mol}$$

We obtain the amount of oil from the mass and the molar mass.

$$n_{\text{oil}} = \frac{m}{M} = \frac{1.20 \times 10^4 \text{ g}}{885.4 \text{ g mol}^{-1}} = 13.6 \text{ mol}$$

We need three times as much H_2 as we have oil for complete reaction to occur. As 44.5 is larger than 3×13.6 we have excess H_2 and the oil is the limiting reagent.

Excess hydrogen is easily recovered from a gas-phase reactor, so margarine manufacturers make the oil the limiting reagent to ensure complete conversion of oil into margarine. The excess H_2 gas is recovered and reused.

The balanced chemical equation shows that 13.6 mol of oil will react with 40.8 mol (3×13.6) of H_2 to give 13.6 mol of margarine. Therefore, the amount of unreacted H_2 will be $(44.5 - 40.8) = 3.7 \text{ mol}$.

Using the ideal gas equation, we calculate the pressure of hydrogen at the end of the reaction.

$$p = \frac{nRT}{V} = \frac{(3.7 \text{ mol})(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(473 \text{ K})}{2.50 \times 10^{-1} \text{ m}^3} = 0.61 \times 10^5 \text{ Pa}$$

Now we calculate the mass of margarine.

$$m = nM = (13.6 \text{ mol})(891.5 \text{ g mol}^{-1}) = 1.21 \times 10^4 \text{ g} = 12.1 \text{ kg}$$

Is our answer reasonable?

In this example, oil is the limiting reagent and not all the H_2 will react. Therefore, some H_2 will be left, but we expect the pressure of H_2 at the end of the reaction to be lower than at the start, which it is. Notice that the mass of margarine produced (12.1 kg) is only slightly greater than the mass of oil we started with (12.0 kg). This is to be expected, as the molar masses of coconut oil and margarine are very similar.

PRACTICE EXERCISE 6.10

In the industrial production of nitric acid, one step is the oxidation of nitrogen oxide.

A reaction chamber is charged with $5.00 \times 10^5 \text{ Pa}$ each of NO and O_2 . If the reaction gives the maximum possible amount of $\text{NO}_2(\text{g})$ at constant temperature and volume, calculate the final pressures of each reagent.

Summary of mole conversions

On the microscopic level, moles are the currency of chemistry; therefore, all stoichiometric calculations require amounts. On the macroscopic level, we measure mass, volume, temperature and pressure. Table 6.2 lists three equations that can be used to convert between the microscopic and macroscopic levels. Each of these equations applies to a particular category of chemical substances. You should have a working knowledge of these three equations, as well as with the category of substances to which they apply.

TABLE 6.2 Summary of stoichiometric relationships

Substance	Relationship	Equation
pure solid, liquid or gas	$\text{amount (mol)} = \frac{\text{mass (g)}}{\text{molar mass (g mol}^{-1}\text{)}}$	$n = \frac{m}{M}$
solution	$\text{amount (mol)} = \text{concentration (mol L}^{-1}\text{)} \times \text{volume (L)}$	$n = cV$
gas	$\text{amount (mol)} = \frac{\text{pressure (Pa)} \times \text{volume (m}^3\text{)}}{\text{constant (J mol}^{-1}\text{ K}^{-1}\text{)} \times \text{temperature (K)}}$	$n = \frac{pV}{RT}$

Worked example 6.11 uses all three relationships. Viewed as a whole, the example may seem complicated. However, as the solution illustrates, breaking the problem into separate parts allows each part to be solved using simple chemical and stoichiometric principles. Complicated problems are often simplified considerably by looking at them one piece at a time.

WORKED EXAMPLE 6.11
General stoichiometry

The reaction of magnesium metal with acid (see figure 6.20) generates hydrogen gas and an aqueous solution of ions. Suppose that 3.50 g of magnesium metal is dropped into 0.150 L of 6.00 mol L⁻¹ HCl in a 5.00 L cylinder at 25.0 °C. The initial gas pressure of the cylinder is 1.00 × 10⁵ Pa, and it is immediately sealed. Find the final partial pressure of hydrogen, the total pressure in the container and the concentration of Mg²⁺ in solution.

FIGURE 6.20 Magnesium reacting with aqueous HCl

Analysis

Data are given for all reactants. We must first write a balanced chemical equation and then use the equations in table 6.2, along with the stoichiometry of the reaction, to calculate the required pressures and concentrations.

Solution

We begin by writing the balanced chemical equation, which we have seen previously in practice exercise 6.9.

The problem asks for pressures and ion concentrations. The final pressure can be determined from p – V – T data and n_{H_2} . The amount of hydrogen can be found from the mass of magnesium and the stoichiometric ratio. Here is a summary of the data.

$$V_{\text{container}} = 5.00 \text{ L} = 5.00 \times 10^{-3} \text{ m}^3 \quad T = 298 \text{ K}$$

$$m_{\text{Mg}} = 3.50 \text{ g}$$

$$V_{\text{solution}} = 0.150 \times 10^{-3} \text{ m}^3$$

$$p_{\text{air}} = 1.00 \times 10^5 \text{ Pa} \quad [\text{HCl}] = 6.00 \text{ mol L}^{-1}$$

Now we analyse the stoichiometry of the reaction. The starting mass of Mg and the volume and concentration of HCl are given, and we can use these data to find the limiting reactant.

$$n_{\text{Mg}} = \frac{m}{M} = \frac{3.50 \text{ g}}{24.31 \text{ g mol}^{-1}} = 0.144 \text{ mol}$$

$$n_{\text{HCl}} = cV = (6.00 \text{ mol L}^{-1})(0.150 \text{ L}) = 0.900 \text{ mol}$$

The amount of HCl needs to be two times the amount of Mg for complete reaction, but in this example it is more than six times the amount of Mg. Therefore, Mg is the limiting reagent.

From the stoichiometry of the balanced chemical equation, we can show that 0.144 mol of Mg will form 0.144 mol H₂. We therefore use this amount to calculate the pressure of H₂. However, before doing this, we must visualise the reaction vessel. The container's total volume is 5.00 × 10⁻³ m³, but 0.150 × 10⁻³ m³ is occupied by the aqueous solution. This leaves 4.85 × 10⁻³ m³ for the gas mixture. The partial pressure of hydrogen is calculated using the ideal gas equation and assuming that no H₂ remains in solution; this is a good approximation because hydrogen gas is not very soluble in water.

$$p_{\text{H}_2} = \frac{nRT}{V} = \frac{(0.144 \text{ mol})(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K})}{4.85 \times 10^{-3} \text{ m}^3} = 0.736 \times 10^5 \text{ Pa}$$

Assuming that the amount of air originally present does not change in the reaction, the pressure exerted by the air

remains constant at 1.00×10^5 Pa. The final total pressure is the sum of the partial pressures.

$$p_{\text{total}} = p_{\text{H}_2} = p_{\text{initial}} = 0.736 \times 10^5 \text{ Pa} + 1.00 \times 10^5 \text{ Pa} \\ = 1.74 \times 10^5 \text{ Pa}$$

We can calculate the final concentration of Mg^{2+} by using the initial amount of Mg and the volume of the solution.

$$[\text{Mg}^{2+}] = \frac{0.144 \text{ mol}}{1.50 \text{ L}} = 0.960 \text{ mol L}^{-1}$$

PRACTICE EXERCISE 6.11

Repeat the calculations from worked example 6.11 with all conditions the same except that 14.0 g of Mg is added to the HCl solution.

6.7 Real gases

LEARNING OBJECTIVE 6.7 Extend the description of gases to those that deviate from ideal behaviour.

In the chapter on chemical bonding and molecular structure, we looked at what holds atoms and ions together, and we listed three types of bonding forces: ionic, covalent and metallic. In addition to these relatively strong bonding forces, there are much weaker forces that exist between atoms, ions and molecules. In the previous sections of this chapter, we looked at ideal gases, assuming that there are no attractive forces between either atoms or molecules. However, weak attractive forces do occur in real gases, and much stronger forces are present in liquids and solids. In the absence of these **intermolecular forces**, all molecules would move independently, and all molecular substances would be gases. These intermolecular forces are essentially due to attractions between polarised molecules, but they also include polar interactions between ions and molecules as well as atoms. The name, intermolecular forces, is therefore somewhat inaccurate, but it can be justified by the fact that an overwhelming number of all chemical compounds are molecules.

The halogens

The halogens, the elements from group 17 of the periodic table, provide an introduction to intermolecular forces. These elements exist as diatomic molecules: F_2 , Cl_2 , Br_2 and I_2 . Each molecule contains two atoms held together by a single covalent bond that can be described by end-on overlap of valence p orbitals.

Although they have similar covalent bonding, bromine and iodine differ from chlorine and fluorine in their macroscopic physical appearance and in their molecular behaviour. As figure 6.21 shows, at room temperature and pressure, chlorine (like fluorine) is a gas, bromine is a liquid and iodine is a solid.

FIGURE 6.21

Under normal conditions, chlorine is a pale yellow-green gas, bromine is a dark red liquid, and iodine is a dark crystalline solid.

Gases and condensed phases (a term used to collectively describe liquids and solids) look very different at the molecular level. Molecules of F_2 or Cl_2 move freely throughout their gaseous volume, travelling many molecular diameters before colliding with one another or with the walls of their container. Because much of the volume of a gas is empty space, samples of gaseous F_2 and Cl_2 readily expand or contract in response to changes in pressure. This freedom of motion exists because the intermolecular forces between these molecules are small with respect to their kinetic energy.

Molecules of liquid bromine also move about relatively freely, but there is not much empty space between molecules. A liquid cannot be compressed significantly by increasing the pressure, because its molecules are already in close contact with one another. Neither does a liquid expand significantly if the pressure is reduced, because the intermolecular forces in a liquid are strong enough to prevent the molecules from breaking away from one another. This is no longer the case, however, if the pressure is reduced enough to reach the boiling point of the liquid.

Solid iodine, like liquid bromine, has little empty space between molecules. Like liquids, solids have sufficiently strong intermolecular forces that they neither expand nor contract significantly when the pressure changes. In solids, the intermolecular forces are strong enough to prevent molecules from moving freely past one another. Instead, the I_2 molecules in the solid phase are arranged in ordered arrays. Each molecule vibrates back and forth around a single most stable position, but it cannot slide easily past its neighbours.

The balance between molecular kinetic energies and intermolecular attractive forces accounts for these striking differences (figure 6.22). Recall from section 6.2 that molecules are always moving. Intermolecular attractive forces tend to hold molecules together in a condensed phase, but molecules that are moving fast enough can overcome these forces and move freely in the gas phase. When the average kinetic energy is large enough, molecules remain separated from one another, and the substance is a gas. Conversely, when intermolecular attractive forces are large enough, molecules remain close to one another, and the substance is a liquid or solid.

The bars in figure 6.23 compare the attractive energies arising from intermolecular forces acting on the halogens. The figure also shows the average molecular kinetic energy at room temperature. For fluorine and chlorine, the attractive energy generated by intermolecular forces is smaller than the average molecular kinetic energy at room temperature. Thus, these elements are gases under these conditions. In contrast, bromine molecules have enough kinetic energy to move freely about, but their energy is insufficient to overcome the intermolecular forces of the liquid phase. Finally, attractive forces in iodine are strong enough to lock the I_2 molecules in position in the solid state.

FIGURE 6.22

A substance exists in a condensed phase when its molecules have too little average kinetic energy to overcome intermolecular forces of attraction.

FIGURE 6.23

The balance of average kinetic energy (red line) and intermolecular energies of attraction favours the gas phase for F_2 and Cl_2 , and the condensed phases for Br_2 and I_2 .

Properties of real gases

As we described in section 6.3, the ideal gas model makes two assumptions: a gas has negligible forces between its constituent atoms or molecules, and gas atoms or molecules have negligible volumes. Neither of these assumptions is true for a real gas. At sufficiently high pressures and sufficiently low temperatures, all gases can be liquefied.

How close do real gases come to ideal behaviour? To answer this question, we rearrange the ideal gas equation to examine the ratio $\frac{pV}{nRT}$. Figure 6.24 shows how the $\frac{pV}{nRT}$ ratio varies with pressure for chlorine gas at room temperature. If chlorine were an ideal gas, the $\frac{pV}{nRT}$ ratio would always be 1, as shown by the red line on the graph. Instead, chlorine shows deviations from 1 as the pressure increases.

Notice in the inset of figure 6.24 that chlorine is nearly ideal at pressures around 1×10^5 Pa. In fact, $\frac{pV}{nRT}$ deviates from 1.0 by less than 4% at pressures below 4×10^5 Pa. As the pressure increases, however, the deviations become increasingly significant. With increasing pressure, the $\frac{pV}{nRT}$ ratio for chlorine drops below 1. This is because the chlorine molecules are close enough together for attractive forces to play a significant role. These intermolecular attractions hold molecules together and reduce the forces exerted when the molecules strike the walls of the container. Intermolecular attractions tend to make the pressure of a real gas lower than the ideal value.

Figure 6.24 also shows that at pressures greater than 375×10^5 Pa, $\frac{pV}{nRT}$ becomes *larger* than 1. This is due to the effect of molecular size. At high enough pressure, the molecules are packed so close together that the total volume of the molecules is no longer negligible compared with the overall volume of the container. The result is that the container volume is effectively decreased by the molecules' volume and the pressure of the real gas tends to be greater than that of the ideal gas.

Every gas shows deviations from ideal behaviour at high pressure. Figure 6.25 shows $\frac{pV}{nRT}$ for He, F₂, CH₄ and N₂, all of which are gases at room temperature. Notice that $\frac{pV}{nRT}$ for helium increases steadily as pressure increases. Interatomic forces for helium are too small to reduce the ratio below 1, but the finite size of the helium atom generates deviations from ideal behaviour that become significant at pressures above 100×10^5 Pa.

FIGURE 6.24

The variation in $\frac{pV}{nRT}$ with pressure shows that chlorine is not an ideal gas.

FIGURE 6.25

Variations in $\frac{pV}{nRT}$ for He, N₂, F₂ and CH₄ at 300 K

Given that every gas deviates from ideal behaviour to some degree, can we use the ideal gas model to discuss the properties of real gases? The answer is yes, as long as conditions do not become too extreme. The gases with which chemists often work, such as chlorine, helium and nitrogen, are nearly ideal at room temperature at pressures below about 10×10^5 Pa, but, at very high pressures or near the condensation points of substances, deviations from the ideal gas equation become large.

The van der Waals equation

It would be useful to have an equation that describes the relationship between pressure and volume for a real gas, just as $\frac{pV}{nRT}$ describes an ideal gas. One way to approach real gas behaviour is to modify the ideal gas equation to account for attractive forces and molecular volumes. The result is the **van der Waals equation**, named after the scientist who first proposed it in 1873, Johannes van der Waals (1837–1923; Nobel Prize in physics, 1910).

$$\left(p + \frac{n^2 a}{V^2}\right)(V - nb) = nRT$$

The van der Waals equation adds two correction terms to the ideal gas equation. Each correction term includes a constant that has a specific value for every gas. The first correction term, $\frac{n^2a}{V^2}$ adjusts for attractive intermolecular forces. The van der Waals constant a reflects the strength of intermolecular forces for the gas; the stronger the forces, the larger the value of a . The second correction term, nb , adjusts for molecular sizes. The van der Waals constant b reflects the size of gas atoms or molecules; the larger they are, the larger the value of b .

The van der Waals constants for a number of gases are given in table 6.3, and the magnitude of van der Waals corrections is explored in worked example 6.12.

TABLE 6.3 Values of van der Waals constants for a variety of gases

Substance	a ($\text{m}^6 \text{Pa mol}^{-2}$)	b ($\text{m}^3 \text{mol}^{-1}$)	Substance	a ($\text{m}^6 \text{Pa mol}^{-2}$)	b ($\text{m}^3 \text{mol}^{-1}$)
He	3.457×10^{-3}	2.37×10^{-5}	Cl_2	6.579×10^{-1}	5.622×10^{-5}
Ne	2.135×10^{-2}	1.709×10^{-5}	CO_2	3.640×10^{-1}	4.267×10^{-5}
Ar	1.363×10^{-1}	3.219×10^{-5}	H_2O	5.536×10^{-1}	3.049×10^{-5}
H_2	2.476×10^{-2}	2.661×10^{-5}	NH_3	4.225×10^{-1}	3.707×10^{-5}
N_2	1.408×10^{-1}	3.913×10^{-5}	CH_4	2.283×10^{-1}	4.278×10^{-5}
O_2	1.378×10^{-1}	3.183×10^{-5}	C_2H_6	5.562×10^{-1}	6.38×10^{-5}
CO	1.505×10^{-1}	3.985×10^{-5}	C_6H_6	1.824×10^{-1}	1.154×10^{-5}
F_2	1.156×10^{-1}	2.90×10^{-5}			

WORKED EXAMPLE 6.12

Magnitudes of van der Waals corrections

Gases such as methane are sold and shipped in compressed gas cylinders. A typical cylinder has a volume of 15.0 L and, when full, contains 62.0 mol of CH_4 . After prolonged use, 0.620 mol of CH_4 remains in the cylinder.

Use the van der Waals equation to calculate the pressures in the cylinder both when full and after use, then compare the values with those obtained from the ideal gas equation. Assume a constant temperature of 25 °C.

Analysis

We are asked to calculate and compare the pressures of methane gas using the van der Waals equation and the ideal gas equation. Van der Waals constants a and b must be looked up in a data table such as table 6.3. To calculate pressures, we rearrange the van der Waals equation and the ideal gas equation.

$$p_{\text{real}} = \frac{nRT}{V - nb} - \frac{n^2a}{V^2} \quad \text{and} \quad p_{\text{ideal}} = \frac{nRT}{V}$$

Solution

The van der Waals constants for CH_4 are as follows.

$$a = 2.283 \times 10^{-1} \text{ m}^6 \text{Pa mol}^{-2} \quad b = 4.278 \times 10^{-5} \text{ m}^3 \text{mol}^{-1}$$

$$V = 15.0 \times 10^{-3} \text{ m}^3 \quad T = (25 + 273.15) \text{ K} = 298 \text{ K}$$

When the tank is full, $n = 62.0$ mol.

$$\begin{aligned} p_{\text{real}} &= \frac{(62.0 \text{ mol})(8.314 \text{ J mol}^{-1} \text{K}^{-1})(298 \text{ K})}{15.0 \times 10^{-3} \text{ m}^3 - (62.0 \text{ mol})(4.278 \times 10^{-5} \text{ m}^3 \text{mol}^{-1})} - \frac{(62.0 \text{ mol})^2(2.283 \times 10^{-1} \text{ m}^6 \text{Pa mol}^{-2})}{(15.0 \times 10^{-3} \text{ m}^3)^2} \\ &= \frac{1.537 \times 10^5 \text{ J}}{1.24 \times 10^{-2} \text{ m}^3} - 3.900 \times 10^6 \text{ Pa} = 85.5 \times 10^5 \text{ Pa (recall that } 1 \text{ Pa} = 1 \text{ J m}^{-3}) \\ p_{\text{ideal}} &= \frac{nRT}{V} = \frac{(62.0 \text{ mol})(8.314 \text{ J mol}^{-1} \text{K}^{-1})(298 \text{ K})}{15.0 \times 10^{-3} \text{ m}^3} = 1.02 \times 10^7 \text{ Pa} \end{aligned}$$

After use, $n = 0.620$ mol.

$$\begin{aligned} p_{\text{real}} &= \frac{(0.620 \text{ mol})(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K})}{15.0 \times 10^{-3} \text{ m}^3 - (0.620 \text{ mol})(4.278 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1})} - \frac{(0.620 \text{ mol})^2(2.283 \times 10^{-1} \text{ m}^6 \text{ Pa mol}^{-2})}{(15.0 \times 10^{-3} \text{ m}^3)^2} \\ &= \frac{1.537 \times 10^3 \text{ J}}{1.50 \times 10^{-2} \text{ m}^3} - 3.90 \times 10^2 \text{ Pa} = 1.02 \times 10^5 \text{ Pa} \\ p_{\text{ideal}} &= \frac{nRT}{V} = \frac{(0.620 \text{ mol})(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K})}{15.0 \times 10^{-3} \text{ m}^3} = 1.02 \times 10^5 \text{ Pa} \end{aligned}$$

Organise the results to make a comparison.

$$p_{\text{full, real}} = 85.5 \times 10^5 \text{ Pa} \quad \text{and} \quad p_{\text{full, ideal}} = 1.02 \times 10^7 \text{ Pa}$$

$$p_{\text{used, real}} = 1.02 \times 10^5 \text{ Pa} \quad \text{and} \quad p_{\text{used, ideal}} = 1.02 \times 10^5 \text{ Pa}$$

Notice that the van der Waals correction is appreciable (16.2%) at the high pressure of the full bottle, but is negligible for the used bottle with a pressure very close to atmospheric pressure (1.013×10^5 Pa).

Is our answer reasonable?

As can be seen in figure 6.25, methane behaves nearly ideal at ambient pressure, but a substantial correction is required at a pressure 100 times larger. This is consistent with our calculation.

PRACTICE EXERCISE 6.12

Methane boils at -164°C . Use the ideal gas equation to calculate the molar volume of methane gas at -155°C and 1.013×10^5 Pa pressure. Then use the van der Waals

equation to calculate the pressure exerted by 1.00 mol of the gas if it occupies this volume at -155°C .

Melting and boiling points

Melting points and boiling points can be used as indicators of the strengths of intermolecular forces. Remember that the temperature increases with the average kinetic energy of molecular motion. The boiling point of a substance is the temperature at which the average kinetic energy of molecular motion balances the attractive energy of intermolecular attractions. When the pressure is 1.013×10^5 Pa, that temperature is the **normal boiling point**. For example, the normal boiling point of bromine is 332 K (59°C). Above this temperature, the average kinetic energy exceeds the attractive energies created by intermolecular forces of attraction, and bromine exists as vapour. Under atmospheric pressure, bromine is a liquid at temperatures below 332 K. Note that, because boiling points are determined primarily by intermolecular attractive forces, factors other than the molar mass of the molecule may be important. For example, carbon tetrachloride, CCl_4 ($M = 153.81 \text{ g mol}^{-1}$), has a lower boiling point (77°C) than the lighter molecule phenol, $\text{C}_6\text{H}_5\text{OH}$ ($M = 94.12 \text{ g mol}^{-1}$, bp = 182°C), because of the much stronger intermolecular forces in phenol.

The conversion of a liquid into a gas is called **vaporisation**. A liquid vaporises when molecules leave the liquid phase faster than they are captured from the gas. **Condensation** is the reverse process. A gas condenses when molecules leave the gas phase more rapidly than they escape from the liquid. We explore these processes in more detail in the chapter on condensed phases.

The molecules in a liquid are able to move about freely. When a liquid is cooled, however, the kinetic energies decrease. At temperatures below the freezing point, the molecules become locked in place and the liquid solidifies. When the pressure is 1.013×10^5 Pa, that temperature is the **normal freezing point**. A liquid freezes when liquid molecules have too little kinetic energy to slide past one another. Conversely, a solid melts when its molecules have enough kinetic energy to move freely past one another. Just as intermolecular forces determine the normal boiling point, these forces also determine the freezing point. The stronger the intermolecular forces, the higher the freezing point; fluorine freezes at 53.5 K, chlorine at 172 K and bromine at 266 K.

Boiling points and melting points depend on the strengths of intermolecular forces. This is because the rates of escape and capture from a phase depend on the balance between molecular kinetic energies and intermolecular forces of attraction. A substance with large intermolecular forces must be raised to a high temperature before its molecules have sufficient kinetic energies to overcome those forces. A substance with small intermolecular forces must be cooled to a low temperature before its molecules have small enough kinetic energies to coalesce into a condensed phase. Table 6.4 lists the boiling and melting points of some elemental substances.

TABLE 6.4 Normal melting and boiling points of selected elements

Substance	mp (K)	bp (K)	Substance	mp (K)	bp (K)
He	0.95 ^(a)	4.2	Br ₂	266	332
H ₂	14.0	20.3	I ₂	387	458
N ₂	63.3	77.4	P ₄	317	553
F ₂	53.5	85.0	Na	371	1156

6.8 Intermolecular forces

LEARNING OBJECTIVE 6.8 Identify and explain intermolecular forces.

In the chapter on chemical bonding and molecular structure, we encountered ionic and covalent bonding that hold atoms and ions together. In addition, so-called intermolecular forces exist between all molecules (hence the name), but they also include attractive forces between atoms and ions other than bonding forces. Intermolecular forces are typically much weaker than bonding forces and generally influence physical properties of compounds (e.g. whether they are gaseous, liquid or solid at ambient conditions) rather than their chemical properties. As stated earlier in this chapter, intermolecular forces are caused by differences in polarity (permanent or temporary) between entities (see below). In this section, we will talk only about molecules, but the discussion also encompasses ions and atoms.

Different intermolecular forces can be thought of as points along a bonding continuum; they all rely on the attraction between positively and negatively charged parts of neighbouring molecules (i.e. electron clouds and nuclei), and the distinction between them is in some cases rather fluid. Forces in order of increasing strength are:

- instantaneous dipole-induced dipole forces (also called dispersion forces)
- dipole-induced dipole forces
- dipole–dipole forces (including hydrogen bonds, which are typically relatively strong dipole–dipole interactions). These are also called dipolar forces.

Analogous forces also exist between ions and both dipoles and induced dipoles. Ion–dipole forces and ion-induced dipole forces are stronger than the intermolecular forces above.

Dispersion forces are the attractions between the negatively charged electron cloud of one molecule and the positively charged nuclei of neighbouring molecules. All substances display dispersion forces. They arise because the electron distribution around a molecule, which is symmetrical on average, is not symmetrical at every instant of time. This creates an instantaneous dipole, which in turn can induce a dipole in a neighbouring molecule.

Dipole-induced dipole forces are somewhat stronger than dispersion forces; the difference is that, in this case, a molecule with a permanent dipole induces a dipole in a neighbouring molecule.

Dipole–dipole forces are the attractions between the negatively charged end of a polar molecule and the positively charged ends of neighbouring polar molecules. Dipole–dipole forces exist only for compounds that possess permanent dipole moments (see the discussion in the chapter on chemical bonding and molecular structure). These dipole–dipole forces are called hydrogen bonds if the positively charged end

is formed by a hydrogen atom. Dispersion forces, dipole–dipole forces and hydrogen bonds are all much weaker than intramolecular covalent bonds. For example, the average C—C bond energy is 345 kJ mol^{-1} , whereas dispersion forces are just 0.1 to 5 kJ mol^{-1} for small alkanes such as propane. Dipole–dipole forces between polar molecules such as acetone range between 5 and 20 kJ mol^{-1} , and hydrogen bonds range between 5 and 50 kJ mol^{-1} . This generalisation, however, needs to be treated with care. In a large molecule, the sum of all the weak dispersion forces may be much stronger than a dipole–dipole interaction in a different molecule, leading to a higher melting or boiling point.

Dispersion forces

Dispersion forces exist because the electron clouds of molecules can be distorted. For example, consider what happens when two halogen molecules approach each other. Each molecule contains positive nuclei surrounded by a cloud of negative electrons. As two molecules approach, the nucleus of one molecule attracts the electron cloud of the other. Electrons are highly mobile, so the electron clouds change shape in response to this attraction. At the same time, the two electron clouds repel each other, which leads to further distortion to minimise electron–electron repulsion. As figure 6.26 indicates, this distortion of the electron clouds creates a charge imbalance, giving the molecule a slight positive charge at one end and a slight negative charge at the other. Dispersion forces are the net attractive forces between molecules generated by all these induced charge imbalances.

The magnitude of dispersion forces depends on how easy it is to distort the electron cloud of a molecule. This ease of distortion is called the **polarisability** because distortion of an electron cloud generates a temporary polarity, called an instantaneous dipole, within the molecule. We can explore how polarisability varies by examining boiling points of the halogens, as shown in figure 6.27. The data reveal that boiling points increase with the total number of electrons. Fluorine, with 18 total electrons, has the lowest boiling point (85 K). Iodine, with 106 electrons, has the highest boiling point (458 K). The large electron cloud of I_2 distorts more readily than the small electron cloud of F_2 . Figure 6.28 shows schematically how a large electron cloud distorts more than a small one, generating larger dispersion forces and leading to a higher boiling point.

FIGURE 6.26

Exaggerated view of how dispersion forces arise

FIGURE 6.27

Boiling points of the halogens increase with the number of electrons.

FIGURE 6.28

With many more electrons, the electron cloud of iodine is much larger and more polarisable than that of fluorine.

Molecular size increases with the number as well as the size of individual atoms. Figure 6.29 shows how the boiling points of alkanes increase as the carbon chain gets longer. As alkanes get longer, their electron clouds become larger and more polarisable, making dispersion forces larger and raising the boiling point. As examples, methane (CH_4 , 10 electrons) is a gas at 298 K , pentane (C_5H_{12} , 42 electrons) is a

low-boiling-point liquid, decane ($\text{C}_{10}\text{H}_{22}$, 82 electrons) is a high-boiling-point liquid and icosane ($\text{C}_{20}\text{H}_{42}$, 162 electrons) is a waxy solid. The boiling point increases progressively as molecules become larger and more polarisable.

FIGURE 6.29

The boiling points of alkanes increase with the length of the carbon chain, because a large electron cloud is more polarisable than a small one.

Dispersion forces increase in strength with the number of electrons because larger electron clouds are more polarisable than smaller electron clouds. For molecules with comparable numbers of electrons, the shape of the molecule makes an important secondary contribution to the magnitude of dispersion forces. For example, figure 6.30 shows the shapes of pentane and 2,2-dimethylpropane. Both of these molecules have the formula C_5H_{12} , with 72 total electrons. Notice that 2,2-dimethylpropane has a more compact structure than pentane. This compactness results in a less polarisable electron cloud and smaller dispersion forces. Accordingly, pentane has a boiling point of 309 K, while 2,2-dimethylpropane boils at 283 K.

FIGURE 6.30

The boiling point of pentane is higher than the boiling point of 2,2-dimethylpropane because an extended electron cloud is more polarisable than a compact one.

Dipolar forces

Dispersion forces exist between all molecules, but some substances remain liquid at much higher temperatures than can be accounted for by dispersion forces alone. Consider 2-methylpropane and propanone (acetone), whose structures are shown in figure 6.31. These molecules have similar shapes and nearly the same number of electrons (34 versus 32). They are so similar that we might expect the two to have nearly equal boiling points, but acetone is a liquid at room temperature, whereas 2-methylpropane is a gas.

Why does acetone remain a liquid at temperatures well above the boiling point of 2-methylpropane? The reason is that acetone has a large dipole moment. Remember from the chapter on chemical bonding and molecular structure that chemical bonds are polarised toward the more electronegative atom. Thus, the C=O bond of acetone is highly polarised, with a partial negative charge on the O atom ($\chi = 3.5$) and a partial positive charge on the C atom ($\chi = 2.5$). The C—H bonds in these molecules, in contrast, are only very slightly polar, because the electronegativity of hydrogen ($\chi = 2.1$) is only slightly smaller than that of carbon.

When two polar acetone molecules approach each other, they align so that the $\delta+$ end of one molecule is close to the $\delta-$ end of the other (see figure 6.31). In a liquid array, this repeating pattern of head-to-tail alignment creates significant net attractive dipolar forces between the molecules.

These dipolar forces, in addition to dispersion forces, which are nearly the same in acetone and 2-methylpropane, increase the total intermolecular attraction between acetone molecules substantially compared to that between molecules of 2-methylpropane. Consequently, acetone boils at a considerably higher temperature than 2-methylpropane.

FIGURE 6.31

Acetone and 2-methylpropane have similar molecular shapes, but acetone has a large dipole moment resulting from its polar C=O bond.

WORKED EXAMPLE 6.13

Boiling points and structure

The line structures of butane, methoxyethane and acetone are shown. Explain the trend in boiling points: butane (273 K), methoxyethane (281 K) and acetone (329 K).

Analysis

These boiling points can be explained in terms of dispersion and dipolar forces. First, assess the magnitudes of dispersion forces, which are present in all substances, and then look for polarity within the molecules.

Solution

A table helps to organise the available information.

Substance	Boiling point	Total electrons
butane	273 K	34
methoxyethane	281 K	34
acetone	329 K	32

The table shows that dispersion forces alone cannot account for the range in boiling temperatures. Methoxyethane and butane have the same number of electrons and similar shapes; yet their boiling points are different. In addition, acetone, which has two fewer electrons

than the other compounds, boils at the highest temperature. The order of boiling points indicates that acetone is a more polar molecule than methoxyethane, which in turn is more polar than butane.

We expect butane to be non-polar because of the small electronegativity difference between carbon and hydrogen. Acetone and methoxyethane, on the other hand, both contain polar carbon–oxygen bonds. Molecular geometry reveals why acetone is more polar than methoxyethane. The full structures of these molecules show that the oxygen atom in the ether has four sets of electron pairs and a bent geometry. The two C–O bond dipoles in methoxyethane partially cancel each other, leaving a relatively small molecular dipole moment. On the other hand, the polar C=O

bond in acetone is unopposed, so acetone has a larger dipole moment and is more polar than methoxyethane.

Is our answer reasonable?

For the molecules in this example, we would expect those containing electronegative oxygen atoms to have higher boiling points than butane because of the presence of significant permanent dipoles. An O atom bonded to only one atom results in a large dipole moment for the molecule as explained previously, and therefore we expect acetone to have a higher boiling point than methoxyethane. Experimental values for the dipole moments are: butane, 0 C m; methoxyethane, 3.74×10^{-30} C m; and acetone, 9.62×10^{-30} C m.

PRACTICE EXERCISE 6.13

Acetaldehyde, CH_3CHO , has a structure similar to acetone but with a CH_3 group replaced by H. This substance boils

at 294 K. Explain its boiling point relative to the three compounds described in worked example 6.13.

The interaction between an ion and the permanent dipole of a molecule can be significant. Such interactions are called ion–dipole interactions, and can be viewed as lying between dipole–dipole interactions and pure ionic interactions. In addition, ions polarise neighbouring molecules, leading to induced dipole interactions, which are much weaker than ion–dipole interactions.

Hydrogen bonds

Methoxyethane is a gas at room temperature (boiling point = 281 K), but propan-1-ol (figure 6.32) is a liquid (boiling point = 370 K). The compounds have the same molecular formula, $\text{C}_3\text{H}_8\text{O}$, and each has a chain of four inner atoms, C–O–C–C and O–C–C–C. Consequently, the electron clouds of these two molecules are about the same size, and their dispersion forces are comparable. Each molecule has an sp^3 -hybridised oxygen atom with two polar single bonds, so their dipolar forces should be similar. The very different boiling points of propan-1-ol and methoxyethane make it clear that dispersion and dipolar forces do not reveal the entire story of intermolecular attractions.

The forces of attraction between propan-1-ol molecules are stronger than those between methoxyethane molecules because of an intermolecular interaction called a hydrogen bond. A hydrogen bond occurs between a small, highly electronegative atom with a lone pair of electrons and a positively polarised hydrogen atom. These interactions can be considered a special example of dipole–dipole interactions, and their strengths generally lie between those of dispersion forces and covalent bonds.

There are two requirements for hydrogen bond formation. First, there must be an electron-deficient hydrogen atom that can be attracted to an electron pair. Hydrogen atoms in O–H, F–H and N–H bonds meet this requirement. Second, there must be a small, highly electronegative atom with an electron pair that can interact with the electron-deficient hydrogen atom. Three second-row elements, O, N and F, meet this requirement, and there is evidence that S and Cl atoms can also form hydrogen bonds, but these are much weaker than those involving F, O and N atoms. Figure 6.33 shows representative examples of hydrogen bonding. The hydrogen bonds are shown as dotted lines to indicate the weak nature of these dipolar interactions.

FIGURE 6.32

The structural formula and a ball-and-stick model of propan-1-ol

FIGURE 6.33

Examples of hydrogen bonding.

Notice from the examples shown in figure 6.34 that hydrogen bonds can form between different molecules (e.g. $\text{H}_3\text{N} \cdots \text{H}_2\text{O}$) or between identical molecules (e.g. $\text{HF} \cdots \text{HF}$). Also notice that molecules can form more than one hydrogen bond (e.g. glycine) and that hydrogen bonds can form between molecules as well as within a molecule (e.g. salicylic acid).

WORKED EXAMPLE 6.14

Formation of hydrogen bonds

In which of the following systems will hydrogen bonding play an important role: CH_3F , $(\text{CH}_3)_2\text{CO}$ (acetone), CH_3OH , and NH_3 dissolved in $(\text{CH}_3)_2\text{CO}$?

Analysis

Hydrogen bonds require electron-deficient hydrogen atoms in polar $\text{H}-\text{X}$ bonds and small, highly electronegative atoms with nonbonding pairs of electrons. Use structural formulae to determine whether these requirements are met.

Solution

The structural formulae of the four molecules are shown with nonbonding electron pairs indicated.

Acetone and CH_3F contain electronegative atoms with nonbonding pairs, but neither has any highly polar $\text{H}-\text{X}$ bonds. Thus, we do not expect any hydrogen bonding between molecules of these substances.

The $\text{O}-\text{H}$ bond in CH_3OH meets both of the requirements for hydrogen bonding. The $\text{O}-\text{H}$ hydrogen atom on one molecule interacts with the oxygen atom of a neighbouring molecule.

For a solution of ammonia in acetone, we must examine both components. Acetone has an electronegative oxygen atom with nonbonding pairs, whereas NH_3 has a polar N—H bond. Consequently, a mixture of these two compounds displays hydrogen bonding between the hydrogen atoms of ammonia and oxygen atoms of acetone, and, depending on the concentration, there will also be hydrogen bonds between ammonia molecules.

Is our answer reasonable?

Methanol has a considerably higher boiling point than the alkanes methane and ethane, consistent with significant hydrogen bonding. Ammonia dissolves readily in acetone, also consistent with significant hydrogen bonding.

PRACTICE EXERCISE 6.14

Draw a picture that shows the hydrogen-bonding interactions of an acetone molecule dissolved in water.

Hydrogen bonding is particularly important in biochemical systems, because biomolecules contain many oxygen and nitrogen atoms that participate in hydrogen bonding. The most important example of biological hydrogen bonding is seen in DNA, where hydrogen bonds hold the two strands of DNA together in a double helix geometry. Likewise, the amino acids from which proteins are made contain —NH_2 (amino) and $\text{—CO}_2\text{H}$ (carboxylic acid) groups, and four different types of hydrogen bonds exist in these systems: $\text{O} \cdots \text{H—N}$, $\text{N} \cdots \text{H—O}$, $\text{O} \cdots \text{H—O}$ and $\text{N} \cdots \text{H—N}$. When biological molecules contain S atoms, $\text{S} \cdots \text{H—O}$ and $\text{S} \cdots \text{H—N}$ hydrogen bonds can also form. Figure 6.33 includes a view of hydrogen bonding between molecules of the amino acid glycine. More details of hydrogen bonding in biomolecules are examined in the chapters on amino acids, proteins and DNA.

Binary hydrogen compounds

Boiling points of binary hydrogen compounds illustrate the interplay between different types of intermolecular forces. Figure 6.34 shows that there are periodic trends in the boiling points of these compounds. In general, the boiling points of the binary hydrogen compounds increase from top to bottom of each column of the periodic table. This trend is due to increasing dispersion forces; the more electrons the molecule has, the stronger are the dispersion forces and the higher is the boiling point. In group 16, for example, H_2S (18 electrons) boils at 213 K, H_2Se (36 electrons) at 232 K and H_2Te (54 electrons) at 269 K.

As figure 6.34 shows, ammonia, water and hydrogen fluoride depart dramatically from the periodic behaviour. This is because their molecules experience particularly large intermolecular forces resulting from hydrogen bonding. In hydrogen fluoride, for instance, hydrogen bonds form between the highly electronegative fluorine atom of one HF molecule and the electron-deficient hydrogen atom of another HF molecule. Similar interactions among many HF molecules result in chains of hydrogen-bonded HF molecules leading to a boiling point much higher than those of HCl, HBr and HI. Note that the boiling point of HCl is also higher than if it were on a trendline parallel to those for groups 15 and 16, indicating that dipolar interactions are present.

Fluorine has the highest electronegativity of any element, so the strongest individual hydrogen bonds are those in HF. Every hydrogen atom in liquid HF is involved in a hydrogen bond, but there is only one polar hydrogen atom per molecule. Thus, each HF molecule may participate in two hydrogen bonds with two other HF partners. There is one hydrogen bond involving the partially positive hydrogen atom and a second involving the partially negative fluorine atom, leading to the formation of HF chains.

FIGURE 6.34

Periodic trends in the boiling points of binary hydrogen compounds. The expectation that the boiling point for substances decreases with molar mass is not followed by all of the binary hydrogen compounds. NH_3 , H_2O and HF are clear exceptions to that trend.

Water has a substantially higher boiling point than hydrogen fluoride, which indicates that the overall hydrogen bonding in H_2O is stronger than that in HF , even though the individual hydrogen bonds in HF are stronger. The higher boiling point of water reflects the fact that it forms more hydrogen bonds of significant strength per molecule than hydrogen fluoride. A water molecule has two hydrogen atoms that can form hydrogen bonds and two nonbonding electron pairs on each oxygen atom. This permits every water molecule to be involved in four hydrogen bonds to four other H_2O partners (figure 6.35a).

FIGURE 6.35

Two representations of the structure of ice. (a) Each oxygen atom is at the centre of a distorted tetrahedron of hydrogen atoms. The tetrahedron is composed of two short covalent O—H bonds and two long $\text{H} \cdots \text{O}$ hydrogen bonds. (b) Water molecules in ice are held in a network of these tetrahedra.

Hydrogen bonding in ice creates a three-dimensional network (figure 6.35b) that puts each oxygen atom at the centre of a distorted tetrahedron. Two arms of the tetrahedron are regular covalent O—H bonds, whereas the other two arms of the tetrahedron are hydrogen bonds to two different water molecules.

Therefore, both the strength and number of hydrogen bonds that a binary hydrogen compound can form determine its boiling point. We will discuss the role of hydrogen bonding in solids in the chapter on condensed phases.

CHEMICAL CONNECTIONS

Atmospheric carbon dioxide

In the periodic table, elemental gases are relatively rare — and that translates to the fact that not many compounds overall are gases. This does not, however, indicate that they aren't important in our everyday lives, and indeed it might be argued they are what we depend on most.

We are immersed in a gaseous atmosphere with an approximate composition of 78% N_2 and 21% O_2 , along with a number of other gaseous substances in very small concentrations. The concentration of one of the minor species, CO_2 , is creating much controversy in the debate on climate change.

Figure 6.36 shows the increase in the concentration of CO_2 in the atmosphere over the past 250 years. There is clearly a very strong increase since the start of the Industrial Revolution in the mid 1800s. While the overall levels of CO_2 might be small, it is the rapid relative change that threatens to bring Earth to the brink of disaster. The ability for CO_2 to act as a greenhouse gas was discovered as far

back as 1856 by the American scientist and women's rights campaigner Eunice Newton Foote (1819–1888; figure 6.37). After more than a century and a half of indifference, she is now widely credited with being the first person to discover the greenhouse effect of CO_2 . What has been in the media much less than the greenhouse effect, is the negative effects of an increasing CO_2 concentration on the acidity of our oceans and consequently on the health of World Heritage listed natural features such as the Great Barrier Reef (figure 6.38). As you will see in later chapters, there is a complex interplay between the increasing concentration of CO_2 in the atmosphere, the solubility of CO_2 in sea water and the oceans' acidity — and its effect on the oceans' health.

FIGURE 6.36

The atmospheric concentration of CO_2 has increased over the past 250 years, most notably as CO_2 emissions associated with human activity have increased.

FIGURE 6.37

Eunice Newton Foote is credited as the first scientist to recognise the role of CO_2 as a greenhouse gas.

FIGURE 6.38

There is a complex relationship between the concentration of CO_2 in the atmosphere and the solubility of CO_2 in the ocean. Changing amounts of CO_2 in the ocean affects the water's acidity, with consequences for the health of marine life. Corals like those of the Great Barrier Reef are particularly sensitive to such changes.

SUMMARY

6.1 List the three common states of matter.

The three most important states of matter are solid, liquid and gas. Most substances can exist in any of these states, and the state adopted by a particular substance under defined conditions is determined by the magnitude of the forces between individual atoms, molecules or ions in the substance.

6.2 Describe qualitatively the macroscopic characteristics of gases.

Gases occupy all of the space in which they are contained. The pressure exerted by a gas is due to the collisions of rapidly moving gas atoms or molecules with the walls of the container. The SI unit of pressure is the pascal (Pa). Atmospheric pressure is measured with a barometer in which a pressure of 1 standard atmosphere (1 atm) will support a column of mercury 760 mm high. This is a pressure of 760 torr. By definition, $1 \text{ atm} = 1.01325 \times 10^5 \text{ Pa}$, and standard pressure (p°) = $1 \times 10^5 \text{ Pa}$. Manometers are used to measure the pressure of trapped gases. Boyle's Law, Charles' Law and Avogadro's Law describe the relationships between volume and pressure, volume and temperature, and volume and amount of a gas, respectively. The combination of these three laws gives the ideal gas equation as follows.

$$pV = nRT$$

In the ideal gas equation, p = pressure (Pa), V = volume (m^3), n = amount (mol), R = the gas constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$) and T = temperature (K).

6.3 Outline and apply the molecular description of gases.

In order to determine the kinetic energy of a gas molecule, it is necessary to measure the speed with which it is moving. This can be done using a molecular beam apparatus. This shows that molecules within a particular gas sample do not all move with the same speed and that small molecules move, on average, faster than large molecules. However, the most probable kinetic energy of a gas molecule is the same, regardless of its mass, and all gases have an identical molecular kinetic energy distribution. The average kinetic energy of a mole of any gas is related to the temperature in kelvin through the following equation.

$$E_{\text{kinetic, molar}} = \frac{3}{2}RT$$

An ideal gas is one for which the volume of the molecules and the forces between the molecules are so small as to be insignificant. An ideal gas obeys the ideal gas equation exactly. Real gases approximate ideal behaviour under conditions of low pressure and high temperature.

The root-mean-square speed of a gas ($\bar{u}_{\text{RMS}}$) can be found from the following equation.

$$\bar{u}_{\text{RMS}} = \left(\frac{3RT}{M} \right)^{\frac{1}{2}}$$

The movement of gas molecules can be described as either effusion (the movement of molecules through a hole small enough to suppress collisions between molecules) or diffusion (the movement of one type of molecule through molecules of the same or another type).

6.4 Describe the behaviour of gas mixtures.

Each gaseous component in a mixture of ideal gases exerts a partial pressure. The sum of partial pressures of all gases in a mixture equals the total pressure. This is a statement

of Dalton's law of partial pressures, which can also be expressed as follows.

$$p_{\text{total}} = p_1 + p_2 + p_3 + \dots + p_i$$

The mole fraction (x_A) of a substance A equals the ratio of the amount of A (n_A), to the total amount (n_{total}) of all the components of a mixture, that is, $x_A = \frac{n_A}{n_{\text{total}}}$. In terms of mole fractions, $p_A = x_A p_{\text{total}}$. The composition of a gas mixture can also be expressed in terms of parts per million (ppm) or parts per billion (ppb).

6.5 Apply the ideal gas equation to pure gases and mixtures.

Combination of the ideal gas equation with the stoichiometric equation, $n = \frac{m}{M}$, allows determination of the molar mass and density of an unknown gas.

6.6 Complete stoichiometric calculations involving gases.

The ideal gas equation can be used to determine amounts, through rearrangement into the form $n = \frac{pV}{RT}$, and can therefore be used in stoichiometric calculations involving pure gases and gas mixtures.

6.7 Extend the description of gases to those that deviate from ideal behaviour.

Intermolecular forces are partially responsible for the fact that real gases do not exactly obey the ideal gas laws. The variation from ideal behaviour can be shown by plotting $\frac{pV}{nRT}$ versus pressure; for an ideal gas, $\frac{pV}{nRT}$ should always equal 1. Values less than 1 are a result of significant intermolecular interactions between individual gas molecules, while values greater than 1 arise from the nonzero volume of the gas molecules. Every gas shows deviation from ideal behaviour at high pressures and at temperatures near the condensation point. The van der Waals equation for a real gas, shown below, makes corrections for the volume of the gas molecules and for the attractive forces between them.

$$\left(p + \frac{n^2 a}{V^2} \right) (V - nb) = nRT$$

The van der Waals constant a reflects the attractive forces between molecules, whereas the constant b reflects the relative size of the gas molecules. Melting points and, especially, boiling points give good indications of the strengths of intermolecular forces. The normal boiling point is the temperature at which the average kinetic energy of molecular motion balances the attractive energy of intermolecular attractions at a pressure of $1.013 \times 10^5 \text{ Pa}$. Under these conditions, the substance is converted from a liquid to a gas in a process called vaporisation. The reverse process is called condensation. The normal freezing point is the temperature at which a liquid solidifies at a pressure of $1.013 \times 10^5 \text{ Pa}$.

6.8 Identify and explain intermolecular forces.

There are three general types of intermolecular forces: dispersion forces, dipole-induced dipole forces and dipole-dipole forces (which include hydrogen bonds). These range in strength from 0.1 to 5 kJ mol^{-1} , 5 to 20 kJ mol^{-1} and 5 to 50 kJ mol^{-1} , respectively.

Dispersion forces result from the asymmetrical distribution of a molecule's electrons at any instant of time, leading to the formation of instantaneous dipoles within the molecule. The ease of distortion of an electron cloud is called the polarisability

of the molecule; molecules with large electron clouds have high polarisabilities and consequently display large dispersion forces. Dispersion forces occur in all molecules.

Polar molecules attract each other by dipolar forces, which arise because the positive end of a permanent dipole attracts the negative end of a dipole in a neighbouring molecule.

Hydrogen bonding, a special case of dipole–dipole attractions, occurs between molecules in which hydrogen is covalently

bonded to a small, very electronegative atom — principally, nitrogen, oxygen or fluorine — and molecules containing atoms that have lone pairs of electrons on small atoms (again mainly nitrogen, oxygen or fluorine). Hydrogen bonding is much stronger than the other types of intermolecular attractions and is the reason for the anomalous behaviour of water, ammonia and hydrogen fluoride when compared with other binary hydrogen compounds.

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation
Ideal gas equation	6.2	This can be used when any three of the four variables p , V , T or n , are known and we wish to calculate the value of the fourth. $pV = nRT$
Dalton's law of partial pressures	6.4	We use this law to calculate the partial pressure of one gas in a mixture of gases. This requires the total pressure and either the partial pressures of the other gases or their mole fractions. If the partial pressures are known, their sum is the total pressure. $p_{\text{total}} = p_1 + p_2 + p_3 + \dots + p_i$
Mole fractions	6.4	Given the composition of a gas mixture, we can calculate the mole fraction of a component. The mole fraction can then be used to find the partial pressure of the component given the total pressure. If the total pressure and partial pressure of a component are known, we can calculate the mole fraction of the component. $p_A = x_A p_{\text{total}}$
Relationship between inter-molecular forces and molecular structure	6.8	From the molecular structure, we can determine whether a molecule is polar or has a permanent dipole and whether it has N—H, O—H or F bonds. This lets us predict and compare the strengths of intermolecular attractions. You should be able to identify when dispersion forces, dipolar forces or hydrogen bonding occur.
van der Waals equation	6.8	The van der Waals equation can be used to calculate the departure of gas behaviour from ideal. $\left(p + \frac{n^2 a}{V^2}\right)(V - nb) = nRT$
Boiling points of substances	6.8	These allow us to compare the strengths of intermolecular forces in substances.

KEY TERMS

barometer An instrument for measuring atmospheric pressure.

condensation Conversion of a vapour into its liquid.

Dalton's law of partial pressures The law stating that in a gas mixture, each gas exerts a pressure equal to the pressure that it would exert if present by itself under otherwise identical conditions.

diffusion The movement of one type of gas molecule through molecules of another type.

dipole–dipole force The attractive force between molecules with permanent dipoles that results from the negative end of one molecule aligning with the positive end of its neighbour.

dipole-induced dipole force The force resulting from the induction of a dipole in a molecule by a neighbouring molecule having a permanent dipole.

dispersion force The attraction between an instantaneous dipole in one molecule and the induced dipole in the other.

effusion The escape of a gas through a pinhole from a container into a vacuum.

gas constant (R) The proportionality constant used in the ideal gas equation.

ideal gas A gas that behaves as described by the ideal gas equation, that is, in which molecular volumes and intermolecular forces are both negligible.

ideal gas equation The equation describing the behaviour of an ideal gas, $pV = nRT$.

intermolecular forces Attractive forces that exist between molecules.

manometer A bent tube, containing a liquid and open at both ends, used to measure differences in pressure.

mole fraction (x) The number of moles of a component in a solution divided by the total number of moles of material in the solution.

normal boiling point The boiling point of a substance under one atmosphere ($1.013\,25 \times 10^5$ Pa) of pressure.

normal freezing point The freezing point of a substance under one atmosphere ($1.013\,25 \times 10^5$ Pa) of pressure.

partial pressure The pressure exerted by one component of a gaseous mixture.

parts per billion (ppb) The number of entities of one particular component present in one billion objects.

parts per million (ppm) The number of entities of one particular component present in one million objects.

pascal (Pa) The SI unit of pressure, $1\,\text{N m}^{-2}$.

polarisability The ease with which the electron distribution about an atom or molecule can be distorted.

pressure Force per unit area.

root-mean-square speed Average speed obtained by taking the square root of the mean value of the squares of the individual speeds.

van der Waals equation An equation that can be used to calculate the departure of gas behaviour from ideal.

vaporisation Conversion of a liquid into its vapour.

REVIEW QUESTIONS

Describing gases

LO2

- 6.1** Describe what would happen to the barometer in figure 6.3 if the tube holding the mercury had a pinhole at its top.
- 6.2** Explain how the difference between an empty and an inflated balloon shows that gas molecules exert pressure.
- 6.3** Express the following in units of pascal.
- 784 torr
 - 2.15 atm
 - 0.500 torr
 - 1.20×10^{-5} atm
- 6.4** A sample of air was compressed to a volume of $25 \times 10^{-3}\,\text{m}^3$. The temperature was 298 K and the pressure was 6.67×10^3 Pa. What amount of gas was in the sample? If the sample was collected from air at a pressure of 1.00×10^5 Pa with a temperature of 298 K, what was the original volume of the gas?
- 6.5** Rearrange the ideal gas equation to give the following expressions.
- an equation that relates p_i , T_i , p_f and T_f when n and V are constant
 - $V = ?$
 - an equation that relates p_i , V_i , p_f and V_f when n and T are constant
- 6.6** It requires 0.446 L of air to fill a metal foil balloon to 1.013×10^5 Pa pressure at 25°C . The balloon is tied off and placed in a freezer at -25°C . What is the new volume of air in the balloon?
- 6.7** Under which of the following conditions could you use the equation $p_i V_i = p_f V_f$?
- A gas expands at constant T .
 - A gas-phase chemical reaction occurs.
 - A container of gas is heated.
 - A container of liquid is compressed at constant T .

Molecular view of gases

LO3

- 6.8** Redraw figure 6.7b to show the distribution of molecules if the temperature of the oven is halved.
- 6.9** Draw a single graph showing the speed distributions of N_2 at 200 K, N_2 at 300 K and Ne at 300 K.
- 6.10** Calculate the root-mean-square speed and total kinetic energy per mole for each of the following.
- He at 527°C
 - O_2 at 127°C
 - SF_6 at 527°C

- 6.11** Explain in molecular terms why each of the following statements is true.
- At very high pressure, no gas behaves ideally.
 - At very low temperature, no gas behaves ideally.

- 6.12** The figure represents an ideal gas in a container with a movable friction-free piston.

- The external pressure on the piston exerted by the atmosphere is 1.013×10^5 Pa. If the piston is not moving, what is the pressure inside the container? Explain in terms of molecular collisions.
 - Redraw the sketch to show what would happen if the temperature of the gas in the container is halved. Explain in terms of molecular collisions.
- 6.13** Describe the molecular changes that account for the result in question 6.6.
- 6.14** Determine the root-mean-square speed of SF_6 molecules at 1.520×10^5 Pa and 25°C .
- 6.15** A student proposes to separate CO from N_2 by an effusion process. Is this likely to work? Why or why not?

Gas mixtures

LO4

- 6.16** The concentration of NO_2 in a smoggy atmosphere was measured as 0.75 ppm. The barometric pressure was 1.011×10^5 Pa. Calculate the partial pressure of NO_2 in Pa.
- 6.17** In dry atmospheric air, the four most abundant components are N_2 , $x = 0.7808$; O_2 , $x = 0.2095$; Ar, $x = 9.34 \times 10^{-3}$; and CO_2 , $x = 3.25 \times 10^{-4}$. Calculate the partial pressures of these four gases, in Pa, under standard atmospheric conditions.

- 6.18** The figures below represent very small portions of three gas mixtures, all at the same volume and temperature.

- (a) Which sample has the highest partial pressure of gas B?
 (b) Which sample has the highest mole fraction of gas C?
 (c) In sample I, what is the concentration of gas A in ppm?
- 6.19** A sample of car exhaust is analysed. The gas is found to contain 513.4 ppm CO_2 , 10.3 ppb NO and 4.2 ppb CO. Calculate the partial pressures of these gases if the exhaust is emitted at a pressure of 111.1 kPa.

Applications of the ideal gas equation

LO5

- 6.20** What is the density (g L^{-1}) of WF_6 gas at 1.013×10^5 Pa and 25°C ?

Gas stoichiometry

LO6

- 6.21** Humans consume glucose to produce energy. The products of glucose consumption are CO_2 and H_2O .

What volume of CO_2 is produced under body conditions (37°C , 1.013×10^5 Pa) during the consumption of 5.00 g of glucose?

- 6.22** Sodium metal reacts with molecular chlorine gas to form sodium chloride. A closed container of volume 3.00×10^3 mL contains chlorine gas at 27°C and 1.67×10^5 Pa. Then 6.90 g of solid sodium is introduced, and the reaction goes to completion. What is the final pressure if the temperature rises to 52°C ?
- 6.23** Ammonia is produced industrially by reacting N_2 with H_2 at elevated pressure and temperature in the presence of a catalyst.

Assuming 100% yield, what mass of ammonia would be produced from a 1 : 1 mole ratio mixture in a reactor that has a volume of 8.50×10^3 L, under a total pressure of 275×10^5 Pa at 475°C ?

- 6.24** In practice, the reaction of question 6.23 gives a yield of only 17%. Repeat the calculation taking this into account.

Real gases

LO7

- 6.25** Predict whether the effects of molecular volume and intermolecular attractions become more or less significant when the following changes are imposed.
- (a) A gas expands into a larger volume at constant temperature.
 (b) More gas is introduced into a container of constant volume at constant temperature.
 (c) The temperature of a gas increases at constant pressure.

- 6.26** From the following experimental data, calculate the percentage deviation from ideal behaviour. One mole CO_2 in a 1.20 L container at 25°C exerts 19.7×10^5 Pa pressure.

- 6.27** Chlorine gas is commercially produced by electrolysis of sea water and is stored under pressure in metal tanks. A typical tank has a volume of 18.0 L and contains 1.25 kg of Cl_2 . Use the van der Waals equation to calculate the pressure in this tank if the temperature is 298 K, and compare the result with the ideal gas value.

Intermolecular forces

LO8

- 6.28** Arrange the following in order of ease of liquefaction: CCl_4 , CH_4 and CF_4 . Explain your ranking.

- 6.29** Arrange the following in order of increasing boiling point: Cl_2 , I_2 , Br_2 and F_2 . Explain your ranking.

- 6.30** List ethanol, $\text{CH}_3\text{CH}_2\text{OH}$, propane, $\text{CH}_3\text{CH}_2\text{CH}_3$, and pentane, $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3$, in order of increasing boiling point, and explain what features determine this order.

- 6.31** Which of the following will form hydrogen bonds with another molecule of the same substance? Draw molecular pictures illustrating these hydrogen bonds.

- (a) CH_2Cl_2
 (b) H_2SO_4
 (c) H_3COCH_3
 (d) $\text{H}_2\text{NCH}_2\text{COOH}$

- 6.32** Which of the following molecules form hydrogen bonds with water? Draw molecular pictures illustrating these hydrogen bonds.

- (a) CH_4
 (b) I_2
 (c) HF
 (d) H_3COCH_3
 (e) $(\text{CH}_3)_3\text{COH}$

REVIEW PROBLEMS

- 6.33** The figure below shows three chambers with equal volumes, all at the same temperature, separated by closed valves. Each chamber contains helium gas, with amounts proportional to the number of dots representing atoms. **LO2**

Answer each of the following questions, briefly stating your reasoning.

- (a) Which of the three has the highest pressure?
 (b) If the pressure in B is 1.0×10^5 Pa, what is the pressure in A?
 (c) If the pressure in A starts at 1.0×10^5 Pa, and then all of the atoms from B and C are transferred to A, what will be the new pressure?
 (d) If the pressure in B is 0.50×10^5 Pa, what will the pressure be after the valves are opened?

- 6.34** In the two figures shown, the molecule represented by the green sphere is about to strike the wall of its container. Assuming all other conditions are identical, which collision will exert greater pressure on the wall? Explain in terms of intermolecular interactions. **LO2**

- (a) Which container has a higher total gas pressure? Explain.
 (b) Which container has a higher partial pressure of molecular hydrogen? Explain.
 (c) One of the two gas mixtures (A or B) was used in a pulsed molecular beam experiment. The result of the experiment is shown below. Which of the two gas samples, A or B, was used for this experiment? Explain.

- 6.35** People often remark that ‘the air is thin’ at higher elevation. Explain this comment in molecular terms using the fact that the atmospheric pressure at the top of Mount Everest is about 3.33×10^4 Pa. **LO2**
6.36 At an altitude of 40 km above the Earth’s surface, the temperature is about -32°C , and the pressure is about 4.0×10^2 Pa. Calculate the average molecular speed of ozone, O_3 , at this altitude. **LO3**
6.37 Consider two gas bulbs of equal volume, one filled with H_2 gas at 0°C and 2×10^5 Pa, the other containing O_2 gas at 25°C and 1×10^5 Pa. Which bulb has (a) more molecules, (b) a greater mass, (c) a higher average kinetic energy of molecules, and (d) a higher average molecular speed? **LO3**
6.38 Molecular beam experiments on ammonia at 425 K give the speed distribution shown in the figure. **LO3**

- (a) What is the most probable speed?
 (b) What is the most probable kinetic energy?

- 6.39** The figures below represent mixtures of argon atoms and hydrogen molecules. The volume of container B is twice the volume of container A. **LO2,3**

- 6.40** Nitrogen gas is available commercially in pressurised 1.8 m^3 steel cylinders. If a tank has a pressure of 163×10^5 Pa at 298 K, what amount of N_2 is in the tank? What mass of N_2 is in the tank? **LO5**
6.41 Molecular clouds composed mostly of hydrogen molecules have been detected in interstellar space. The molecular density in these clouds is about 10^{10} molecules per m^3 , and their temperature is around 25 K. What is the pressure in such a cloud? **LO5**
6.42 Describe a gas experiment that would show that the element oxygen exists naturally as diatomic molecules. **LO5**
6.43 A mixture of cyclopropane gas, C_3H_6 , and oxygen, O_2 , in a 1.00 : 4.00 mol ratio is used as an anaesthetic. What mass of each of these gases is present in a 1.50 L bulb at 22.3°C if the total pressure is 1.013×10^5 Pa? **LO5**
6.44 A sample of gas is found to exert a pressure of 6.00×10^4 Pa when it is in a 2.00 L flask at 0.00°C . Calculate the following. **LO5**
 (a) the new volume if p becomes 1.53×10^5 Pa and T is unchanged
 (b) the new pressure if V becomes 2.50 L and T is unchanged
 (c) the new pressure if the temperature is raised to 88.3°C and V is unchanged
6.45 Determine whether each of the following statements is true or false. If false, rewrite the statement so that it is true. **LO5**
 (a) At constant T and p , V is inversely proportional to the amount of gas.
 (b) At constant V , the pressure of a fixed amount of gas is directly proportional to T .
 (c) At fixed n and V , the product of p and T is constant.
6.46 A 3.00 g sample of an ideal gas at 22°C and 0.900×10^5 Pa occupies 0.900 L. What is its volume at 15°C and 1.00×10^5 Pa? **LO5**
6.47 Two chambers are connected by a valve. One chamber has a volume of 12 L and contains N_2 gas at a pressure of 2.2×10^5 Pa. The other has a volume of 2.8 L and contains O_2 gas at a pressure of 2.8×10^5 Pa. The valve is opened, and the two gases are allowed to mix thoroughly. The temperature is constant at 300 K throughout this process. **LO5**
 (a) What amount of each of N_2 and O_2 is present?
 (b) What are the final pressures of N_2 and O_2 , and what is the total pressure?
 (c) What fraction of the O_2 is in the smaller chamber after mixing?

ADDITIONAL EXERCISES

6.48 Recently, carbon dioxide levels at Cape Grim, Tasmania, reached 403.3 ppm by volume. (The 1976 reading was 330.6 ppm by volume.) Convert this reading to a partial pressure in Pa. At this level, how many CO₂ molecules are there in 1.0 L of dry air at 5 °C? **LO6**

6.49 Liquid oxygen, used in some large rockets, is produced by cooling dry air to –183 °C. How many litres of dry air at 25 °C and 1.013×10^5 Pa have to be processed to produce 175 L of liquid oxygen (density = 1.14 g mL^{-1})? Assume that air is 21% O₂ by volume. **LO6**

6.50 In an explosion, a compound that is a solid or a liquid decomposes very rapidly, producing large volumes of gas. The force of the explosion results from the rapid expansion of the hot gases. For example, TNT (trinitrotoluene) explodes according to the following balanced equation. **LO6**

- What amount of gas is produced in the explosion of 1.4 kg of TNT?
 - What volume will these gases occupy if they expand to a total pressure of 1.0×10^5 Pa at 25 °C?
 - Calculate the partial pressure of each gas at 1.0×10^5 Pa total pressure.
- 6.51** The Haber synthesis of ammonia occurs in the gas phase at high temperature (400 to 500 °C) and pressure (100 to 300×10^5 Pa). The starting materials for the Haber synthesis are placed inside a container, in proportions shown in the figure. Assuming 100% yield, sketch the system at the end of the reaction. **LO6**

6.52 A 0.1054 g mixture of KClO₃ and a catalyst was placed in a quartz tube and heated vigorously to drive off all the oxygen as O₂.

The O₂ was collected at 25.00 °C and a pressure of 1.012×10^5 Pa. The volume of gas collected was 22.96 mL. **LO6**

- What amount of O₂ was produced?
- What amount of KClO₃ was in the original mixture?
- What was the mass percent of KClO₃ in the original mixture?

6.53 Which gas deviates more from ideal $\frac{pV}{nRT}$ behaviour, F₂ or Cl₂? Explain your choice. **LO7**

6.54 List the different kinds of forces that must be overcome to convert each of the following from a liquid to a gas. **LO8**

- NH₃
- CHCl₃
- CCl₄
- CO₂

6.55 For each of the following pairs of substances, identify which has the higher boiling point, and identify the type of force that is responsible. **LO8**

- H₃COCH₃ and CH₃OH
- SO₂ and SiO₂
- HF and HCl
- Br₂ and I₂

6.56 Does the boiling point of HCl (see figure 6.34) suggest that it may form hydrogen bonds? Explain your answer and draw a molecular picture that shows the possible dipole–dipole interactions between HCl molecules. **LO8**

6.57 Molecular hydrogen and atomic helium both have two electrons, but He boils at 4.2 K, whereas H₂ boils at 20 K. Neon boils at 27.1 K, whereas methane, which has the same number of electrons, boils at 114 K. Explain why molecular substances boil at a higher temperature than atomic substances with the same number of electrons. **LO8**

Condensed phases: liquids and solids

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 7.1** describe qualitatively the macroscopic characteristics of liquids
 - 7.2** describe qualitatively the macroscopic characteristics of solids
 - 7.3** explain the phase changes between the common states of matter
 - 7.4** describe order in solid structures
 - 7.5** explain how X-ray diffraction helps to analyse order in solid structures
 - 7.6** describe the characteristics of amorphous solids
 - 7.7** describe the consequences of imperfections in crystal structures
 - 7.8** outline some modern ceramics.
-

In the chapter about gases, we learned that gas is one of the three common states of matter. Icebergs floating in the ocean exemplify the two other common states of matter: liquid and solid. Ice is quite unusual because it is less dense than its liquid phase and, therefore, floats on the surface of water. This has wide-ranging consequences for life on Earth; it means that ice will accumulate at the surface of a body of water, rather than at the bottom, ensuring that aquatic life can survive even in cold winters. It also means that a full bottle of drink that you put into the freezer might crack because water expands when it changes phase from liquid to solid (see figure 7.1).

FIGURE 7.1

H₂O is an unusual substance in that it is less dense (i.e. it occupies a greater volume) in the solid state (ice) than the liquid state (water). If you have ever tried to cool a drink quickly by placing it in the freezer and then forgotten to get it out, you will have experienced this.

In this chapter, we will investigate liquids and solids, the two condensed phases of matter. We will also look at what happens when substances change phase between solid, liquid and gas, and how these phase changes depend on both temperature and pressure. Finally, we will examine order in solids and some applications of modern materials.

7.1 Liquids

LEARNING OBJECTIVE 7.1 Describe qualitatively the macroscopic characteristics of liquids.

In the chapter on gases, we saw that, although many gases behave like an ideal gas under ambient conditions, all of them have intermolecular forces, which may cause deviations from ideal behaviour. One consequence of these intermolecular forces is that a gas condenses to a liquid if it is cooled sufficiently. Condensation occurs when the average kinetic energy of the molecules falls below the value needed for them to move about independently. In a liquid, intermolecular forces are strong enough to confine the molecules to a specific volume, but not strong enough to keep molecules from moving freely within the liquid. As a consequence, like gases, liquids are fluid, and most flow easily from place to place. Unlike gases, however, liquids are compact, so they cannot expand or contract much.

Properties of liquids

Intermolecular forces in liquids lead to three important properties: surface tension, capillary action and viscosity.

Surface tension is a measure of the resistance of a liquid to an increase in its surface area. This property is caused by attractive intermolecular forces between the molecules in a liquid. These attractive forces are known as cohesive forces.

Figure 7.2 illustrates at the molecular level why liquids exhibit surface tension. A molecule in the interior of a liquid is completely surrounded by other molecules. A molecule at a liquid surface, on the other hand, has other molecules beside it and beneath it, but very few above it in the gas phase. This difference means that there is a net attractive force on molecules at the surface that pulls them towards the interior of the liquid, resulting in as few particles as possible at the surface. A liquid will therefore adopt a shape with the minimum possible surface area. Small amounts of a liquid will adopt a spherical shape because spheres have less surface area per unit volume than any other shape. For example, water drips from a tap in nearly spherical liquid droplets. Large drops are distorted from ideal spheres by the force of gravity.

FIGURE 7.2

In the interior of a liquid (bottom), each molecule experiences equal forces in all directions (represented by the arrows). A molecule at the surface of a liquid (top) is pulled back into the liquid by intermolecular forces.

Molecules in contact with the surface of their container experience two sets of intermolecular forces. Cohesive forces attract molecules in the liquid to one another. *Adhesive forces* attract molecules in the liquid to the walls of the container.

One result of adhesive forces is the curved surface of a liquid, called a **meniscus**. Water in a glass tube forms a concave meniscus that increases the number of water molecules in contact with the walls of the tube. This is because the adhesive forces between water and glass are stronger than the cohesive forces between water molecules.

Figure 7.3 shows another result of adhesive forces. In a tube of small enough diameter, water actually climbs the walls because the adhesive forces between water and glass are stronger than the force of gravity. This upward movement of water against the downward force of gravity is called **capillary action** and is due to attractions between polar water molecules and oxygen atoms in glass (mainly SiO_2). Similarly, capillary action involving sap and the cellulose walls of wood fibre plays a role in how trees transport sap from their roots to their highest branches.

FIGURE 7.3

Water rises inside a small-diameter tube because of capillary action. The water in this photo has been coloured to show the effect of capillary action more clearly. (Refer back to figure 2.16 to remind yourself of the colours we use in this text to represent atoms of the various elements in space-filling and ball-and-stick models.)

Water can be poured very quickly from one container to another, while oil pours more slowly, and honey sometimes seems to take forever. A liquid's resistance to flow is called its **viscosity**; the greater the viscosity, the more difficult the liquid is to pour. Viscosity is a measure of how easily molecules slide past one another. Viscosity is, therefore, affected by a combination of molecular shape and the strength of the intermolecular forces. The greater the contact area of each molecule in a liquid, the higher the viscosity of the liquid. The molecules in liquids such as water, acetone and benzene are small and compact; they have small contact areas and thus low viscosity. In contrast, molecules with a large surface area, such as the sugars in honey and the hydrocarbons found in oils, have large areas of contact and thus high viscosity.

Viscosity is affected by temperature. This dependence is quite noticeable for highly viscous substances such as honey and syrup, which are much easier to pour when hot than when cold. At higher temperature, the average kinetic energy of the molecules in the liquid is higher, which allows them to overcome the intermolecular forces more easily. Thus, viscosity decreases as temperature increases.

Vapour pressure

Our senses tell us that molecules escape from a liquid. For example, both the smell of petrol around an open tank and the evaporation of a rain puddle in the sunshine suggest that molecules escape from the liquid into the vapour phase. The red-brown vapour phase that can be observed above liquid bromine suggests that bromine molecules are present in both phases.

Recall from the chapter on gases that any collection of molecules has a distribution of kinetic energies. In a liquid, the distribution of kinetic energies is such that molecules can move about within the liquid, but on average they do not have sufficient kinetic energy to escape into the gas phase. Nevertheless, the distribution of molecular energies guarantees that some of the molecules in any liquid have enough kinetic energy to overcome the intermolecular forces that confine the liquid. These molecules escape into the vapour phase whenever they are at the surface of the liquid. If the surface of a liquid is in contact with a gas phase, some of its molecules will escape into the gas phase.

The number of molecules of a liquid that have enough energy to escape into the vapour phase depends both on the strength of intermolecular forces within the liquid and the temperature. As figure 7.4 shows, at a particular temperature more molecules can escape from liquid bromine than from liquid water. This is because the intermolecular forces between water molecules are stronger than those between bromine molecules. A water molecule needs more kinetic energy to escape the liquid phase. Figure 7.4b illustrates that, when the temperature rises, the fraction of molecules having enough energy to escape increases.

FIGURE 7.4

The fraction of molecules with enough kinetic energy to escape a liquid depends on the strength of intermolecular forces and temperature. (a) At 300 K, more bromine molecules can escape than water molecules because bromine has weaker intermolecular forces than water. (b) More bromine molecules can escape at 320 K (area under orange curve to the right of escape energy) than at 300 K (area under the blue curve to the right of escape energy) because there are more molecules with at least the escape energy.

A liquid in an open container continually loses molecules until eventually it has evaporated completely. However, in a closed container such as the one shown in figure 7.5, the partial pressure of the vapour increases as more and more molecules enter the gas phase. As this partial pressure builds, increasing numbers of molecules from the vapour strike the liquid surface and return to the liquid. Eventually, as figure 7.5 illustrates, the number of molecules escaping from the liquid exactly matches the number of molecules being captured by the liquid. There is no net change in the total number of molecules in the gas and the liquid, and we call this a dynamic equilibrium. The pressure at which this equilibrium exists is the **vapour pressure** of the liquid. The vapour pressure of any liquid rises with increasing temperature because more molecules have sufficient kinetic energy to escape the liquid phase into the gas phase.

FIGURE 7.5

As the partial pressure of a substance in the gas phase above a liquid in a closed container increases, the difference between the number of molecules escaping into the gas phase (represented by the upward red arrows) and the number re-entering the liquid phase (represented by the downward red arrows) decreases until, at the vapour pressure of the substance, equilibrium is established.

Once the vapour pressure of the liquid in an open container reaches the external pressure, the liquid starts to boil. Water, H_2O , for instance, boils at 100°C at average atmospheric pressure at sea level ($1.013 \times 10^5 \text{ Pa}$). As we learned in the chapter on gases, the temperature at which a liquid boils at this pressure is known as the normal boiling point. At lower pressure, such as we would find on top of a high mountain, the boiling point is lower because the required vapour pressure is reached at a lower temperature. For example, on top of New Zealand's Aoraki/Mount Cook, which is 3754 m high, average atmospheric pressure is $0.637 \times 10^5 \text{ Pa}$ and water boils at about 85°C . Conversely, a pressure cooker works on the principle that if you increase the pressure above a liquid's surface the boiling point increases. For instance, at normal atmospheric pressure, you cannot heat liquid water to above 100°C , whereas in a household pressure cooker temperatures of up to 120°C can be reached. Figure 7.6 shows the dependence of vapour pressure on temperature for a range of liquids. The variation between vapour pressures of different substances is due to the different strengths of intermolecular forces.

FIGURE 7.6

Vapour pressure as a function of temperature for diethyl ether, water, acetic acid and propane-1,3-diol

7.2 Solids

LEARNING OBJECTIVE 7.2 Describe qualitatively the macroscopic characteristics of solids.

The vast majority of compounds are solids under ambient conditions. A substance is a solid when its ions, atoms or molecules are held together so strongly that they cannot easily move past each other. Unlike gases and liquids, solids are characterised by rigidity, which gives them the stable shapes that we see in structures ranging from bones to aeroplane wings. One of the most active areas of research in chemistry, physics and engineering is the development of new or improved solid materials. Solids continue to play a large role in society, from capacitors and solid-state battery components in mobile phones and laptops to new tissue-compatible solids for surgical implants. In this section, we describe the various types of solids.

Magnitudes of forces

In the chapter on gases, we saw that the melting points of solids span an immense range (e.g. He melts at 0.95 K and Fe melts at 1808 K). These values indicate that the forces in solids range from very small to very large. This is because the ions, atoms or molecules in solids can be bound together by various attractive forces: intermolecular forces, metallic bonding, covalent bonds and ionic interactions.

The molecules of a **molecular solid** are held in place by intermolecular forces: dispersion forces and dipolar interactions, including hydrogen bonds. The atoms of a **metallic solid** are held in place by delocalised bonding involving mobile electrons. A **network solid** contains an array of covalent bonds linking every atom to its neighbours throughout the whole structure. An **ionic solid** contains cations and anions, attracted to one another by electrostatic forces as described in the chapter on chemical bonding and molecular structure. Table 7.1 contrasts the forces and energies associated with these four types of solids.

TABLE 7.1 Characteristics of different types of solids

	Solid type					
	atomic/ molecular	molecular	molecular	metallic	network	ionic
Attractive forces	dispersion	dispersion + dipolar	dispersion + dipolar + hydrogen bonding	delocalised bonding	covalent	electrostatic
Energy (kJ mol^{-1})	0.05–40	5–25	5–50	75–1000	150–500	400–4000
Example	Ar	HCl	H_2O	Cu	SiO_2	NaCl
Melting point ($^{\circ}\text{C}$)	–189	–114	0	1088	1713	801
Schematic diagram						

Molecular solids

Molecular solids are aggregates of molecules bound together by intermolecular forces. The forces can be dispersion forces, dipolar forces, hydrogen bonding or a combination of these.

Many larger molecules have sufficient dispersion forces to exist as solids at room temperature. One example is naphthalene, C_{10}H_8 , the active substance in mothballs. Naphthalene is a white solid that melts at 80°C . Naphthalene has a planar structure with a cloud of 10 π electrons delocalised above and below the molecular plane (figure 7.7). Naphthalene molecules are held in the solid state by strong dispersion forces involving these highly polarisable π electrons. The molecules in crystalline naphthalene are arranged to maximise these dispersion forces, thus leading to the formation of plate-like macroscopic crystals.

Dimethyl oxalate, $\text{CH}_3\text{OC}(\text{O})\text{C}(\text{O})\text{OCH}_3$, the structure of which is shown in figure 7.8, is an example of a molecular solid (mp = 52°C) in which neighbouring molecules are held together predominantly by dipolar interactions. The two carbonyl C atoms have significant $\delta+$ character, due to the fact that each is bonded to two electronegative O atoms. The $\delta+$ C atoms are involved in attractive dipolar interactions with the $\delta-$ O atoms of neighbouring molecules.

FIGURE 7.7

**FIGURE 7.8**

Structural formula of dimethyl oxalate

In addition to dispersion and dipolar forces, molecular solids often involve hydrogen bonding. Benzoic acid, $\text{C}_6\text{H}_5\text{COOH}$, whose sodium salt is a common food preservative, provides a good example, as

illustrated in figure 7.9. Molecules of benzoic acid are held in place by a combination of dispersion forces between the π electrons and hydrogen bonding between the —COOH groups. With fewer π electrons, benzoic acid has weaker dispersion forces than naphthalene, but its hydrogen bonding gives benzoic acid a higher melting point of 122°C .

FIGURE 7.9

(a) Crystals of benzoic acid contain (b) pairs of molecules held together head-to-head by hydrogen bonds. These pairs then stack in planes that are held together by dispersion forces.

The effect of extensive hydrogen bonding is revealed by the relatively high melting point of glucose, $\text{C}_6\text{H}_{12}\text{O}_6$, the sugar found in blood and human tissue. Glucose melts at 155°C because each of its molecules has five —OH groups that form hydrogen bonds to neighbouring molecules (figure 7.10). Although glucose lacks the highly polarisable π electrons found in naphthalene and benzoic acid, its extensive hydrogen bonding gives this sugar the highest melting point of these three compounds.

FIGURE 7.10

The structural formula of glucose, $\text{C}_6\text{H}_{12}\text{O}_6$

Network solids

In sharp contrast to molecular solids, network solids have very high melting points. Compare the behaviour of phosphorus and silicon, third-row neighbours in the periodic table. White phosphorus melts at 44°C , but silicon melts at 1410°C . White phosphorus is a molecular solid that contains individual P_4 molecules (see figure 7.11), but silicon is a network solid in which covalent bonds connect every Si atom to each of its four neighbours throughout the structure (see figure 7.12).

FIGURE 7.11

Representation of a P_4 molecule in white phosphorus

FIGURE 7.12

Part of the structural model of silicon, showing silicon atoms connected to each other to form a three-dimensional network

The cause of the great difference in the melting points of these two elements is evident from table 7.1. Covalent bonds are much stronger than intermolecular forces. For solid silicon to melt, a significant fraction of its Si—Si covalent bonds must break. The average Si—Si bond energy is 225 kJ mol^{-1} , whereas attractive energies due to intermolecular forces in P_4 are much lower (as shown in table 7.1, intermolecular forces are generally less than 50 kJ mol^{-1}) so it takes a much higher temperature to melt silicon than white phosphorus.

Diamond and graphite, the two forms of elemental carbon that occur naturally on Earth, have very different physical and chemical properties. Diamond contains a three-dimensional array of σ bonds, with each sp^3 -hybridised carbon atom linked to each of its four neighbouring carbon atoms through covalent bonds resulting in a tetrahedral geometry around each carbon atom (identical to the Si structure mentioned above, see figure 7.13a). It is thus a network solid. Its three-dimensional network of strong covalent bonds makes diamond extremely strong and hard. Covalent bonds connecting atoms in three dimensions make network solids extremely durable.

FIGURE 7.13

Part of the structural models of: (a) diamond, showing carbon atoms connected to each other to form a three-dimensional network and (b) graphite, showing the two-dimensional layers

The sp^2 -hybridised carbon atoms in graphite, in contrast, are connected to only three neighbouring carbon atoms via covalent bonds in a planar arrangement. The bonding is supplemented by delocalised π bonding above and below the plane of the σ bonds (see figure 7.13b). Each two-dimensional layer is attracted to its neighbouring layers only by dispersion forces between the π electrons. As a result, planes of carbon atoms easily slide past one another, making graphite a brittle lubricant.

Compounds such as silica (silicon dioxide, SiO_2) may also exist as network solids. Opals are composed of nanosized silica spherulites. Their prized colour is due to the way they diffract light, rather than the impurities that give most other gemstones their colour. Another example is silicon carbide, SiC , which has a similar structure to diamond (every second C in diamond is replaced by Si) and is used as an abrasive in sandpaper and as an edge on cutting tools as it is less expensive to produce. These substances have very high melting points because their atoms are held together by networks of strong σ covalent bonds.

Metallic solids

The bonding in solid metals differs from that in other types of solids because it derives primarily from electrons in highly delocalised valence orbitals. Recall from the molecular orbital theory discussed in the chapter on chemical bonding and molecular structure that overlap of n valence atomic orbitals gives rise to n molecular orbitals. When n is very large, as is the case in 1 mol of a solid metal, then a large number of molecular orbitals are formed. The energies of these molecular orbitals are so close together that they essentially form a continuum of energies, called a band, which extends over all of the atoms in the metal. Therefore, an electron in a partially filled orbital is delocalised over all the atoms, and is consequently able to move throughout the entire metal. Hence, we can view a metal as consisting of a regular array of metal atom cores embedded in a 'sea' of mobile valence electrons (see figure 7.14). The properties of metals, such as electrical and thermal conductivity, can be explained on the basis of this model.

Metals display a wide range of melting points, indicating that the strength of metallic bonding is variable. The group 1 metals are quite soft and melt at relatively low temperatures (see figure 7.15a and c). Sodium, for example, melts at 98 °C and caesium melts at 28.5 °C. Bonding is weak in these metals because each atom of a group 1 metal contributes only one valence electron to the bond-forming energy band. Metals near the middle of the *d* block, on the other hand, are very hard and have some of the highest known melting points: tungsten melts at 3407 °C (figure 7.15b), rhenium at 3180 °C and chromium at 1857 °C. Atoms of these metals contribute several *d* electrons to bond formation, leading to extremely strong metallic bonding.

FIGURE 7.14

A diagrammatic representation of metallic bonding. The metal atom cores are embedded in a 'sea' of mobile valence electrons.

FIGURE 7.15

(a) Sodium, Na, can be cut with a knife. (b) Tungsten, W, can be heated to incandescence without melting, which is why it is used as the filament in certain light bulbs. (c) Group 1 metals melt at relatively low temperatures whereas metals near the middle of the *d* block have some of the highest known melting points.

(a)

(b)

(c)

Metals are ductile, meaning they can be drawn into wires, and malleable, meaning they can be hammered into thin sheets. When a piece of metal forms a new shape, its atoms change position. However, because the bonding electrons are fully delocalised, changing the positions of the atoms does not cause corresponding changes in the energy levels of the electrons. The 'sea' of electrons is largely unaffected by the pattern of metal atoms, as figure 7.16 illustrates. Thus, metals can be forced into many shapes (e.g. sheets and wires) without destroying their bonding nature.

The *d*-block metals display a range of properties. Copper and silver are much better electrical conductors than chromium. Tungsten has very low ductility. Mercury is a liquid at room temperature. These differences arise in part because of variations in the number of valence electrons. The *d*-block metals vanadium and chromium have five or six valence electrons per atom, respectively, all of which occupy bonding orbitals in the metal atoms. As a result, there are strong attractive forces between the metal atoms, and vanadium and chromium are strong and hard. Beyond the middle of the *d*-block series, the additional valence electrons occupy antibonding orbitals, which reduces the net bonding. This effect is most pronounced at the end of the *d* block, where the number of antibonding electrons nearly matches the number of bonding electrons. Zinc, cadmium and mercury, with $d^{10}s^2$ configurations, have melting temperatures that are more than 600 °C lower than those of their immediate neighbours.

Ionic solids

As described in the chapter on chemical bonding and molecular structure, ionic solids contain cations and anions strongly attracted to each other by electrostatic forces. Ionic solids must be electrically neutral, so their stoichiometries are determined by the charges carried by the positive and negative ions.

FIGURE 7.16

When a metal changes shape, its atoms shift position. However, because the valence electrons are fully delocalised, the energy of these electrons is unaffected.

Many ionic solids contain metal cations and polyatomic anions. Here again, the stoichiometry of the solid is dictated by the charges on the ions and the need for the solid to maintain electrical neutrality. Some examples of 1 : 1 ionic solids containing polyatomic anions are NaOH, KNO_3 , CuSO_4 , BaCO_3 and NaClO_3 . Some metallic ores have 1 : 1 stoichiometry, such as scheelite, CaWO_4 (contains WO_4^{2-}), zircon, ZrSiO_4 (contains SiO_4^{4-}) and ilmenite, FeTiO_3 (contains TiO_3^{2-}). Ilmenite is the source of TiO_2 , which is used as a white pigment in paper and paints.

Minerals often contain more than one cation or anion. For example, apatite, $\text{Ca}_5(\text{PO}_4)_3\text{OH}$, the main substance in tooth enamel, contains both phosphate and hydroxide anions. Beryl, $\text{Be}_3\text{Al}_2\text{Si}_6\text{O}_{18}$, contains beryllium and aluminium cations as well as the $\text{Si}_6\text{O}_{18}^{12-}$ polyatomic anion. Beryl is the substance that makes up emeralds. An even more complicated mineral is garnierite, $(\text{Ni}, \text{Mg})_6\text{Si}_4\text{O}_{10}(\text{OH})_2$, which has a variable composition of Ni^{2+} and Mg^{2+} cations. Although the relative proportions of Mg^{2+} and Ni^{2+} vary, garnierite always has six cations and two anions of OH^- for every anion of $\text{Si}_4\text{O}_{10}^{10-}$.

Some mixed oxides that contain rare earth metals are *superconductors*. Below a certain temperature, a superconductor can carry an immense electrical current without incurring losses from resistance. Optimal superconducting behaviour often requires a slight deviation from stoichiometric composition, which we will learn more about in section 7.8.

7.3 Phase changes

LEARNING OBJECTIVE 7.3 Explain the phase changes between the common states of matter.

In the chapter on gases and the first two sections of this chapter, we have examined the three most common phases of matter (gas, liquid and solid) in isolation. We will now investigate what governs a **phase change** — the transition of a substance from one phase to another. Substances can undergo phase changes given the appropriate conditions. Phase changes depend on temperature, pressure, and the magnitudes of bonding and intermolecular forces.

We are all familiar with the phase changes of water at ambient pressure, which are illustrated in figure 7.17. Consider taking ice cubes from the freezer at -18°C and placing them in a container at room temperature. At first the water is in the solid phase (stage 1). Outside the freezer, the temperature of the ice cubes begins to increase. When the temperature of the ice cubes reaches 0°C , they begin to melt and we get a mixture of solid and liquid water (stage 2). The temperature of this mixture does not increase until all the ice has melted. Once the ice has completely melted, the temperature of the liquid will start increasing (stage 3). If we apply heat to the container the liquid will increase in temperature (stage 3) until

it reaches 100 °C. The water then starts to boil (stage 4) and we get water vapour. The system remains at 100 °C until all of the water has evaporated. Continued heating of the water vapour once all of the water has evaporated will result in its temperature increasing above 100 °C (this is only possible in a confined space and will increase the pressure above 1.013×10^5 Pa, stage 5). The temperature of the container will also increase once all the water has evaporated, which is why it is not a good idea to allow a saucepan to boil dry on a hotplate.

FIGURE 7.17

When heat is supplied to a sample of H_2O in a sealed container at a constant pressure of 1.013×10^5 Pa, phase changes occur at 0 °C and 100 °C. The x-axis represents the heat required for each individual process. It should be noted that there are molecules in the vapour phase above both solid and liquid water, but these have been omitted in stages 1, 2 and 3 for clarity.

Source: Adapted from: *Chemistry: The molecular nature of matter and change*, 3rd edition, Martin S Silberberg, p. 424, © 2003 The McGraw-Hill Companies, Inc.

Phase changes require that energy (usually in the form of heat) be either supplied to or removed from the substance undergoing the phase change. Restricting ourselves to molecular substances, but recognising that similar arguments hold for atomic and ionic substances, a molecular perspective reveals why this is so. Any phase change that results in increased molecular mobility requires that intermolecular forces be overcome. For example, hydrogen bonds in ice must be broken to change the ice to liquid water, and hydrogen bonds in liquid water must be broken to convert it to water vapour. About 41 kJ of heat must be supplied to transfer 1 mol of water molecules from the liquid phase into the vapour phase. Similarly, 41 kJ of heat must be removed to liquefy 1 mol of water vapour. As figure 7.17 indicates, the heat required to change between the liquid and solid phases is considerably less.

As you will see in more detail in the chapter on thermodynamics, the amount of heat transferred at constant pressure is equal to a quantity called the enthalpy change (ΔH). The magnitude of the change depends on the strength of intermolecular forces in the substance undergoing the phase change.

The amount of heat required to vaporise a substance also depends on the amount in the sample. The energy required to vaporise 2 mol of water is twice that needed for 1 mol. The heat needed to vaporise 1 mol of a substance at its normal boiling point is called the **molar enthalpy of vaporisation** ($\Delta_{\text{vap}}H$). For example, $\Delta_{\text{vap}}H$ of water is about 41 kJ mol^{-1} .

Energy must also be provided to melt a solid substance. This energy is used to overcome the intermolecular forces that hold molecules in fixed positions in the solid phase. The heat required to melt 1 mol of a substance at its normal melting point is called the **molar enthalpy of fusion** ($\Delta_{\text{fus}}H$). For example, $\Delta_{\text{fus}}H$ of water is about 6 kJ mol^{-1} .

Phase changes between solid and liquid, and between liquid and gas, are the most common, but a phase change in which a solid converts directly to a gas without passing through the liquid phase is also possible. This transition is known as **sublimation** (**deposition** is the opposite transition). Dry ice (solid CO_2) sublimates at 195 K with the **molar enthalpy of sublimation** ($\Delta_{\text{sub}}H$) = 25.2 kJ mol^{-1} . Another

compound that sublimes, rather than melts, at ambient pressure is uranium hexafluoride, UF_6 . In contrast to CO_2 , UF_6 is a solid at ambient temperature and sublimates at 58°C .

Phase changes can go in either direction; ice melts upon adding heat, and liquid water freezes on removing heat from the system. Heat is absorbed as a solid melts to a liquid and is released as a liquid freezes to a solid. To make ice cubes, for instance, water is placed in a freezer that absorbs the heat released during the formation of ice. The heat released when liquid water changes to ice is equal in magnitude to the heat required to change ice to liquid water.

By convention, tabulated values of enthalpies of phase changes are always specified in terms of the phase change that requires the addition of heat. The reverse processes have the same magnitude but the opposite sign.

Note that $-\Delta_{\text{fus}}H$ may also be called $\Delta H_{\text{solidification}}$, $-\Delta_{\text{vap}}H$ may be called $\Delta H_{\text{condensation}}$ and $-\Delta_{\text{sub}}H$ may be called $\Delta H_{\text{deposition}}$.

Table 7.2 lists values of $\Delta_{\text{fus}}H$, $\Delta_{\text{vap}}H$, melting points and boiling points for a number of selected chemical substances.

TABLE 7.2 Phase change data for selected chemical substances

Substance	Formula	mp (K)	$\Delta_{\text{fus}}H$ (kJ mol ⁻¹)	bp (K)	$\Delta_{\text{vap}}H$ (kJ mol ⁻¹)
argon	Ar	83	1.3	87	6.3
oxygen	O ₂	54	0.45	90	9.8
methane	CH ₄	90	0.84	112	9.2
ethane	C ₂ H ₆	90	2.85	184	15.5
diethyl ether	(C ₂ H ₅) ₂ O	157	6.90	308	26.0
bromine	Br ₂	266	10.8	332	30.5
ethanol	C ₂ H ₅ OH	156	7.61	351	39.3
benzene	C ₆ H ₆	278	10.9	353	31.0
water	H ₂ O	273	6.01	373	40.79
mercury	Hg	234	23.4	630	59.0

WORKED EXAMPLE 7.1

Enthalpy of phase change

A swimmer emerging from a pool is covered with a film containing about 125 g of water. How much heat must be supplied to evaporate this water?

Analysis

Energy in the form of heat is required to evaporate the water from the swimmer's skin. The energy needed to vaporise the water can be found using the molar enthalpy of vaporisation and the amount of water.

Solution

$\Delta_{\text{vap}}H$ of water is $40.79 \text{ kJ mol}^{-1}$ (see table 7.2). The molar mass of water is 18.02 g mol^{-1} , so 125 g of water is

6.94 mol. Therefore, the heat that must be supplied is as follows.

$$n\Delta_{\text{vap}}H = (6.94 \text{ mol})(40.79 \text{ kJ mol}^{-1}) = 2.83 \times 10^2 \text{ kJ}$$

Is our answer reasonable?

If the swimmer's body must supply all this heat, a substantial chilling effect occurs. Thus, swimmers usually towel off (to reduce the amount of water that must be evaporated) or lie in the sun (to let the sun provide most of the heat required).

PRACTICE EXERCISE 7.1

Determine how much heat is involved in freezing 125 g of water in an ice-cube tray. What is the direction of heat flow in this process?

Recall from our discussion of figure 7.17 that adding heat to boiling water does not cause the temperature of the water to increase. Instead, the added energy is used to overcome intermolecular attractions, so more molecules leave the liquid phase and enter the gas phase. Other two-phase systems show similar behaviour. This can be used to hold a chemical system at a fixed temperature. A temperature of 100 °C can be maintained by a boiling water bath, and an ice bath holds a system at 0 °C. Lower temperatures can be achieved with other substances. Dry ice (solid CO₂) suspended in liquid acetone maintains a temperature of −78 °C (195 K); a bath of liquid nitrogen has a constant temperature of −196 °C (77 K); and liquid helium, which boils at 4.2 K, is used for research requiring ultracold temperatures as well as to keep magnetic resonance imaging (MRI) machines running in hospitals.

At the start of this section, we mentioned that pressure is also involved in phase changes. The effect of pressure is mainly seen for phase transitions involving gases. Recall from the chapter on gases that gas density increases with pressure. A gas at constant temperature can be liquefied by increasing the pressure. This is important in the storage of liquefied petroleum gas (LPG), a mixture of propane and butane that is used as a fuel for cars, barbecues and heaters. Propane and butane are gases at room temperature and normal atmospheric pressure. To make the storage and transport of the fuel practicable, it is liquefied by placing it under pressure. The pressure at which a gas liquefies at a specific temperature is known as the condensation point.

Supercritical fluids

We have learned about the three phases we are familiar with from everyday life: solids, liquids and gases. We have seen that we can liquefy gases by cooling or increasing the pressure. As the pressure on a gas increases, the gas is compressed into an ever-smaller volume. If the temperature is low enough, this compression eventually results in liquefaction. At high enough temperature, however, no amount of compression can cause liquefaction; that is, the liquid–gas transition is no longer possible. Instead, the substance becomes a **supercritical fluid**. A supercritical fluid is a fluid that has certain characteristics of both liquids and gases but is neither.

Imagine that you have a liquid in a sealed container. On heating, the vapour pressure increases as more molecules from the liquid escape into the gas phase, thus increasing the density in the gas phase while also decreasing the density in the liquid phase. As we continue heating the container, the densities in the gas phase and the liquid phase approach the same value. At the point where they become equal we can no longer distinguish between the liquid and gas phases; that is, we cannot observe a phase boundary. The temperature at which this occurs is called the **critical temperature** (T_c); the associated pressure is called the **critical pressure**. The combination of the critical temperature and the critical pressure is called the **critical point**. The substance is now in its supercritical state (figure 7.18). It has the viscosity typical of a liquid, but it is able to expand or contract like a gas.

The critical point of water is $T = 647 \text{ K}$, $p = 221 \times 10^5 \text{ Pa}$, of CO₂ is $T = 304 \text{ K}$, $p = 73.9 \times 10^5 \text{ Pa}$, and of N₂ is $T = 126 \text{ K}$, $p = 33.9 \times 10^5 \text{ Pa}$. Although critical pressures are many times greater than atmospheric pressure, supercritical fluids have important commercial applications. The most important of these is the use of supercritical carbon dioxide as a solvent. Supercritical CO₂ diffuses through a solid matrix rapidly, and it transports materials well because it has a lower viscosity than liquids. Supercritical CO₂ is currently used as a solvent for dry cleaning, for petroleum extraction, for decaffeination and for polymer synthesis. Compared with solvents used previously for some of these processes, such as dichloromethane, CH₂Cl₂, and tetrachloromethane, CCl₄, supercritical CO₂ is a much better choice.

Phase diagrams

The phase behaviour of a substance as a function of temperature and pressure can be conveniently summarised in a **phase diagram**. An example is provided in figure 7.19. Pressure is plotted along the y -axis, and temperature is plotted along the x -axis. In the region of low T and high p , the substance exists

as a solid. In the region of high T and low p , the substance exists as a gas. In some intermediate range of T and p , the substance exists as a liquid.

FIGURE 7.18

(a) Below the critical temperature for CO_2 you can clearly see the phase boundary between the liquid and the gas phase. (b) As the temperature rises the liquid becomes less dense, the vapour phase becomes more dense, and the phase boundary blurs. (c) Above the critical temperature the phase boundary has disappeared and only a supercritical fluid exists.

FIGURE 7.19

The general form of a phase diagram. Any point on the diagram corresponds to a specific temperature and pressure. Boundary lines trace conditions where neighbouring phases coexist (see the chapter on equilibrium), and the blue arrows show six types of phase transitions. The red arrows highlight a sequence of phase changes on changing temperature at constant pressure, or on changing pressure at constant temperature.

Figure 7.19 illustrates many of the characteristic features of phase diagrams.

1. Boundary lines between phases separate the regions where each phase is thermodynamically stable. Substances can exist as a metastable phase outside their thermodynamically determined boundaries; for example, carbon can exist as diamond, rather than graphite, under ambient conditions.
2. Movement across a boundary line corresponds to a phase change. The blue arrows on the figure show six different phase changes: sublimation and its reverse, deposition; fusion (melting) and its reverse, solidification (freezing); and vaporisation and its reverse, condensation.
3. On a boundary line, the two neighbouring phases coexist (see the chapter on equilibrium). In addition, at a given pressure, for example, when heat is added or removed, the temperature of this two-phase system does not change until all of one phase has converted to the other. The normal melting point and

- normal boiling point of a substance (shown by red dots) are the points where the phase boundary lines intersect the horizontal line that represents $p = 1.013 \times 10^5$ Pa.
4. Three boundary lines meet at a single point (shown by another red dot), called a **triple point**. All three phases are present simultaneously at this unique combination of temperature and pressure. Notice that, although two phases are stable under any of the conditions specified by the boundary lines, three phases can be simultaneously stable only at a triple point.
 5. Above the temperature specified by the critical point (again shown by a red dot), the gas cannot be liquefied under any pressure. Instead, if the pressure is high enough a supercritical fluid forms. It has the viscosity typical of a liquid, but it is able to expand or contract like a gas.
 6. What happens to a substance as temperature changes at constant pressure can be determined by drawing a horizontal line at the appropriate pressure on the phase diagram (shown as a horizontal red line).
 7. What happens to a substance as pressure changes at constant temperature can be determined by drawing a vertical line at the appropriate temperature on the phase diagram (shown as a vertical red line).
 8. The temperature for conversion between the gas phase and a condensed phase depends strongly on pressure. Qualitatively, this is because compressing a gas increases the collision rate and makes condensation more favourable.
 9. The melting temperature is almost independent of pressure, making the boundary line between solid and liquid nearly vertical. Qualitatively, this is because moderate pressure has hardly any effect on the condensed liquid and solid phases.
 10. The solid–gas boundary line extrapolates to $p = 0$ Pa and $T = 0$ K. This is a consequence of the direct link between temperature and energy. At 0 K, atoms, ions and molecules have minimum energy, so they cannot escape from the solid lattice. At 0 K, the vapour pressure of every solid substance would be 0 Pa.

The phase diagram for water, shown in figure 7.20, illustrates these features for a familiar substance. The figure shows that liquid water and solid ice coexist at the normal melting point (mp), $T = 273.15$ K and $p = 1.013 \times 10^5$ Pa. Liquid water and water vapour coexist at the normal boiling point (bp), $T = 373.15$ K and $p = 1.013 \times 10^5$ Pa. The triple point (tp) of water occurs at $T = 273.16$ K and $p = 0.0061 \times 10^5$ Pa. The figure shows that when p is lower than 0.0061×10^5 Pa, there is no temperature at which water is stable as a liquid. At those low pressures, ice sublimates but does not melt.

FIGURE 7.20

The phase diagram for water. The critical point is at $T = 647$ K, $p = 221 \times 10^5$ Pa, well outside this diagram.

The dashed lines on figure 7.20 show two paths that involve phase changes for water. The horizontal dashed line shows what happens as the temperature increases at a constant pressure of 1.013×10^5 Pa. As ice is warmed from a low temperature, it remains in the solid phase until the temperature reaches 273.15 K. At that temperature, solid ice melts to liquid water, and water remains liquid as the temperature increases, until it reaches 373.15 K. At 373.15 K, liquid water changes to water vapour. When the pressure is 1.013×10^5 Pa, water exists in the gas phase at all higher temperatures. The vertical dashed line shows what happens as the pressure on water is reduced at a constant temperature of 298 K (approximately room temperature). Water remains in the liquid phase until the pressure drops to 3.04×10^3 Pa. At 298 K, water exists in the gas phase at any pressure lower than this. Notice that at 298 K there is no pressure at which water exists in the solid state.

Given that the temperature of the triple point is slightly higher than the temperature of the normal melting point, we can conclude that the slope of the boundary line between the solid and liquid phases has to be negative. As shown in the magnified section of figure 7.20, if you start with solid H_2O at a temperature just below the triple point and increase the pressure at constant temperature you will cause a phase change from solid to liquid (dashed line). Ice-skaters make use of this pressure-induced phase transition. The thin blades of their ice skates put pressure on the ice, changing it to liquid water which refreezes once the pressure is removed. This shows, as we discussed in the opening paragraph of this chapter, that the density of the liquid is higher than the density of the solid, which is why ice floats on water. This property is relatively uncommon among substances. Most solids have higher density than their corresponding liquids. For water, the lower density is caused by the larger average number of hydrogen bonds per water molecule in ice compared with liquid water.

All phase diagrams of pure substances share the 10 common features listed previously. However, the detailed appearance of a phase diagram is different for each substance, as determined by the strength of the interactions between its constituents. Figure 7.21 shows two examples, the phase diagrams for nitrogen and carbon dioxide. Both of these substances are gases under normal conditions. In contrast to H_2O , which has a triple point close to 298 K, N_2 and CO_2 have triple points that are well below room temperature. Although both are gases at ambient temperature and pressure, they behave differently when cooled at atmospheric pressure. Molecular nitrogen liquefies at 77.4 K and then solidifies at 63.29 K, whereas carbon dioxide condenses directly to the solid phase at 195 K. This difference in behaviour arises because the triple point of CO_2 , in contrast to the triple points of H_2O and N_2 , occurs at a pressure greater than $1.013 \times 10^5 \text{ Pa}$. The phase diagram of CO_2 shows that at a pressure of $1.013 \times 10^5 \text{ Pa}$, there is no temperature at which CO_2 exists in the liquid phase.

FIGURE 7.21 Phase diagrams for nitrogen and carbon dioxide, two substances that are gases at room temperature and pressure (sp = normal sublimation point)

Phase diagrams are constructed by measuring the temperatures and pressures at which phase changes occur. Approximate phase diagrams such as those shown in figures 7.20 and 7.21 can be constructed from the triple point, normal melting point and normal boiling point of a substance.

WORKED EXAMPLE 7.2

Constructing a phase diagram

Ammonia is a gas under ambient conditions. Its normal boiling point is 239.8 K, and its normal melting point is 195.5 K. The triple point for NH_3 is $p = 0.0612 \times 10^5 \text{ Pa}$ and $T = 195.4 \text{ K}$. Use this information to construct an approximate phase diagram for NH_3 .

Analysis

The normal melting and boiling points and the triple point give three points on the phase boundary curves. To construct the curves from knowledge of these three points, use the common features of phase diagrams: the gas–liquid and gas–solid boundaries of phase diagrams slope upwards,

the liquid–solid line is nearly vertical, and the gas–solid line begins at $T = 0\text{ K}$ and $p = 0\text{ Pa}$.

Solution

Begin by choosing appropriate scales, drawing the line at $p = 1.013 \times 10^5\text{ Pa}$ and locating the given data points. An upper temperature limit of 300 K encompasses all the data.

Next, connect the points and label the domains.

Is our answer reasonable?

Check that pressure is on the y-axis and temperature is on the x-axis and that you have not accidentally interchanged the solid, liquid and gas phases. Also check that the slope of the solid–gas phase boundary is less steep than that of the liquid–gas phase boundary near the triple point and that the solid–liquid phase boundary is nearly vertical.

PRACTICE EXERCISE 7.2

Molecular chlorine melts at 172 K, boils at 239 K and has its triple point at $0.014 \times 10^5\text{ Pa}$ and 172 K. Sketch the phase diagram for this compound.

Phase diagrams can be used to determine which phase of a substance is stable at any particular pressure and temperature. They also summarise what phase changes occur as either condition is varied.

WORKED EXAMPLE 7.3

Interpreting a phase diagram

A chemist wants to perform a synthesis in a vessel at $p = 0.50 \times 10^5\text{ Pa}$ using liquid NH_3 as the solvent. What temperature range would be suitable? When the synthesis is complete, the chemist wants to boil off the solvent without raising T above 220 K. Is this possible?

Analysis

The phase diagram for NH_3 (refer to worked example 7.2) shows the boundary lines for the liquid domain. These

boundary lines can be used to determine the conditions under which phase changes occur.

Solution

Because the chemist wants to work at $p = 0.50 \times 10^5\text{ Pa}$, we draw a horizontal line across the phase diagram at $p = 0.50 \times 10^5\text{ Pa}$.

The horizontal line intersects the boundary lines at about 235 K and 195 K. Liquid NH_3 is stable between these temperatures at this pressure.

At the completion of the synthesis, the chemist wants to remove the solvent without raising T above 220 K. A vertical line at 220 K on the phase diagram represents this condition.

The line intersects the liquid–gas boundary at about 0.35×10^5 Pa. A vacuum pump capable of reducing p below

0.35×10^5 Pa can be used to vaporise and remove the NH_3 while ensuring the temperature remains below 220 K.

Is our answer reasonable?

Check that the lines for pressure and temperature are entered correctly. Since $\text{NH}_3(\text{l})$ boils at 235 K and 0.5×10^5 Pa, for $\text{NH}_3(\text{l})$ to boil at the lower temperature of 220 K we need a reduced pressure, as we have determined.

PRACTICE EXERCISE 7.3

A sample of N_2 gas is at $p = 0.1 \times 10^5$ Pa and $T = 63.1$ K. Use figure 7.21 to determine what will happen to this

sample if the temperature remains fixed while the pressure slowly increases to 1×10^5 Pa.

The phase diagrams we have studied are the simplest ones that occur for pure substances. However, many substances have more than one solid phase. For example, there are 14 different known forms of ice! Phase diagrams of solids are particularly useful in geology, as many minerals undergo solid–solid phase transitions at the very high temperatures and pressures found deep in the Earth's crust. Figure 7.22 is the phase diagram for silica (silicon dioxide, SiO_2), an important geological substance. Notice that the scale reflects geological pressures and temperatures. Notice also that there are six different forms of crystalline silica, each stable in a different temperature–pressure region. A geologist who encounters a sample of stishovite can be confident that it solidified under extremely high pressure conditions.

If we have more than one component in a mixture, phase diagrams become even more complicated, and treatment of these is beyond the scope of this text.

FIGURE 7.22

The phase diagram for silica shows six different forms of the solid, each stable under different temperature and pressure conditions.

Chemistry and cool jackets

Athletes have long used 'ice jackets' to reduce their body temperature before big races to enhance their performance, but have often suffered undesirable side-effects such as shivering, 'ice burn' and headaches. An advanced cooling jacket (figure 7.23) developed at RMIT is filled with a solid material that changes phase on heating. The process is endothermic, therefore cooling the surroundings (including the wearer of the jacket). Many compounds do of course do this, most notably water (the 'ice jackets' mentioned above operate on this principle) but in order for the wearer to be comfortable, the phase change needs to occur at around room temperature. The material developed by RMIT consists of a mixture of straight-chain alkanes that forms a waxy semi-solid solid below 18 °C. When the jacket is worn, the body heat of the wearer causes a phase change to occur in the material from a semi-solid to a liquid (the chains lose their alignment) at about 20 °C. This is an endothermic process that removes heat from the surroundings, thereby leading to a cooling effect for the wearer. The process can be reversed by simply cooling the jacket to a temperature below 18 °C again. This causes an exothermic phase change (one that gives out heat to the surroundings) of the material back to a semi-solid and the jacket is again ready for use.

Because heat is withdrawn from the body at close to normal skin temperature, and not at ice temperature, the cooling processes are more comfortable, efficient and effective. The jackets were developed in conjunction with the Australian Institute of Sport and are used by many of Australia's elite athletes in preparation for major sporting events such as the Olympic Games.

The vests also have potential in the treatment of medical conditions. Applications might include control of heat-induced hand tremors and dizziness in people with multiple sclerosis, as well as the effective and safe cooling of people who have suffered brain injuries or cardiac trauma.

7.4 Order in solids

LEARNING OBJECTIVE 7.4 Describe order in solid structures.

In contrast to molecules in gases and liquids which can move relatively freely, the atoms, molecules or ions in a solid are in relatively fixed positions. Generally, their motions are restricted to vibrations about these fixed positions. In this section, we examine the principles that govern the relative arrangements of atoms, molecules and ions in solids. To start our exploration of order in solids, we will look at some simple cases.

Close-packed structures

Most elements in the periodic table are metals and, apart from mercury, all metals are solids at standard conditions. In order to develop a picture of metal structures, we will assume that we can approximate a metal atom with a sphere. Figure 7.24 shows both square and hexagonal arrangements of identical spheres. We can see that the hexagonal arrangement is able to fit more spheres into the same area; every sphere in the hexagonal arrangement has six direct neighbours, but only four in the square arrangement. The hexagonal arrangement of identical spheres is the most dense packing that you can achieve in one layer of spheres. You can see this when you place the balls in the triangle at the start of a game of pool (figure 7.25). Only if you arrange them in this way can all of the balls fit into the triangle.

Now add a second layer of spheres to the hexagonal arrangement. Let's call the first layer 'A' and the second layer 'B'. To achieve the most compact arrangement, each sphere in layer B sits in one of the 'dimples' between a triangle of spheres in layer A. There are six dimples around any sphere in layer A. You can see that the centres of two neighbouring dimples are closer together than the diameter of the spheres. Hence, it is impossible to place a sphere over every dimple. For example, if we place spheres as

indicated by the red rings in figure 7.26, we can see that it is impossible to place spheres in the positions indicated by the blue rings at the same time.

FIGURE 7.24

Comparison of (a) square and (b) hexagonal arrangement of identical spheres. Moving the spheres outside the square in (b) into the empty space at the other side of the square (lighter shaded spheres, you can see that in (b) there is space left over at the top of the square, while in (a) there is no space left over, indicating that the spheres in the hexagonal arrangement are closer together.

FIGURE 7.25

Pool balls fit into the triangle in a hexagonal arrangement.

If we fill the dimples corresponding to the red rings, we create a second layer as shown in figure 7.27b. This adds three more adjoining spheres for each sphere in layer A. As additional spheres are added, layer B eventually looks identical to layer A, except that it is offset slightly to allow the spheres to nestle in the dimples formed by the layer below. There is no difference between filling all dimples corresponding to the red rings or the blue rings; the resulting arrangements of spheres are indistinguishable.

Now consider adding a third layer of spheres. This new layer can be placed in two different ways because there are two sets of dimples in layer B. Figure 7.28 shows a close-up of figure 7.27b. Notice in figure 7.28 that the view through one set of dimples (highlighted in orange) reveals the orange spheres of layer A. The view through the other set of dimples (highlighted in blue) reveals the unfilled dimples of layer A.

FIGURE 7.26

It is impossible to place a sphere over every dimple. We can place spheres only in the red positions or blue positions, not both at the same time.

**FIGURE 7.27**

(a) Spheres close-packed in a layer generate a hexagonal pattern. (b) When a second layer is packed on top of the first, each sphere in the second layer nestles in a dimple formed between three adjacent spheres in the lower layer.

**FIGURE 7.28**

A third layer of spheres can be placed in two different ways, as shown by the orange and blue rings.

If spheres in the third layer lie in the dimples highlighted in orange, the third layer is directly above the first, and the structure is called **hexagonal close-packed (hcp)**. If the spheres of the third layer lie in the dimples highlighted in blue, the third layer is offset from both of the lower layers. This arrangement is called **cubic close-packed (ccp)**. Figure 7.29a shows that in the hexagonal close-packed structure the positioning of the third layer corresponds to that of layer A and therefore we also label it A. In the cubic close-packed structure (figure 7.29b), the positioning is different and so we label the third layer 'C'. Comparing the two diagrams, we can see that in the hexagonal close-packed structure one set of dimples is never covered, while in the cubic close-packed structure, they are. If we continue this layering pattern, we find that a hexagonal close-packed structure has the pattern ABAB etc., while a cubic close-packed structure has the pattern ABCABC etc.

FIGURE 7.29

Top-down views of hexagonal and cubic close-packed arrangements. (a) The hexagonal close-packed structure has a layer repeating pattern ABAB etc. (b) The cubic close-packed structure has a layer repeating pattern ABCABC etc.

The two structure types described are called **close-packed structures** because they achieve maximum space filling for identical spheres. In either of these arrangements, 74% of the total space is filled, and each sphere has 12 nearest neighbours (i.e. neighbours with the same shortest distance to that sphere): six in the same plane, three above and three below. This is shown for the hexagonal and cubic close-packed structures in figure 7.30. The number of nearest neighbours is also called the coordination number, and therefore spheres in close-packed structures have a coordination number of 12.

FIGURE 7.30

In close-packed structures, each sphere has 12 nearest neighbours: six in the same plane, three above and three below.

Many metals form crystals with hexagonal or cubic close-packed geometries, since metal bonding that involves sharing of valence electrons benefits from close contact between participating metal atoms. For instance, magnesium and zinc crystallise with their atoms in a hexagonal close-packed array, while silver, aluminium and gold crystallise in the cubic close-packed arrangement. Other spherical entities, such as argon atoms, and methane and C_{60} molecules, also form close-packed arrangements. Argon solidifies at low temperature as a cubic close-packed crystal, and neon can solidify in either the hcp or ccp form.

The crystal lattice and the unit cell

In a solid, the number of atoms, ions or molecules is enormous. If you could imagine being at the centre of even a small sample of a solid, you would find that the atoms, ions or molecules go on as far as you can see in every direction. Describing all the individual positions is impossible and, fortunately, unnecessary if we are able to identify a repeating pattern within the solid.

There are a number of rules to consider when defining such a repeating pattern, and to start off we will look at examples in two dimensions. We can recognise a repeating motif in the wallpaper design of figure 7.31a. How can we describe this pattern? In order to concentrate on the repeating features of the pattern, we start by randomly selecting a point and then mark every other point on the wallpaper that has an identical environment (to make that easier to see we choose the eye of the rearmost of the three fish).

FIGURE 7.31

Defining a repeating pattern. (a) There is a repeating pattern in the wallpaper design. (b) The pattern can be described by a set of points with identical environments. (c) The resulting pattern is a lattice and each black dot is a lattice point.

Figure 7.31b shows this set of points, which have been connected by lines. In figure 7.31c we take away the wallpaper, leaving just the connected points. We call this pattern of points a **lattice**, and every individual point is a **lattice point**. Since we selected a set of points by requiring each one to have an identical environment, this set of points represents the repeating feature of our wallpaper design, and every lattice point represents one repeating motif.

In the next step, we must find the smallest repeating unit within our lattice, which in this case is one of the rectangles in figure 7.31c. We call the smallest repeating unit of a lattice the **unit cell** (the rules for the correct choice of unit cell are beyond the scope of this text). Repeating the unit cell in two dimensions will create the lattice. Therefore, all we need to describe any pattern is the lattice and the content of the unit cell.

An important fact about lattices is that the same lattice can be used to describe many different designs or structures. For example, take the square lattice and unit cell in figure 7.32a. In figure 7.32b, we see a design formed by associating a blue heart with each lattice point. Using a square lattice, we could form any number of designs just by using different design elements (e.g. a rose or a diamond), or by changing the lengths of the edges of the unit cell. The only requirement is that the same design element must be associated with each lattice point; that is, each lattice point must have an identical environment. There is no requirement, however, that the lattice point is centred on the object, as illustrated in figure 7.32c and d. You are allowed to shift the entire lattice as long as you still end up with all lattice points having identical environments.

Another example is shown in the picture by the Dutch artist MC Escher (1898–1972) reproduced in figure 7.33. Escher often used symmetrical patterns aligned together to create an overall design. The repeating units can be visualised as tiles placed edge to edge. The faces of unit cells can be squares, rectangles or parallelograms. In figure 7.33a each tile is a parallelogram. Once you have chosen the size and shape of the unit cell, you can move its origin and still create the same overall pattern (figure 7.33b).

FIGURE 7.32

A two-dimensional lattice. (a) A simple square lattice, for which the unit cell is a square with lattice points at the corners. (b) A wallpaper pattern formed by associating a design element (blue heart) with each lattice point. The x centred on each heart corresponds to a lattice point. Notice that the unit cell contains portions of a heart at each corner. (The rest of each heart lies in adjacent unit cells.) (c) and (d) There is no requirement that the lattice point is centred on any object. In (a), (b), (c) and (d), all the information needed to generate the entire array is present in the unit cell, which is repeated over and over.

**FIGURE 7.33**

A drawing by MC Escher that contains a repeating pattern. A two-dimensional unit cell is highlighted in (a). In (b), the unit cell has been shifted and it is shown how repeating it in two dimensions will produce the entire pattern.

For the sake of simplicity we have looked at lattices and unit cells in two dimensions. We can also apply these concepts to three-dimensional patterns. The ions, atoms or molecules in many solids are arranged in regular three-dimensional patterns. Such solids are classified as **crystalline solids**. Diamonds are an example. We can describe crystalline solids using the concepts of a **crystal lattice**, that is, a three-dimensional lattice and a unit cell. It is possible to describe limitless numbers of different compounds with just a limited set of three-dimensional lattices. In fact, only 14 different types of three-dimensional lattices are possible, which means that all crystalline chemical substances must form crystals with one of these 14 lattice types, albeit with different unit cell dimensions. On the following pages, we describe some metal structures with cubic unit cells. These crystal structures can be described such that all the atoms in a unit cell are associated with the lattice points, that is, the number of atoms in the unit cell and the number of lattice points will be identical. This is because all metal atoms in each of these very simple structures have identical surroundings and therefore all can be associated with lattice points. This is not so for most other crystalline solid structures.

Cubic structures

The easiest three-dimensional structure to visualise has a simple cube as the unit cell. In a simple cubic crystal, layers of atoms stack one directly above another, so that all atoms lie along straight lines at right angles, as figure 7.34 shows. Each atom in this structure has a coordination number of 6; there are four nearest neighbours within the same plane, one above the plane and one below the plane. Taking four atoms that form a square, adding an atom on top of (or below) each forms a cube. This structure is called the **primitive cubic structure**, because it has a primitive cubic lattice. In this context, primitive means that there is only one lattice point per unit cell. A method for determining the number of lattice points is described below. The unit cell of the primitive cubic structure is shown in the cutaway portion of figure 7.34. To calculate how many atoms are in the unit cell, we count only that proportion of the atom that is within the unit cell boundaries. An atom that is located on the corner of a cube is shared by eight cubes in total. Therefore, only $\frac{1}{8}$ of that atom counts for any one of those cubes. The unit cell contains $\frac{1}{8}$ of an atom at each of the eight corners of a cube. The total number of atoms in the unit cell is thus $8 \left(\frac{1}{8} \right) = 1$. The same applies to counting lattice points; a unit cell with lattice points only on the corners ends up with one lattice point; that is, a primitive lattice. The fraction of space that is filled by the atoms in this primitive cubic unit cell is only 52%. This is much less than the most efficient packing, which achieves 74% space filling. Consequently, this structure is adopted by only one metal: polonium.

When eight atoms form a cube, there is a cavity at the centre of the cube. The cavity is not large enough to hold an additional atom, but moving the eight corner atoms slightly away from each other does allow the structure to accommodate another atom of the same type in the centre. The result is the body-centred cubic structure, described by a **body-centred cubic lattice (bcc)**, which now has two lattice points: one on a corner and one in the centre of the cube. Each atom in a body-centred cubic lattice is at the centre of a cube and contacts eight neighbouring corner atoms (see figure 7.35). In other words, every atom in the structure can be viewed as the centre atom of one body-centred cube or as a corner atom in another cube. The unit cell of a body-centred cube contains a total of $\left[1 + 8 \left(\frac{1}{8} \right) \right] = 2$ atoms. The views of the iron crystal structure in figure 7.35 illustrate this arrangement.

FIGURE 7.34

(a) The primitive cubic structure is built from square layers of spheres stacked one directly above another. (b) The cutaway view shows one unit cell.

Although the corner atoms are further apart in a body-centred cube than in a primitive cube, the extra atom in the centre of the structure makes the body-centred cubic structure more compact than the primitive cubic structure, filling 68% of the total space, which is close to the maximum possible. All of the group 1 metals, as well as iron and the transition metals from groups 5 and 6, form crystals with body-centred cubic structures.

FIGURE 7.35

Views of the arrangement of atoms in iron: (a) a view of the body-centred crystal lattice and (b) the unit cell

Another common cubic crystal structure is the **face-centred cubic structure (fcc)**, which is the same as the cubic close-packed structure that we encountered earlier. When four atoms form a square, there is open space at the centre of the square. A fifth atom can fit into this space by moving the other four atoms away from one another. Additional atoms can be placed in the centres of all six faces of the simple cube, as figure 7.36 shows.

FIGURE 7.36

The face-centred cubic lattice can be viewed as: (a) a simple cube, (b) with each face expanded just enough to fit an additional atom in the centre, (c) giving eight atoms at the corners and six atoms embedded in the faces. (d) The unit cell has $\frac{1}{2}$ of an atom at the centre of each face and $\frac{1}{8}$ of an atom at each corner. (All atoms in this arrangement are the same. Different colours are used for clarity only.)

The unit cell of the face-centred cube consists of six $\frac{1}{2}$ -atoms embedded in the faces of the cube and eight $\frac{1}{8}$ -atoms at the corners of the cube. This unit cell contains $\left[6\left(\frac{1}{2}\right) + 8\left(\frac{1}{8}\right)\right] = 4$ atoms. Each atom in a face-centred cube contacts 12 neighbouring atoms. Consequently, the face-centred cube is more compact than either of the other cubic structures and fills 74% of the total space. The cubic close-packed structure that we encountered at the beginning of section 7.4 can be described by this face-centred cubic unit cell.

Figure 7.37 shows the relationship between a set of hexagonal layers and a face-centred cubic unit cell. Figure 7.37a shows a top-down view of the hexagonal layers. In figure 7.37b we have removed all but one of the atoms from the top and bottom layers, and have removed all but six atoms in each of the two middle layers. We can see from figure 7.37c that a line drawn between the orange atoms (from the top and bottom layers) represents the body diagonal of a cube. Each face of the cube has an atom at each corner and one atom in the centre, as shown by figure 7.37c. Since all the atoms are identical, this is a face-centred cubic arrangement as revealed in the perspectives of figure 7.37c and d.

FIGURE 7.37

Four views of the hexagonal layers contained within a face-centred cubic arrangement: (a) a top-down view of the hexagonal layers, with an axis shown as a black dot, (b) a side view showing four layers along the axis, (c) tilting (b) leads to the arrangement shown here, with the vertical black line in (b) now the body diagonal of this cube, and (d) the unit cell. (All atoms in this arrangement are the same. Different colours are used for clarity only.)

We can now see that the arrangement of hexagonal layers in an ABCABC fashion is called a cubic close-packed structure, because the structure can be described by a face-centred cubic unit cell (the terms ‘cubic close-packed structure’ and ‘face-centred cubic structure’ are often used synonymously). Equally, the hexagonal close-packed structure gets its name because it can be described by a hexagonal unit cell as shown in figure 7.38.

FIGURE 7.38

Three views of the hexagonal layers contained within a hexagonal close-packed structure: (a) a top-down view of the hexagonal layers with the unit cell indicated, (b) a side view showing three layers and (c) the unit cell. This unit cell contains two atoms and fills 74% of the space. (All atoms in this arrangement are of the same type. Different colours are used for clarity only.)

Up to now, we have described the crystalline arrangements favoured by spherical objects such as atoms, but most molecules are far from spherical. Nonspherical objects require different arrays to achieve maximal stability. To illustrate, compare a stack of bananas with a stack of oranges (figure 7.39). Just as the stacking pattern for bananas is less symmetrical than that for oranges, the structural patterns for most molecular crystals are less symmetrical than those for crystals of spherical atoms, reflecting the lower symmetry of the molecules.

FIGURE 7.39

Nonspherical bananas require different packing schemes from spherical oranges.

Ionic solids

We will now show how the principles discussed previously relate to the actual structures of ionic solids. Recall from figure 7.28 that two sets of dimples are created when we add two hexagonal layers of spheres. This is shown again in figure 7.40a. One set of dimples has an atom directly below (shown in orange), while the other set does not (shown in blue). The open space between the two layers of spheres directly below the orange circle is surrounded by four spheres (one below and three above), while the open space between the two layers of spheres directly below the blue circle is surrounded by six spheres (three below and three above). Figure 7.40b shows that the four spheres associated with the first set of dimples form a tetrahedron, while figure 7.40c shows that the six spheres associated with the second set form an octahedron. The space between the spheres is called an **interstitial hole**. The interstitial holes take up much less space than the spheres that surround them. In general, the more spheres that surround an interstitial hole, the larger the hole is, that is, an octahedral hole is larger than a tetrahedral hole. The number of octahedral holes equals the number of spheres that form the structure, while the number of tetrahedral holes is twice the number of spheres that form the structure.

The packing in ionic crystals requires that ions of opposite charge alternate with one another to maximise attractions and minimise repulsions. The cations and anions are usually different sizes (often the cations are smaller). We can understand ionic structures by assuming that the close-packed structure is formed by the larger ions, while the smaller ions fill the interstitial sites. We can identify a crystal lattice for the larger ions, and then describe how the smaller ions pack within that lattice. Because the crystal is made up of a huge number of identical unit cells, the stoichiometry within the unit cell must match the overall stoichiometry of the compound.

Ionic compounds adopt a variety of structures that depend on the stoichiometry and relative sizes of the ions. For many 1 : 1 ionic crystals such as NaCl, the most stable arrangement is a face-centred cubic array of anions (Cl^-) with the cations (Na^+) packed into the octahedral holes between the anions. This structure appears in figure 7.41a. Notice that every cation is surrounded by six anions and every anion is surrounded by six cations. The unit cell based on close packing of Cl^- is shown. In addition to the face-centred cubic arrangement of chloride ions, the unit cell in figure 7.41b shows $\frac{1}{4}$ of a sodium cation along each edge of the cell, and there is an additional sodium cation in the centre of the unit cell. Summing the components reveals that each unit cell contains four complete NaCl units, thus giving the correct 1 : 1 stoichiometry.

$$\text{chloride anions: } 6 \text{ faces } \left(\frac{1}{2} \text{ anion/face} \right) + 8 \text{ corners } \left(\frac{1}{8} \text{ anion/corner} \right) = 4 \text{ Cl}^- \text{ anions}$$

$$\text{sodium cations: } 12 \text{ edges } \left(\frac{1}{4} \text{ cation/edge} \right) + 1 \text{ in centre} = 4 \text{ Na}^+ \text{ cations}$$

Many ionic solids have the same structure type as sodium chloride. Examples are all the halides of Li^+ , Na^+ , K^+ and Rb^+ , as well as the oxides of Mg^{2+} , Ca^{2+} , Sr^{2+} and Ba^{2+} .

FIGURE 7.40

- (a) Two sets of dimples are created when two hexagonal layers of spheres are combined, one with a sphere directly below and one without, indicated by the orange and blue circles, respectively.
(b) The four spheres (three red, one orange) below the orange ring surround a tetrahedral hole.
(c) The six spheres (three red, three orange) below the blue ring surround an octahedral hole.

**FIGURE 7.41**

- (a) The structure of sodium chloride can be described as a face-centred cubic arrangement of Cl^- anions (green), with the Na^+ cations (orange) occupying the interstitial octahedral sites.
(b) Because Cl^- anions are considerably larger than Na^+ cations, the commonly used unit cell places anions at the corners. There is a cation at the centre of this unit cell.

Caesium chloride, in which the relative size of the cation is much larger than in sodium chloride, forms a different type of structure. Because its cation and anion are close to the same size, caesium chloride is most stable in a primitive cubic lattice. There are Cl^- anions at the corners of the cube, with a Cs^+ in the centre, as figure 7.42 shows. The unit cell contains $8 \left(\frac{1}{8} \right) = 1$ chloride ion and 1 caesium ion. The caesium chloride structure type is also found for CsBr, CsI and several other 1 : 1 ionic crystals in which the cations and anions have similar sizes.

In zinc sulfide, ZnS , the relative size ratios are such that the zinc cation is too small for octahedral sites and instead occupies tetrahedral holes in the structure. Since there are twice as many tetrahedral sites as spheres that form the structure, only half will be occupied by Zn^{2+} cations in a regular fashion. We have seen previously that a face-centred arrangement of anions leads to four anions in the unit cell. We can see in figure 7.43 that there are also four cations within the unit cell, resulting in the correct 1 : 1 stoichiometry. In this structure, as seen in figure 7.43b, every cation is surrounded by four anions, and every anion is surrounded by four cations in a tetrahedral arrangement.

FIGURE 7.42

The caesium chloride structure consists of a primitive cubic array of chloride anions with a caesium cation at the centre of each unit cell.

FIGURE 7.43

(a) The unit cell of cubic zinc sulfide has anions in a face-centred cubic arrangement. (b) Each Zn^{2+} cation is surrounded by four S^{2-} anions in the form of a tetrahedron.

(a)

(b)

Many ionic compounds have stoichiometries that differ from 1 : 1. To give an example, the fluorite structure is named for the naturally occurring form of CaF_2 and is common for salts of the general formula MX_2 . It is easiest to describe this structure by thinking of the Ca^{2+} cations arranged in a face-centred cubic structure. In this arrangement, the F^- anions fill all the tetrahedral holes in the lattice, forming a simple cube of eight anions in the interior of the face-centred cube. This is in contrast to zinc sulfide, where only half of the tetrahedral holes were filled. Figure 7.44a shows the unit cell of the fluorite structure, which contains a total of four Ca^{2+} cations and eight F^- anions (consistent with the number of tetrahedral holes being twice the number of spheres that form the structure).

$$\text{calcium anions: } 6 \text{ faces } \left(\frac{1}{2} \text{ cation/face} \right) + 8 \text{ corners } \left(\frac{1}{8} \text{ cation/corner} \right) = 4 \text{ Ca}^{2+} \text{ cations}$$

$$\text{fluoride anions: } 8 \text{ complete anions within the face-centred cube} = 8 \text{ F}^- \text{ anions}$$

FIGURE 7.44

(a) The unit cell of the fluorite structure has cations in a face-centred cubic arrangement, with a simple cube of anions within the unit cell. (b) All fluoride ions are surrounded by four calcium ions in a tetrahedral arrangement.

(a)

(b)

This gives the correct 1 : 2 stoichiometry, resulting in electrical neutrality. The calcium ions are arranged in a tetrahedron about the fluoride ions as shown in figure 7.44b.

We have briefly mentioned four simple ionic lattices, but there are many others.

7.5 X-ray diffraction

LEARNING OBJECTIVE 7.5 Explain how X-ray diffraction helps to analyse order in solid structures.

The arrangement of atoms, molecules or ions in a crystalline structure can be described by a lattice and a unit cell. X-ray diffraction can be used to determine this arrangement. When the crystal is exposed to X-rays (figure 7.45a), diffracted beams due to constructive interference appear only in specific directions. In other directions, no X-rays appear because of destructive interference. Recall that we learned about constructive (in-phase) and destructive (out-of-phase) interferences of waves in the chapter on atomic energy levels. X-rays coming from the crystal are recorded and form a **diffraction pattern**. The dots (reflections) in the diffraction pattern shown in figure 7.45b are caused by the constructive interference of diffracted X-rays. X-ray diffraction by crystals has enabled scientists to determine the structures of very complex compounds in a particularly elegant way.

FIGURE 7.45

X-ray diffraction: (a) schematic set-up for recording an X-ray diffraction pattern and (b) an X-ray diffraction pattern

In 1913, William Henry Bragg and his Australian-born son William Lawrence Bragg discovered that just a few variables control the appearance of an X-ray diffraction pattern. Figure 7.46 illustrates the conditions necessary to obtain constructive interference of the X-rays from successive layers (planes) of atoms in a crystal. A beam of X-rays with a wavelength λ strikes the layers at an angle θ . For certain distances, d , between the layers, constructive interference causes an intense diffracted beam to emerge at the same angle, θ . The **Bragg equation** relates λ , θ and the distance between the planes of atoms, d , where n is any integer.

$$n\lambda = 2d \sin \theta$$

The Bragg equation is the basic tool used by scientists in the study of solid structures. Let us briefly see how it is used. In any crystal, many different sets of imaginary planes can be passed through the structure. Figure 7.47 illustrates this idea in two dimensions for a simple pattern of points. When a crystal is exposed to X-rays, many diffracted beams are produced because of the diffraction from the many possible sets of planes. An apparatus called a diffractometer (figure 7.48) is used to record the diffraction pattern and allows the determination of the angles at which the diffracted beams emerge from each distinct set of planes. Using the Bragg equation, we can calculate the distances between planes of atoms from the measured angles of diffraction, the wavelength of the X-rays (source dependent) and the value of n (usually 1). The next step is to use the calculated interplanar distances to deduce the unit cell of the lattice. The locations of the atoms within the unit cell are then determined from the relative intensities of the diffracted beams. If this sounds like a difficult task, it is! For all but the simplest crystalline structures, sophisticated mathematics and computers are needed to accomplish it. The efforts, however, are well rewarded because the calculations give very accurate locations for the atoms within the unit cell. This enables us to understand the bonding, intermolecular interactions and properties of crystalline materials.

FIGURE 7.46

Diffraction of X-rays from successive layers of atoms in a crystal. The layers of atoms are separated by a distance d . The X-rays of wavelength λ enter and emerge at an angle θ relative to the layers of the atoms. For the emerging beam of X-rays to have any intensity, the condition $n\lambda = 2d \sin \theta$ must be fulfilled, where n is an integer. In the diagram, the portion of the wave highlighted in yellow is two whole wavelengths. If the wavelength for the same arrangement changes or if the wavelength stays the same, but either d or θ changes, then the condition would not be fulfilled, and destructive interference would lead to no X-rays appearing.

**FIGURE 7.47**

A two-dimensional pattern of points with three of many possible sets of parallel lines shown. In a three-dimensional crystal lattice there are many sets of parallel planes.

**FIGURE 7.48**

WORKED EXAMPLE 7.4

Using crystal structure data to calculate atomic sizes

X-ray diffraction measurements reveal that copper crystallises with a face-centred cubic lattice in which the unit cell length is 3.62×10^{-10} m. What is the radius of a copper atom? What is the copper–copper bond length?

Analysis

Copper atoms are in contact along a face diagonal (the dashed line at right) that runs from one corner of a face to another corner.

Using geometry, we can calculate the length of this diagonal, which equals four times the radius of a copper atom.

Solution

From geometry, the length of the diagonal is $\sqrt{2}$ times the length of the edge of the unit cell.

$$\text{diagonal} = \sqrt{2} \times (3.62 \times 10^{-10}) = 5.12 \times 10^{-10} \text{ m}$$

If we call the radius of the copper atom r_{Cu} , then the diagonal equals $4 \times r_{\text{Cu}}$. Therefore:

$$\begin{aligned} 4 \times r_{\text{Cu}} &= 5.12 \times 10^{-10} \text{ m} \\ r_{\text{Cu}} &= 1.28 \times 10^{-10} \text{ m} \end{aligned}$$

The calculated radius of the copper atom is 1.28×10^{-10} m. The copper–copper bond length is twice this number, that is, 2.56×10^{-10} m.

Is our answer reasonable?

You will know from the chapter on chemical bonding and molecular structure that bond distances between atoms are about 1×10^{-10} m to 3×10^{-10} m and atomic radii are about half of this. The calculated Cu radius and Cu–Cu bond length fall within this range, so our answer is reasonable.

X-ray diffraction has had a profound impact on the study of biochemistry. Biochemists will often use X-ray diffraction to determine the structures of enzymes and other large molecules produced by living systems. The most famous example is the experimental determination of the molecular structure of DNA. DNA is found in the nuclei of cells, and serves to carry an organism's genetic information. In 1953, using X-ray diffraction photographs of DNA fibres obtained by Rosalind Franklin and New Zealand-born Maurice Wilkins, James Watson and Francis Crick came to the conclusion that the DNA structure consists of the now-famous double helix (see figure 7.49). Watson, Crick and Wilkins shared the 1962 Nobel Prize in physiology or medicine for their discovery (Franklin had died of cancer in 1958, and it was not possible to nominate her for the Nobel Prize posthumously).

X-ray diffraction continues to be one of the main tools used to determine the structures of complex proteins and enzymes.

FIGURE 7.49

A computer-generated model of the DNA double helix

7.6 Amorphous solids

LEARNING OBJECTIVE 7.6 Describe the characteristics of amorphous solids.

When a pure liquid is cooled slowly, it often solidifies as a well-ordered crystalline solid. When solids form rapidly, on the other hand, their atoms, molecules or ions may become locked into positions other than those of a regular crystal, giving materials that are **amorphous**, meaning 'without form'. For example, ordinary cane sugar is crystalline, but rapidly cooling melted sugar gives fairy (or candy) floss, which contains long threads of amorphous sugar (figure 7.50). While amorphous solids can be formed in a variety of ways and by different mechanisms, one feature that clearly distinguishes them from crystalline solids is the fact that they do not diffract X-rays (see section 7.5).

What we call **glass** is an entire family of amorphous solids based on silica, SiO_2 (see figure 7.22). Pure SiO_2 is usually found as a crystalline solid containing a regular array of Si and O atoms. This is known as quartz. When quartz is melted and then quickly cooled, it forms fused silica, an amorphous solid glass. Silica glass has many desirable properties. It resists corrosion, transmits light well and withstands wide variations in temperature. Unfortunately, pure silica is very difficult to work with because of its high melting point (1983 K). Consequently, silica glass is used only for special applications.

Mixing sodium oxide, Na_2O , with silica results in a glass that can be shaped at a lower temperature. Sodium—oxygen bonds are ionic, and incorporating sodium ions into the mixture breaks the Si—O—Si chain of covalent bonds. This weakens the lattice strength of the glass, lowers its melting point and reduces the viscosity of the resulting liquid. However, the weakened lattice also means that glass made from mixed sodium and silicon oxides is vulnerable to chemical attack.

A desirable glass melts at a reasonable temperature, is easy to work with and yet is chemically inert. Such a glass can be prepared by adding a third component that has bonding characteristics between those of purely ionic sodium oxide and purely covalent silicon dioxide. Several different components are used, depending on the properties required for the glass.

The glass used for windowpanes and bottles is soda–lime–silica glass, a mixture of sodium oxide, calcium oxide and silicon dioxide. The addition of CaO strengthens the lattice enough to make the glass chemically inert to most common substances (strong bases and HF , however, attack this glass). Pyrex[®], the glass used in coffeepots and laboratory glassware, is a mixture of B_2O_3 , CaO and SiO_2 . This glass can withstand rapid temperature changes that would crack soda–lime–silica glass. Lenses and other optical components are made from glass that contains PbO . Light rays are strongly bent as they pass through lenses made of this glass. Coloured glasses contain small amounts of coloured metal oxides such as Cr_2O_3 (amber), NiO (green) or CoO (brown).

FIGURE 7.50

(b) ordinary cane sugar is crystalline.

(a)

(b)

7.7 Crystal imperfections

LEARNING OBJECTIVE 7.7 Describe the consequences of imperfections in crystal structures.

The two extremes of ordering in solids are perfect crystals with complete regularity and amorphous solids that have no order. Many solid materials are crystalline but contain defects. **Crystalline defects** can profoundly alter the properties of a solid material, often in ways that have useful applications. Doped semiconductors are solids into which impurity ‘defects’ are introduced deliberately in order to modify electrical conductivity. Some gemstones are crystals containing impurities that give them their colour. Sapphires and rubies are imperfect crystals of colourless Al_2O_3 ; Ti^{3+} or Fe^{3+} makes sapphires blue, and Cr^{3+} makes rubies red (figure 7.51).

Yttrium barium copper oxide superconductors have optimal properties when they have a slight deficiency of oxygen, as indicated by the δ sign in the formula $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$. This departure from stoichiometric composition is accommodated by defects in the crystal structure. The superconductor crystal has oxygen anions missing from some positions in the crystal lattice, and the number of missing anions can vary sufficiently to give the material a variable composition. The solid remains electrically neutral when its anion content is varied because some of the cations take on different charges. The copper

cations in the superconductor can have a +2 or +3 charge. The relative number of Cu^{3+} ions decreases as oxygen anions are removed from the structure.

FIGURE 7.51 The vivid colours of sapphires and rubies arise due to imperfections in their crystal structures.

Substitutional impurities replace one atom with another, while interstitial impurities occupy the spaces between regular atoms. Interstitial impurities create imperfections that play important roles in the properties of metals. For example, small amounts of impurities are deliberately added to iron to improve its mechanical properties. Pure iron is relatively soft, easily deformed and corrodes readily, but the addition of a small amount of carbon creates steel, a much harder material. Carbon atoms fill some of the open spaces between iron atoms in the crystalline structure of steel. Although carbon atoms fit easily into these spaces, their presence reduces the ability of adjacent layers of iron atoms to slide past each other, as illustrated in figure 7.52.

FIGURE 7.52

The presence of even a few carbon atoms (represented by the black spheres) in the interstitial holes in an iron lattice prevents adjacent layers of iron atoms from sliding past one another and hardens the iron into steel.

7.8 Modern ceramics

LEARNING OBJECTIVE 7.8 Outline some modern ceramics.

Ceramics are materials composed of inorganic components that have been heat treated. They have a long history, dating to prehistoric times. Examples of pottery about 13 000 years old have been found in several parts of the world. Today, ceramics include common inorganic building materials such as brick, cement and glass. We find ceramics around the home as porcelain dinner-ware, tiles, sinks, toilets, and artistic pottery and figurines. We also find ceramics in places we might not expect, such as mobile phones, diesel engines and bullet-proof vests.

Many manufactured ceramics are made from inorganic minerals such as clay, silica (sand) and other silicates (compounds containing anions composed of silicon and oxygen), which are taken from the Earth's crust. In recent times, an entirely new set of materials with high-tech applications, generally referred to as advanced ceramics, has been prepared by chemists. We will focus our discussions mainly on these.

Properties of ceramics

There are some properties that ceramics have in common, and there are others that can be tailored by controlling the ceramic's composition and method of preparation. For example, many ceramic materials are very hard and have very high melting points. Table 7.3 contains a list of some advanced ceramic materials and their properties, along with the properties of some metals in common use. The hardest substance known is diamond, and some ceramics have hardnesses that approach diamond. Silicon carbide, which is relatively inexpensive to make in bulk, has long been used as an abrasive in sandpaper and grinding wheels.

TABLE 7.3 Some properties of ceramic materials, diamond, steel and aluminium

Ceramic material	Hardness ^(a) (GPa)	Melting point (°C)	Elastic modulus ^(b) (GPa)	Density (g mL ⁻¹)
diamond, C	80	3800	910	3.52
boron nitride, BN	50	2730	660	3.48
titanium carbide, TiC	28	3067	470	4.93
silicon carbide, SiC	26	2760	480	3.22
zirconium carbide, ZrC	25	3445	400	6.63
tungsten carbide, WC	23	2776	720	15.72
titanium nitride, TiN	21	2950	590	5.40
aluminium oxide, Al ₂ O ₃ (alumina)	21	2047	400	3.98
beryllium oxide, BeO (beryllia)	15	2550	390	3.03
zirconium oxide, ZrO ₂ (zirconia)	12	2677	190	5.76
aluminium nitride, AlN	12	2250	350	3.36
titanium dioxide, TiO ₂ (titania)	11	1867	205	4.25
stainless steel	2.35	1420	200	7.89
aluminium	1.51	658	69	2.70

^(a) Pressure required to dent the material: the larger the value, the harder the material.

^(b) Force per unit cross-sectional area required to elongate (stretch) the solid: the larger the value, the stronger the material and the more it resists stretching.

Notice that all of the listed ceramics are harder than steel and also have lower densities and very high melting points. Those with high strength and relatively low density are useful, for example, for applications in space.

Because of their high melting points, we often find ceramics used as **refractories** (heat-resistant materials) for lining furnaces and rocket engine exhausts. When given a glassy porcelain surface, ceramics are impervious to water, but under the right conditions they can be made porous and used as filters in applications where high temperatures would destroy other materials.

Most ceramics do not conduct electricity, so they are used as insulators for high-voltage power lines, car spark plugs and in TV sets. However, some ceramic materials become excellent conductors of electricity when cooled to very low temperatures. There is a whole class of these materials that are superconductors with many potential applications (discussed below).

Table 7.3 shows that ceramics generally contain metals in relatively high positive oxidation states, combined with small nonmetals (e.g. O, N and C) with high negative oxidation states. As we discussed earlier, the assignment of a formal oxidation state does not mean that the electrons have completely

transferred from one bonding partner to another; that is, it allows for all forms of chemical bonding. Actually, the ceramic compounds listed in table 7.3 possess substantial covalent bonding between the atoms. Imagining that the compounds were purely ionic, small cations with high charges would be able to pull electron density from highly charged anions into the region between the ions, causing the bonds to become substantially covalent. Furthermore, elements such as oxygen, nitrogen and carbon are able to form covalent bonds between two or more atoms. Therefore, a mixture of ionic and covalent bonding between the atoms, that is, very polar covalent bonds, causes both the strength and high melting points of ceramic materials.

Applications of advanced ceramics

The field of high-tech ceramics is very competitive and new materials with new applications are continually being developed. Their uses are extremely varied and we will briefly explore a few examples.

Thin ceramic films are used as antireflective coatings on optical surfaces and as filters for lighting. Tools such as drill bits are given thin coatings of titanium nitride, TiN, to make them more wear resistant (figure 7.53).

Partially stabilised zirconia (ZrO_2 with small amounts of other metal oxides) is used to make portions of hip-joint replacements. This application is possible because of the toughness of the ceramic.

FIGURE 7.53

Drill bits with a thin golden coating of titanium nitride, TiN, will retain their sharpness longer than uncoated steel drill bits.

One form of boron nitride powder, BN, is composed of flat, platelike crystals that can easily slide over one another. It is used in cosmetics, where it gives a silky texture. Another boron-containing ceramic, boron carbide, is used along with KevlarTM polymer to make bullet-proof vests. When a bullet strikes the vest, it is either shattered by the ceramic, or it cracks the ceramic, which then absorbs most of the kinetic energy. Residual energy is absorbed by the Kevlar backing.

Silicon nitride, Si_3N_4 , is used to make components for diesel engines because it is wear resistant and extremely hard. It has a high stiffness with low density, and can withstand extremely high temperatures and harsh chemical environments.

Piezoelectric ceramics produce an electric potential when their shape is deformed. They also deform when an electric potential is applied to them. This makes piezoelectric ceramics very useful for many applications, including the production of ultrasound waves, for example, for use in medical imaging. Some smart materials incorporate piezoelectric devices to provide both sensing and action capability. They adaptively respond to changing stimuli.

High-temperature superconductors

A **superconductor** is a material which offers no resistance to the flow of electricity. Many compounds are superconductors at very low temperatures, which can be reached only by using liquid helium for cooling. Because liquid helium is very expensive, materials have been sought with critical temperatures, T_c (the

temperature at which they become superconductors), above 77.4 K, the boiling point of liquid nitrogen. The refrigeration technology for producing and handling liquid nitrogen is well known and relatively simple, and liquid nitrogen costs about as much as milk or orange juice. In 1987, a ceramic mixed metal oxide, $\text{YBa}_2\text{Cu}_3\text{O}_7$, was discovered with a T_c of 93 K. Materials that have T_c values above about 30 K are called *high-temperature superconductors*. Materials with T_c values above 130 K (at atmospheric pressure) have been found.

The chief problem with ceramic superconductors is that they are brittle, but during the 1990s scientists and engineers successfully made wire-like superconducting materials that could be used to build electrical cables. The cables can carry up to three times more electricity than standard electrical cables. New-generation magnets made with high-temperature superconducting wires are now commercially available.

One of the most fascinating properties of superconducting materials is that they can be levitated by a magnetic field. Besides zero electrical resistance, a substance in its superconducting state permits no magnetic field within itself. A weak magnetic field is actually repelled by a superconductor (the Meissner effect), and this is what makes the levitation of superconductors possible (figure 7.54).

FIGURE 7.54

Levitation of a magnet above a superconductor. When a ceramic is cooled below T_c , it becomes superconducting and repels a magnetic field. That repulsion is sufficient to hold a magnet suspended above it.

CHEMICAL CONNECTIONS

Fast trains on superconductors

The Dutch scientist Heike Kamerlingh-Onnes was awarded the Nobel Prize in physics for his 1911 discovery of superconductors. These become perfect electrical conductors when cooled below a critical temperature, T_c , where they show no resistance to the flow of electrical current. Therefore, superconducting wires can potentially be used to carry electricity with no loss. Until 1986, all known superconductors had to be cooled using liquid helium. The record T_c at the time was 23 K. That year, physicists Georg Bednorz and Alex Müller discovered the first of the so-called high-temperature superconductors (HTS) with $T_c \approx 30$ K. This set in motion an international race to discover HTS with higher T_c values. Over the next few years, T_c increased an astounding sevenfold. Today there are more than 70 known HTS.

Most HTS are brittle ceramics that cannot be easily manufactured into wires. The most useful is $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10}$, or BSCCO (figure 7.55). It was first identified by a research group working in New Zealand and its T_c of 108 K means that it can be cooled using liquid nitrogen, which is much cheaper than liquid helium. Products made using this material include magnets for ion implantation, research, testing of computer hard drives, synchrotron dipole magnets, coils for motors and generators, and nuclear magnetic resonance instruments.

FIGURE 7.55

BSCCO wires: (a) precursor materials are loaded into a silver billet, extruded, (b) rebundled into 55 hexagonal tubes, re-extruded, (c) drawn down to about 1 mm diameter, and then (d) rolled flat to form a multifilamentary tape. This is then reacted at high temperature to complete the formation of the final BSCCO product.

Another aspect of superconductors is that they expel magnetic fields perfectly, which can be used to float a magnet over a superconductor, or vice versa. One large-scale application of this phenomenon is a magnetic levitation (maglev) train (see figure 7.56). Commercial maglev lines are in operation in China, Japan and South Korea. Japan is building a 285 km line to connect Tokyo with Nagoya, which is expected to support travel speeds of 500 km h^{-1} in standard operation.

FIGURE 7.56

Magnetic levitation (maglev) trains use superconducting magnets to create a magnetic field that enables the trains to levitate over the tracks.

Many aspects of HTS science are yet to be understood and this is an ongoing research focus around the globe. The ultimate goal is the discovery of room temperature superconductors, which would revolutionise the production and use of electricity on our planet.

SUMMARY

7.1 Describe qualitatively the macroscopic characteristics of liquids.

Liquids, like gases, are fluid, but cannot expand or contract much. Three properties of liquids, viscosity, surface tension and capillary action, depend mostly on the strengths of intermolecular attractions within the liquid. Cohesive forces occur between molecules in a liquid and are responsible for surface tension. Adhesive forces occur between the liquid molecules and the walls of the container and give rise to a curved meniscus at the surface of a liquid. Adhesive forces are also responsible for capillary action. Viscosity is related to both the shape of the molecules and the magnitude of the intermolecular forces in a liquid.

Liquids evaporate when their molecules have sufficient energy to overcome attractive intermolecular forces. The equilibrium vapour pressure of a liquid is the pressure at which the number of molecules escaping from the liquid exactly matches the number being captured by the liquid. Vapour pressure increases with increasing temperature until the normal boiling point, the point where the vapour pressure equals the external atmospheric pressure, is reached.

7.2 Describe qualitatively the macroscopic characteristics of solids.

Solids are rigid, meaning that their constituent atoms, molecules or ions occupy well-defined positions relative to one another. Solids may be classified as molecular, metallic, network or ionic solids according to the nature of their constituents. Each category has characteristic interactions between its constituents. Molecular solids are held together by dispersion forces. In some solids and liquids, dipolar and hydrogen bonding forces may also occur depending on the nature of the individual molecules. In network solids, the constituents are covalently bonded together, while ionic solids are held together by electrostatic attractions between oppositely charged ions. The bonding in metallic solids is due to a delocalised 'sea' of electrons.

7.3 Explain the phase changes between the common states of matter.

A phase change occurs when a substance undergoes a transition from one phase to another. Energy must be either supplied to, or removed from, a substance undergoing a phase change. This can be quantified by considering the values of the molar enthalpy of vaporisation $\Delta_{\text{vap}}H$ or the molar enthalpy of fusion $\Delta_{\text{fus}}H$, which are the enthalpy changes that occur on vaporising or melting 1 mol of substance, respectively. The reverse of these processes are condensation and solidification, respectively. In addition to these phase changes, sublimation, the direct conversion of a solid to a gas, can also occur, and it has an associated molar enthalpy of sublimation, $\Delta_{\text{sub}}H$. The reverse of this process is called deposition.

Heating a liquid in a closed container results in gradual evaporation and a corresponding increase in pressure. Eventually, a point may be reached at which the liquid and gas phases cannot be distinguished and the substance exists as a supercritical fluid. The temperature and pressure at which this occurs are called the critical temperature and critical pressure.

Temperatures and pressures at which equilibria can exist between phases are shown graphically in a phase diagram. Three equilibrium lines intersect at the triple point. The liquid–gas line terminates at the critical point. Above the critical point, a liquid phase cannot be formed; the single phase that exists is a supercritical fluid. The equilibrium lines also divide a phase diagram into temperature–pressure regions in which a substance exists in just a single phase. Water is different from most substances in

that its melting point decreases with increasing pressure, albeit very slightly.

7.4 Describe order in solid structures.

Approximating atoms as spheres allows us to determine their possible close-packed arrangements. A hexagonal arrangement is more efficient than a square arrangement for a single layer of spheres. Additional layers may be added to give either an ABABAB or ABCABC arrangement, depending on how the additional atoms are arranged relative to the original layer. The former arrangement is called a hexagonal close-packed (hcp) arrangement and the latter is a cubic close-packed (ccp) arrangement. Both are called close-packed structures as they fill 74% of the space, which is the maximum possible for identical spheres.

The overall structure of any crystalline solid can be described in terms of a repeating three-dimensional array of lattice points, which is called a lattice. The simplest portion of a lattice is its unit cell. Many structures can be described by the same lattice by changing the contents and dimensions of the unit cell. Three possible cubic unit cells are: primitive cubic, face-centred cubic and body-centred cubic. In a lattice of spheres, the spaces between the spheres are called interstitial holes.

Sodium chloride and many other alkali metal halides crystallise in a face-centred cubic arrangement, which contains four NaCl units per unit cell. The relative sizes of the cations and anions in ionic crystals determine the structure adopted; hence CsCl, in which the cations and anions are nearly the same size, crystallises in a primitive cubic structure. The ratio of cations to anions is also important; for example, CaF_2 adopts a structure in which the Ca^{2+} ions are arranged in a face-centred cubic array, with the F^- ions filling all the tetrahedral holes.

7.5 Explain how X-ray diffraction helps to analyse order in solid structures.

X-ray diffraction can be used to determine the structure of crystalline solids. The diffraction of X-rays from a crystalline solid results in constructive interference of the X-rays in particular directions as determined by the Bragg equation. This gives a diffraction pattern, which can be analysed to allow the calculation of the structure of the solid.

7.6 Describe the characteristics of amorphous solids.

Some solids, when formed by rapid cooling, do not crystallise with their constituent atoms, molecules or ions in a regular arrangement. These are known as amorphous solids. The most important example is glass, a family of amorphous solids based on silica. Rapid cooling of molten SiO_2 gives an amorphous solid glass, while the addition of compounds such as Na_2O , B_2O_3 and CaO gives different glasses with particular physical and chemical properties.

7.7 Describe the consequences of imperfections in crystal structures.

Crystalline defects can significantly alter the properties of a solid. The introduction of small impurity 'defects' can change the electrical conductivity of a solid, and even its colour. Substitutional impurities arise from the replacement of one atom with another of a different type, while interstitial impurities result from the placement of atoms in interstitial holes.

7.8 Outline some modern ceramics.

Ceramics are composed of inorganic components such as metal oxides or nitrides that have been heat-treated. Most ceramics have high melting points and are very hard. This is a result of significant covalent bonding, which gives rise to

network-type solids. Modern ceramics are used in such diverse areas as coatings, filters, cosmetics and bullet-proof vests. Piezo-electric ceramics can deform in response to an electric potential

and can be used in smart materials. High-temperature superconductors are ceramics and are used in rapid maglev trains.

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation
Boiling points of substances	7.1	The strengths of intermolecular forces in substances can be compared based on their boiling points.
Phase diagram	7.3	We use a phase diagram to identify temperatures and pressures at which equilibrium can exist between phases of a substance and to identify conditions under which only a single phase can exist.
Unit cell	7.4	A unit cell shows how the constituent atoms, molecules or ions are arranged in three dimensions in a crystalline solid. It is the smallest repeating unit of a crystalline structure.
The Bragg equation	7.5	The Bragg equation relates λ , θ and the distance between the planes of atoms, d , and allows the determination of the structures of solids from X-ray diffraction patterns. $n\lambda = 2d \sin \theta$

KEY TERMS

amorphous Without any organised regular repeating pattern.

body-centred cubic lattice (bcc) The crystal structure whose unit cell is a cube with lattice points at its corners and its centre.

Bragg equation $n\lambda = 2d \sin \theta$

capillary action The upward movement of a liquid in a narrow tube against the force of gravity.

ceramics Materials composed of inorganic components that have been heat treated.

close-packed structure The most efficient arrangement for packing atoms, molecules or ions in a regular crystal.

critical point The temperature and pressure above which the distinction between the liquid and vapour phases disappears.

critical pressure The pressure associated with the critical point.

critical temperature (T_c) The temperature associated with the critical point.

crystal lattice The lattice of a crystalline solid.

crystalline defects Imperfections in a regular solid.

crystalline solid A solid that has a regular arrangement of unit cells and diffracts X-rays.

cubic close-packed (ccp) The arrangement in which close-packed layers are stacked in an ABCABC ... pattern.

deposition The phase change in which a vapour converts directly to a solid without passing through the liquid phase.

diffraction pattern The pattern formed from X-rays diffracted by a crystal.

face-centred cubic structure (fcc) A crystalline structure whose unit cell has lattice points at each corner of a cube plus one additional lattice point in the centre of each face of the cube.

glass An amorphous solid that has cooled to a solid state without crystallising.

hexagonal close-packed (hcp) The close packing arrangement in which close-packed layers are stacked in an ABAB pattern.

interstitial hole The space between spheres/atoms.

ionic solid A solid containing cations and anions that are attracted to each other by electrical interactions rather than covalent bonds.

lattice A set of points with identical environments that describes a pattern.

lattice point A point within a lattice.

meniscus The curved surface of a liquid contained in a narrow tube.

metallic solid An elemental solid whose atoms are held together by valence electrons occupying delocalised orbitals spread across the entire solid.

molar enthalpy of fusion ($\Delta_{\text{fus}}H$) The enthalpy change on melting 1 mol of a substance at its normal melting point.

molar enthalpy of sublimation ($\Delta_{\text{sub}}H$) The enthalpy change on sublimation of 1 mol of a substance at its normal sublimation point.

molar enthalpy of vaporisation ($\Delta_{\text{vap}}H$) The enthalpy change on vaporisation of 1 mol of a substance at its normal boiling point.

molecular solid A solid containing discrete molecules that do not have chemical bonds between them.

network solid A solid containing an array of covalent bonds linking every atom to its neighbours.

phase change The transition of a substance from one phase to another.

phase diagram A pressure–temperature graph showing the conditions under which a substance exists as solid, liquid and gas.

primitive cubic structure The crystal form with a unit cell containing one lattice point at each corner of a cube only.

refractory A heat-resistant ceramic material.

sublimation The phase change between solid and vapour.

superconductor A material that offers no resistance to the flow of electricity.

supercritical fluid A phase in which the liquid–vapour transition is no longer possible. A supercritical fluid is able to expand to fill the available space (like a gas), but is resistant to further compression (like a liquid).

surface tension The resistance of a liquid to an increase in its surface area.

triple point The temperature and pressure at which solid, liquid and vapour can coexist at equilibrium.

unit cell The simplest repeating unit of a regular pattern, usually within a crystal.

vapour pressure The partial pressure of a vapour in equilibrium with a condensed phase.

viscosity The resistance to flow of a fluid.

REVIEW QUESTIONS

Liquids

LO1

- 7.1** Hexane is a C_6 hydrocarbon; gasoline contains mostly C_8 hydrocarbons; and fuel oil contains hydrocarbons in the C_{12} range. List these three hydrocarbons in order of increasing viscosity, and explain what molecular feature accounts for the variation.
- 7.2** Aluminium tubing has a thin surface layer of aluminium oxide. What shape meniscus would you expect to find for water and for mercury inside aluminium tubing? Explain your answers in terms of intermolecular forces.
- 7.3** Water forms 'beads' on the surface of a freshly waxed car, but forms a film on the clean windscreen. Why is this?
- 7.4** For each of the following pairs of liquids, choose which has the lower vapour pressure at room temperature and explain your reasoning.
- water, H_2O , or methanol, CH_3OH
 - pentan-1-ol, $C_5H_{12}OH$, or heptan-1-ol, $C_7H_{15}OH$
 - dichloromethane, CH_2Cl_2 , or tetrachloromethane, CCl_4

Solids

LO2

- 7.5** Classify each of the following substances as an ionic, network, molecular or metallic solid: Bi, P_4 , Se, C(diamond) and $Ba(NO_3)_2$.
- 7.6** Describe the differences between network and ionic solids in relation to the following.
- interparticle forces
 - macroscopic properties
- 7.7** Indicate which type of solid (ionic, network, metallic or molecular/atomic) each of the following forms on solidification.
- Br_2
 - KCl
 - Li
 - SiO_2
 - He

Phase changes

LO3

- 7.8** From table 7.2, determine which of each of the following pairs has the higher value. Use intermolecular forces to explain the data.
- enthalpies of vaporisation of ethane and propane
 - enthalpies of vaporisation of ethanol and diethyl ether
 - enthalpies of fusion of argon and methane
- 7.9** Sketch the approximate phase diagram for Br_2 from the following information: normal melting point is 265.9 K, normal boiling point is 331.9 K, triple point is at $p = 5.87 \times 10^3$ Pa and $T = 265.7$ K. Label the axes and the area where each phase is stable.
- 7.10** Using the phase diagram from question 7.9, describe what happens to a sample of Br_2 as the following processes take place. Draw lines on the phase diagram to represent each process.
- A sample at $T = 375$ K is cooled to 225 K at constant $p = 1.013 \times 10^5$ Pa.
 - A sample is compressed from $p = 1.013 \times 10^2$ Pa to $p = 1.013 \times 10^8$ Pa at constant $T = 265.8$ K.
 - A sample is cooled from 375 K to 225 K at constant $p = 2.026 \times 10^3$ Pa.

Order in solids

LO4

- 7.11** The unit cell of a perovskite-type compound is shown in the diagram. What is the empirical formula of this perovskite?

- 7.12** For the pattern shown below, draw a tile that represents a unit cell for the pattern and contains only complete fish. Draw a second tile that is a unit cell but contains no complete fish.

- 7.13** In the unit cell of lithium oxide, the oxide ions adopt a face-centred cubic arrangement. The lithium ions are in the holes within the face-centred cubic unit cell. How many complete lithium ions must be packed within each face-centred cube for the unit cell to be charge-neutral? How many oxygen atoms are in the unit cell?

X-ray diffraction

LO5

- 7.14** Write the Bragg equation and define the symbols used.
- 7.15** Explain in general terms how an X-ray diffraction pattern of a crystal and the Bragg equation provide information that allows chemists to determine the structures of molecules.

Amorphous solids

LO6

- 7.16** What does the word 'amorphous' mean?
- 7.17** What is an amorphous solid? Compare what happens when crystalline and amorphous solids are broken into pieces.
- 7.18** Amorphous silica has a density of about 2.3 g mL^{-1} and crystalline quartz has a density of 2.65 g mL^{-1} . Describe the bonding features that cause these two forms of the same substance to have different densities.

Crystal imperfections

LO7

- 7.19** What are 'substitutional impurities'?
- 7.20** What are 'interstitial impurities'?

Modern ceramics

LO8

- 7.21** What are 'ceramics'?
- 7.22** What are two physical properties that make ceramics useful materials?
- 7.23** What are 'refractories'? Give two uses for refractories.
- 7.24** What are 'superconductors'? Why is it very expensive to use low-temperature superconductors in practical applications?

REVIEW PROBLEMS

- 7.25** List the different kinds of forces that must be overcome to convert each of the following compounds from a liquid to a gas. **L01**

(a) H_2O
 (b) CH_3Cl
 (c) CF_4
 (d) CO_2

- 7.26** List all the intermolecular forces that stabilise the liquid phase of each of the following. **L01**

(a) Xe
 (b) SF_4
 (c) CCl_4
 (d) $\text{CH}_3\text{CH}_2\text{OH}$

- 7.27** For each of the following pairs, identify which has the higher boiling point, and identify the type of force that is responsible. **L01**

(a) H_3COCH_3 and CH_3OH
 (b) SO_2 and SiO_2
 (c) HF and HCl
 (d) Br_2 and I_2

- 7.28** Why do the two isomers represented below have very different melting points? **L02**

- 7.29** Solid sodium metal can exist in two different crystalline forms, body-centred cubic and hexagonal. One form is stable only below 5 K at relatively low pressure; the other is stable under all other conditions. Draw atomic pictures of both phases, identify the phase that is stable only at low temperature and pressure, and explain your choice. **L02**

- 7.30** Tungsten does not melt even when heated to incandescence. How do interatomic forces in tungsten compare with those in other metals such as gold or nickel? **L02**

- 7.31** Tin(IV) chloride, SnCl_4 , forms soft crystals with a melting point of -30.2°C . The liquid is nonconducting. What type of solid (ionic, molecular, covalent or metallic) is formed by SnCl_4 ? **L02**

- 7.32** Elemental boron is a semiconductor, is very hard and has a melting point of about 2250°C . What type of solid is formed by boron? **L02**

- 7.33** Gallium crystals are shiny and conduct electricity. Gallium melts at 29.8°C . What type of solid does gallium form? **L02**

- 7.34** Titanium(IV) bromide forms soft orange-yellow crystals that melt at 39°C to give a liquid that does not conduct electricity. The liquid boils at 230°C . What type of solid does TiBr_4 form? **L02**

- 7.35** The element niobium is shiny, soft and ductile. It melts at 2468°C and the solid conducts electricity. What type of solid does it form? **L02**

- 7.36** Elemental phosphorus consists of soft, white, 'waxy' crystals that are easily crushed and melt at 44°C . The solid does not conduct electricity. What type of solid does phosphorus form? **L02**

- 7.37** Indicate which type of solid each of the following would form when it solidifies. **L02**

(a) Br_2
 (b) RbF
 (c) Na_2O
 (d) W
 (e) PH_3
 (f) KOH
 (g) Si

- 7.38** Indicate which type of solid each of the following would form when it solidifies. **L02**

(a) Li_2SO_4
 (b) Cu
 (c) Xe
 (d) H_2Se
 (e) Ge
 (f) CsCl
 (g) N_2

- 7.39** Molecular hydrogen and atomic helium both have two electrons, but He boils at 4.2 K, whereas H_2 boils at 20 K. Neon boils at 27.1 K, whereas methane, which has the same number of electrons, boils at 114 K. Explain why molecular substances boil at a higher temperature than atomic substances with the same number of electrons. **L02**

- 7.40** Refer to figure 7.21. Describe in detail what occurs when each of the following processes is carried out. **L03**

(a) A sample of CO_2 gas is compressed from $1.013 \times 10^5 \text{ Pa}$ to $5.065 \times 10^6 \text{ Pa}$ at $T = 235 \text{ K}$.
 (b) Dry ice at 166 K is heated to 350 K at $p = 5.30 \times 10^5 \text{ Pa}$.
 (c) A sample of CO_2 gas at $p = 1.013 \times 10^5 \text{ Pa}$ is cooled from 298 K to 50 K.

- 7.41** With reference to figure 7.22, describe what happens to silica as it is slowly heated from room temperature to 2000°C at $30.0 \times 10^5 \text{ Pa}$. **L03**

- 7.42** How many triple points appear on the phase diagram in figure 7.22? For each one, describe the conditions and name the three phases that coexist under these conditions. **L03**

- 7.43** The figure below shows the phase diagram for elemental sulfur (not to scale). Use it to answer the following questions. **L03**

- (a) Under what conditions does rhombic sulfur melt?
 (b) Under what conditions does rhombic sulfur convert to monoclinic sulfur?
 (c) Under what conditions does monoclinic sulfur sublime?

- 7.44** Use the figure in problem 7.43 to answer the following. **LO3**
 (a) How many triple points are there in the diagram?
 (b) Which phases coexist at each triple point?
 (c) If sulfur is at the triple point at 153 °C, what happens if the pressure is reduced to 0.517 Pa?
- 7.45** Sketch the phase diagram for a substance that has a triple point at -25.0°C and $0.75 \times 10^5 \text{ Pa}$, melts at 15.0°C at $1.013 \times 10^5 \text{ Pa}$, and has a normal boiling point of 85°C . **LO3**
- 7.46** Based on the phase diagram in problem 7.45, below what pressure will the substance undergo sublimation? How does the density of the liquid compare with the density of the solid? **LO3**
- 7.47** Construct a qualitative graph similar to the one in figure 7.17 to summarise the energy changes that accompany the following process: A sample of water at 35°C is placed in a freezer until the temperature reaches -25°C . Plot temperature along the y-axis and kilojoules of heat removed along the x-axis. **LO3**
- 7.48** Iron forms crystals in either body-centred cubic or face-centred cubic geometry. Which geometry has the higher density? Explain your choice. **LO4**
- 7.49** Beryllium forms crystals in either body-centred cubic or hexagonal close-packed geometry. Which solid phase has the higher density? Explain your choice. **LO4**
- 7.50** The unit cell of a tungsten oxide appears in the figure below. **LO4**
 (a) Name the cubic lattice compatible with this arrangement of the atoms.
 (b) Calculate the number of tungsten and oxygen atoms in the unit cell and identify the formula of this tungsten oxide.

- 7.51** One form of niobium oxide crystallises in the unit cell shown below. Calculate the number of niobium and oxygen atoms in the unit cell, and identify the formula of niobium oxide. **LO4**

- 7.52** Silver forms face-centred cubic crystals. The atomic radius of a silver atom is 144 pm. Draw the face of a unit cell with the nuclei of the silver atoms at the lattice points. The atoms are in contact along the diagonal. Calculate the length of an edge of this unit cell. **LO4**
- 7.53** The atomic radius of copper is 128 pm. Copper crystallises in a face-centred cubic lattice. What is the length of the edge of the unit cell expressed in picometres? **LO4**

ADDITIONAL EXERCISES

- 7.54** Potassium ions have a radius of 133 pm, and bromide ions have a radius of 195 pm. The crystal structure of potassium bromide is the same as sodium chloride. Estimate the length of the edge of the unit cell in potassium bromide. **LO4**
- 7.55** The unit cell in sodium chloride has an edge length of 564.0 pm. The sodium ion has a radius of 95 pm. What is the diameter of a chloride ion? **LO4**
- 7.56** Caesium chloride, CsCl, crystallises with a cubic unit cell of edge length 412.3 pm. The density of CsCl is 3.99 g mL^{-1} . Show that the unit cell cannot be body-centred cubic or face-centred cubic. **LO4**
- 7.57** Draw the unit cell of the CsCl structure and determine the number of nearest neighbours of opposite charge for each ion in this unit cell. **LO4**
- 7.58** Below is an illustration of a 'herringbone' pattern for patio pavers. Identify the unit cell for this pattern. **LO4**

7.61 The density of silver is 10.6 g mL^{-1} . Based on your answers to exercise 7.60, which cubic lattice is consistent with the given density?

7.62 Which of the following molecules would you expect to wet a greasy glass surface more effectively?

LO1,2

Chemical thermodynamics

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 8.1** explain the difference between spontaneous and nonspontaneous chemical processes
 - 8.2** use the terminology and units of chemical thermodynamics
 - 8.3** carry out calculations related to the first law of thermodynamics
 - 8.4** explain the concept of enthalpy and use Hess's law
 - 8.5** explain the concept of entropy
 - 8.6** state the second law of thermodynamics, and appreciate that any spontaneous process involves an increase in the entropy of the universe
 - 8.7** state the third law of thermodynamics and calculate entropies of reaction
 - 8.8** determine the spontaneity of a process using the change in Gibbs energy.
-

There is some disagreement about the world's first oil well. Some say that Edwin Drake drilled the first well at Titusville, Pennsylvania, USA, in 1859, while others ascribe the first well to James Williams at Enniskillen, Canada, one year earlier. What is not in dispute is the fact that humanity rapidly became dependent on oil and natural gas as means of powering transport, electricity production and heating, a dependence that continues to the present day.

Both oil and natural gas are composed primarily of hydrocarbons, which are molecules containing only carbon and hydrogen atoms. Such molecules burn spontaneously when ignited in air and this process gives out large amounts of heat, hence their use as fuels (figure 8.1). But why is this the case? Where does the heat come from when the molecules are burned? And given that one of the products of such combustion reactions is the greenhouse gas carbon dioxide, is there any way that we can utilise the reverse chemical reaction to re-form the hydrocarbon fuel?

The answer to this, and many other chemical questions, can be found in the science of chemical thermodynamics. In this chapter, we will show how heat (q) and work (w) are related to the important thermodynamic concepts of internal energy (U) and enthalpy (H). We will introduce entropy (S) and detail its relationship to probability, and finally we will show how consideration of Gibbs energy (G) can allow determination of the spontaneity of a chemical reaction or physical process.

FIGURE 8.1

Much of today's global population is dependent on hydrocarbons for fuel for heat, transport and electricity. These are produced by the burning of fossil fuels in power stations like this one.

8.1 Introduction to chemical thermodynamics

LEARNING OBJECTIVE 8.1 Explain the difference between spontaneous and nonspontaneous chemical processes.

When a lump of solid sodium metal is placed in water, a vigorous chemical reaction occurs that forms hydrogen gas and aqueous sodium hydroxide (figure 8.2), in accordance with the following equation.

However, if we try to carry out the reverse reaction by bubbling hydrogen gas through an aqueous solution of sodium hydroxide, no chemical reaction is observed.

Similarly, if a block of ice is left at room temperature and atmospheric pressure, it will eventually melt to give liquid water.

However, liquid water under the same conditions will never solidify into ice.

These examples show that both chemical reactions and physical changes occur in one particular direction only under particular conditions of temperature and pressure, and we say that such changes are **spontaneous**; in other words, once started, they proceed without the involvement of any outside factors. The reaction of sodium with water and the melting of ice described above are examples of spontaneous processes that proceed to completion. However, many spontaneous chemical reactions do not give complete conversion of reactants to products. An example of a spontaneous reaction that does not go to completion is the reaction of N_2O (laughing gas) with oxygen at room temperature and atmospheric pressure to give $\text{NO}_2\text{(g)}$. We can write the balanced chemical equation for this reaction as follows.

However, this does not mean that, if we mixed 2 mol of $\text{N}_2\text{O(g)}$ with 3 mol of $\text{O}_2\text{(g)}$ in a container at room temperature and pressure, we would obtain 4 mol of $\text{NO}_2\text{(g)}$. In fact, we would find that, no matter how long we waited, no more than about 2 mol of $\text{NO}_2\text{(g)}$ would form and there would always be significant amounts of the starting materials present in the reaction mixture. It is important for you to appreciate that *a balanced chemical equation tells us nothing about whether or not a particular reaction proceeds to completion; it simply tells us the mole ratios in which reactants react to give products.*

We can force nonspontaneous reactions to proceed provided that we couple them to a spontaneous process. For example, water does not spontaneously decompose into hydrogen gas and oxygen gas, but, by passing an electric current (a spontaneous flow of electrons) through water, we can force the reaction to proceed (figure 8.3). (Refer back to figure 2.16 to remind yourself of the colours we use in this text to represent atoms of the various elements in space-filling and ball-and-stick models.)

FIGURE 8.2

Metallic sodium reacts violently with water. In the reaction, sodium is converted to Na^+ , and water gives hydrogen gas and hydroxide ions. When the reaction is over, the solution contains sodium hydroxide.

FIGURE 8.3

The electrolysis of water produces H_2 and O_2 gases. It is a nonspontaneous change that continues only as long as electricity is supplied.

This process is called electrolysis. Production of hydrogen and oxygen will continue, however, only as long as the electric current is maintained. As soon as the supply of electricity is cut off, the decomposition ceases. This example demonstrates the difference between spontaneous and nonspontaneous changes. Once a spontaneous event begins, it tends to continue until it stops of its own accord (figure 8.4). A nonspontaneous event, on the other hand, can continue only as long as it receives some sort of outside assistance. You should also note that the electrolysis of water requires some sort of spontaneous mechanical or chemical change to generate the needed electricity. In short, *all nonspontaneous events occur at the expense of spontaneous ones*. Everything that happens can be traced, either directly or indirectly, to spontaneous changes.

FIGURE 8.4

Three common spontaneous events — iron rusts, fuel burns and ice cubes melt at room temperature

As chemists, we are interested in predicting whether a chemical reaction or a physical change is spontaneous under our conditions of interest, and, if it is, how far it will proceed towards completion under those conditions. The science of **chemical thermodynamics** allows us to predict both the direction and extent of spontaneous chemical and physical change under particular conditions. In order to do this, we need to study four important thermodynamic functions: internal energy (U , section 8.3), enthalpy (H , section 8.4), entropy (S , section 8.5) and Gibbs energy (G , section 8.8). Very brief definitions of these are as follows.

- **Internal energy (U)** is the sum of all the energies of all of the individual particles in a sample of matter.
- **Enthalpy (H)** is a function related to the heat absorbed or evolved by a chemical system during a chemical reaction or physical change under conditions of constant pressure.
- **Entropy (S)** is a measure of the number of ways energy is distributed throughout a chemical system.
- **Gibbs energy (G)**, named after the American mathematical physicist Josiah Willard Gibbs (1839–1903), is defined by the following equation, where T is the thermodynamic temperature, measured in kelvin.

$$G = H - TS$$

We will look at these thermodynamic functions in greater detail, and provide exact definitions, in the appropriate sections of this chapter. For now, it is sufficient to state that the value of Gibbs energy, G , allows us to predict spontaneity. We can liken a spontaneous change to a ball at the top of a hill — once pushed, it will roll spontaneously down the hill until it reaches the bottom, the point of minimum energy.

In the same way, we will see that chemical reactions proceed in the direction that leads to a decrease in the Gibbs energy of the system. We will also see that overall chemical and physical change will cease once the Gibbs energy of the system is minimised, and that, under these conditions, the system is at equilibrium.

8.2 Thermodynamic concepts

LEARNING OBJECTIVE 8.2 Use the terminology and units of chemical thermodynamics.

Before we begin our study of chemical thermodynamics, we need to discuss some important thermodynamic concepts.

Heat and temperature

Arguably the most important and indeed most familiar thermodynamic term, **heat (q)**, is perhaps the most conceptually difficult. Heat is the energy that is transferred as the result of a temperature difference. If two bodies having different temperatures are brought into direct contact, there will be heat flow from the hotter to the colder body, until both are at the same temperature. As we will see, we cannot actually measure heat directly. The definition of temperature also follows from the above; two bodies have the same temperature if they are in thermal equilibrium; that is, there is no heat flow between them when they are in direct contact. It is important to note that the **thermodynamic temperature** (sometimes called the absolute temperature) scale is used in nearly all thermodynamic calculations. The thermodynamic temperature is measured in kelvin (K), and a thermodynamic temperature can be converted to a temperature in degrees Celsius by subtracting 273.15. Conversely, a temperature in degrees Celsius can be converted to a temperature in kelvin by adding 273.15. In practice, adding or subtracting 273 gives sufficient accuracy for most calculations. You should note that a temperature *difference* of 1 K is numerically equal to a temperature difference of 1 °C, so, for calculations involving a temperature *change*, the numerical value of this change will be the same, regardless of whether the individual temperatures are expressed in K or °C.

As an example of this, consider heating a beaker of water from an initial temperature of 20 °C to 50 °C. The temperature change, ΔT , measured in degrees Celsius, will be as follows.

$$\Delta T = T_{\text{final}} - T_{\text{initial}} = 50\text{ °C} - 20\text{ °C} = 30\text{ °C}$$

Carrying out the same calculation in K, realising that 20.0 °C = 293 K, and 50.0 °C = 323 K, gives the following.

$$\Delta T = T_{\text{final}} - T_{\text{initial}} = 323\text{ K} - 293\text{ K} = 30\text{ K}$$

You can see that the temperature changes are numerically the same, regardless of the unit used to measure the individual temperatures.

This example illustrates some important terminology often used in thermodynamics. We are usually interested in the *change* in the values of U , H , S , G or T as the result of either a chemical reaction or a change in phase. We denote such a change using Δ (the upper-case Greek letter delta). Therefore, for any thermodynamic quantity X :

$$\Delta X = \text{final value of } X - \text{initial value of } X$$

or, as we wrote in the example above:

$$\Delta X = X_{\text{final}} - X_{\text{initial}}$$

Note that if X_{final} is less than X_{initial} , then ΔX is, by definition, negative. Thus, in the example above, we would say that ΔT for the cooling of water from 50 °C to 20 °C would be as follows.

$$\Delta T = T_{\text{final}} - T_{\text{initial}} = 20\text{ °C} - 50\text{ °C} = -30\text{ °C}$$

System, surroundings and universe

We will use the word **system** to refer to the particular part of the universe (generally one or more chemical species) that we are studying, while everything else is the **surroundings**. Together, the system and surroundings constitute the **universe** (figure 8.5). As we are usually interested in heat flow between the system and surroundings, it is very important to specify the **boundary** across which heat flows. The boundary might be visible (such as the walls of a beaker) or invisible (such as the boundary that separates

warm air from cold air along a weather front). Three types of system are possible, depending on whether matter or energy can cross the boundary.

1. *Open systems* can gain or lose mass and energy across their boundaries. The human body is an example of an open system.
2. *Closed systems* can absorb or release energy, but not mass, across the boundary. The mass of a closed system is constant, no matter what happens inside. A light bulb is an example of a closed system as it can release energy as both heat and light, but its mass is constant.
3. *Isolated systems* cannot exchange matter or energy with their surroundings. Because energy cannot be created or destroyed, the energy of an isolated system is constant, no matter what happens inside. A stoppered vacuum flask is a good approximation of an isolated system. Processes that occur within an isolated system with no heat transfer to the surroundings are called *adiabatic*, from the Greek words *a* and *diabatos* meaning ‘not passable’.

FIGURE 8.5

In thermodynamics, it is important to define the system, surroundings, universe and the boundary.

Units

The SI unit of energy, work (motion against an opposing force) and heat is the **joule (J)**. As described in the chapter on the language of chemistry, the joule is a derived unit and can be expressed in terms of SI base units as follows.

$$1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$$

A joule is the amount of kinetic energy possessed by a 2-kilogram object moving at a speed of 1 metre per second. It is approximately the energy of a single human heartbeat. The joule is actually a rather small amount of energy and in most cases we will use the larger unit, the **kilojoule (kJ)**.

$$1 \text{ kJ} = 10^3 \text{ J}$$

The use of both J and kJ in thermodynamics means that you must be very careful when carrying out calculations. For example, as we shall see, values of ΔH are commonly reported in kJ mol^{-1} while ΔS values are usually given in $\text{J mol}^{-1} \text{ K}^{-1}$. Therefore, when using these data in the important equation below, it is necessary to first ensure the values have consistent units.

$$\Delta G = \Delta H - T\Delta S$$

This will involve either converting ΔH to J mol^{-1} , by multiplying by 1000, or converting ΔS to $\text{kJ mol}^{-1} \text{ K}^{-1}$, by dividing by 1000. This will then ensure that the term $\Delta H - T\Delta S$, and hence ΔG , will have consistent units of either:

$$\text{J mol}^{-1} - (\text{K})(\text{J mol}^{-1} \text{ K}^{-1}) = \text{J mol}^{-1}$$

or:

$$\text{kJ mol}^{-1} - (\text{K})(\text{kJ mol}^{-1} \text{ K}^{-1}) = \text{kJ mol}^{-1}$$

Chemical reactions and phase changes

The thermodynamic functions ΔU , ΔH , ΔS and ΔG , can refer to both chemical and physical changes. Chemical changes generally occur as a result of chemical reactions; in these, the reactants and products are chemically different, as the result of the making and/or breaking of chemical bonds, or the transfer of electrons. Physical changes refer primarily to changes of phase. Here, the chemical identities of the reactants and products are the same, but their physical states are different; for example, liquid water freezing to give ice, and solid iodine subliming to give gaseous iodine. On the occasions when we are referring to the values of these thermodynamic functions *specifically* for chemical reactions, we denote this using the symbols $\Delta_r U$, $\Delta_r H$, $\Delta_r S$ and $\Delta_r G$.

Standard states

Whenever we make any measurement, we do so relative to some reference. This reference can be either arbitrary or absolute. For example, the zero point on the °C temperature scale has been arbitrarily set to the point at which water freezes or ice melts, and all temperatures in °C are measured relative to this. Conversely, any temperature in K is measured relative to absolute zero (0 K), the point at which all atomic and molecular motion ceases, and which is therefore the coldest possible temperature. For this reason, the temperature in K is sometimes called the absolute temperature.

The necessity for a reference is also true of thermodynamic measurements. In this chapter, we will encounter thermodynamic functions such as H (enthalpy) and G (Gibbs energy) for which absolute values cannot be measured, and for which we must therefore assign an arbitrary zero, and S (entropy), for which absolute values can be measured relative to a true zero.

As we shall see, our arbitrary zero for thermodynamic functions such as enthalpy and Gibbs energy involves standard states, the definitions of which depend on the phase of the substance in question. These standard states are given in table 8.1.

TABLE 8.1 Standard states

Phase of substance	Standard state
pure solid	the pure solid at a pressure of $p^\ominus$ (1×10^5 Pa)
pure liquid	the pure liquid at a pressure of $p^\ominus$
pure gas	the pure ideal gas at a pressure of $p^\ominus$
species in solution	the ideal solution at a pressure of $p^\ominus$, having either a molality of $m^\ominus$ (1 mol kg^{-1}) or a concentration of $c^\ominus$ (1 mol L^{-1})

It should be noted that temperature is not part of the definition of any standard state and it must therefore always be specified. However, it is very common to quote thermodynamic measurements at 25 °C. It should also be noted that the standard states for pure gases and species in solution are unattainable and therefore hypothetical; as we have seen in the chapter on gases and will see in the chapter on solutions and solubility, no gases or solutions exhibit ideal behaviour.

Standard thermodynamic functions for physical processes (i.e. phase changes) or chemical reactions refer to processes or reactions in which the unmixed reactants in their standard states are converted to the unmixed products in their standard states. Such functions are denoted by a superscript plimsoll, $^\ominus$, and such processes or reactions are said to be carried out under standard conditions.

State functions

As we will see, U , H , S and G are all examples of a **state function**. This means that the value of each depends only on the current state of the system and it does not matter how the system came to be in its current state or how the system will behave in the future. We can usually define the state of a chemical system by specifying the amount and type of substances present in the system, and the pressure, temperature and volume of the system. When we then change the state of the system by changing one or more of the above variables, the change in the value of any state function X of the system is given by the following equation.

$$\Delta X = X_{\text{final}} - X_{\text{initial}}$$

This depends only on the initial and final states of the system and not on the path taken during the change in the state of the system. This concept is illustrated in figure 8.6. As we will see later, the advantage of recognising that a particular property is a state function is that many calculations become much easier.

FIGURE 8.6

The summit of Aoraki Mount Cook, Australasia's highest mountain, is 3724 m above sea level. Starting at sea level, there are potentially several ways to get to the top. There are a number of different climbing routes that could be taken, a helicopter could drop you off on the top, or you could parachute onto the summit from a high-flying plane. While the actual distance travelled to get to the top will vary using each of these methods, the one thing that will not vary will be the fact that you will be 3724 m above sea level when you finally reach the summit. Therefore, the overall change in height between sea level and the summit is the same regardless of the route taken to get there. In this context, height above sea level is therefore a state function.

ΔG and spontaneity

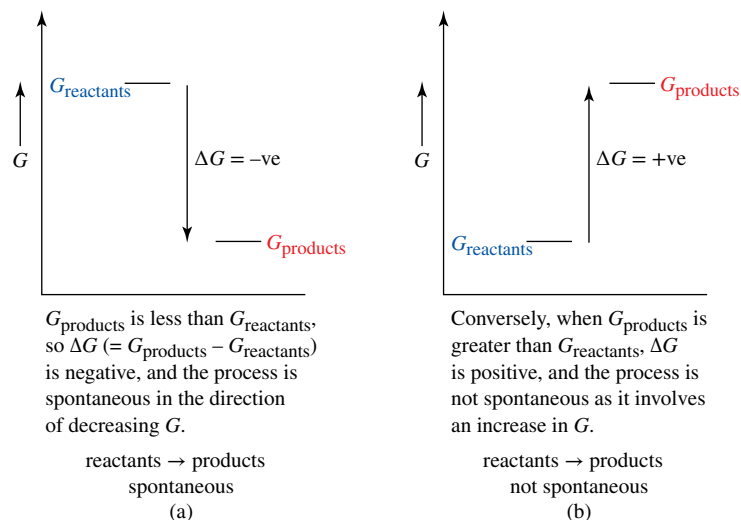

The primary aim of this chapter is to show that the spontaneity of a chemical or physical process at constant temperature and pressure can be predicted from the sign of the Gibbs energy change for the process (ΔG), which itself depends on the values of ΔH and ΔS via the following equation.

$$\Delta G = \Delta H - T\Delta S$$

This is one of the most important equations in all of chemistry. A negative value of ΔG means that the products are of lower G than the reactants; the process must proceed in the direction of decreasing G so it is spontaneous. Conversely, if ΔG is positive, the products are of higher G than the reactants; the process will not be spontaneous as it has to proceed in the direction of increasing G (figure 8.7).

FIGURE 8.7

Diagrams showing the origin of the sign of ΔG

If $\Delta G = 0$, the Gibbs energy of both the reactants and products is the same, and the system is at equilibrium, a state in which no overall chemical or physical change is observed. In short, we can say that, for a process occurring at constant temperature and pressure:

- if $\Delta G < 0$, the process is spontaneous
- if $\Delta G > 0$, the process is nonspontaneous
- if $\Delta G = 0$, the system is at equilibrium.

The magnitude of ΔG under standard conditions is also important in telling us how far a reaction goes towards completion, as we will see in the chapter on chemical equilibrium. In order to determine the value of ΔG , we need to know the values of both ΔH and ΔS . We will begin by defining ΔH using the first law of thermodynamics. In so doing, we will introduce the concepts of heat (q), work (w) and internal energy (U).

8.3 The first law of thermodynamics

LEARNING OBJECTIVE 8.3 Carry out calculations related to the first law of thermodynamics.

A simple statement of the **first law of thermodynamics** is that ‘energy cannot be created or destroyed; it can, however, be transferred as either heat or work’. In mathematical terms, we write this as follows.

$$\Delta U = q + w$$

ΔU is the change in internal energy, q is heat and w is work. Having defined heat in the previous section, we will now consider internal energy and work in detail in order to obtain a fuller understanding of the implications of the first law.

If you have ever dissolved a large amount of sodium chloride, NaCl, in water, you will have noticed that the resulting solution gets colder as the salt dissolves. However, if you dissolve the chemically similar salt lithium chloride, LiCl, in water, you will find that the resulting solution becomes surprisingly hot. The first process absorbs heat from the surroundings while the second gives out heat to the surroundings.

The energy that is transferred as heat comes from an object’s internal energy. Internal energy is the sum of all the nuclear, electronic, vibrational, rotational, translational and interaction energies of all of the individual particles in a sample of matter and is given the symbol U . In studying both chemical and physical changes, we are interested in the *change* in internal energy (ΔU) that accompanies the particular process.

$$\Delta U = U_{\text{final}} - U_{\text{initial}}$$

For a chemical reaction, U_{final} corresponds to the internal energy of the products, so we will write it as U_{products} . Similarly, we will use the symbol $U_{\text{reactants}}$ for U_{initial} . So for a chemical reaction the change in internal energy is given by the following equation.

$$\Delta_r U = U_{\text{products}} - U_{\text{reactants}}$$

Thus, when we dissolve sodium chloride in water, the system *absorbs* energy from its surroundings; its final energy is therefore greater than its initial energy, so $\Delta_r U$ is positive. Conversely, when we dissolve lithium chloride in water, the system gives out energy to its surroundings; its final energy is therefore less than its initial energy, so $\Delta_r U$ is negative.

A chemical system can exchange energy with its surroundings in two ways. The first, as we have seen above, is by either absorbing heat from, or emitting heat to, the surroundings. The second is by doing work on the surroundings, or having the surroundings do work on it. **Work (w)** may be defined simply as motion against an opposing force. For example, lifting a weight against the force of gravity is work, as is stretching or compressing a spring. While there are a number of different types of work possible in chemical systems (such as electrical work and osmotic work), we will consider only the work associated with the compression or expansion of a gas in a closed chemical system to illustrate a number of important thermodynamic concepts. This type of work is often called pressure–volume or pV work, as it involves a change in pressure and volume of a gas sample. When a gas is compressed at constant temperature, the surroundings are doing work on the system, while the expansion of a gas at constant temperature is an example of a system doing work on the surroundings (figure 8.8).

The magnitude of the work done during a volume change, ΔV , against an opposing pressure, p , is given by the following equation.

$$w = -p\Delta V$$

As $\Delta V (V_{\text{final}} - V_{\text{initial}})$ is positive for the expansion of a gas, work is negative for this process at constant temperature where the system does work on the surroundings, while similar reasoning shows that work is positive for the compression of a gas where the surroundings do work on the system.

Heat and work are the only ways by which a closed chemical system can exchange energy with its surroundings. It therefore follows that the change in internal energy of a closed chemical system during a chemical or physical change must be equal to the sum of the heat absorbed or emitted by the system and the work done on or by the system. This is represented by the equation for the first law of thermodynamics that we saw at the start of this section.

$$\Delta U = q + w$$

U is a state function. However, the values of q and w depend on what happens between the initial and final states of any change and, thus q and w are not state functions. This can be illustrated by the discharge of a car battery using two different paths (figure 8.9). Both paths take us between the same initial (fully charged) state and final (fully discharged) state. Because U is a state function ΔU must be the same for both paths. But what about q and w ?

FIGURE 8.8

Pressure–volume work. (a) A gas is confined under pressure in a cylinder fitted with a piston that is held in place by a sliding pin. (b) When the piston is released, the gas inside the cylinder expands and pushes the piston upwards against the opposing pressure of the atmosphere. As it does so, the gas does some pressure–volume work on the surroundings.

FIGURE 8.9

Internal energy, heat and work. The complete discharge of a battery along two different paths involves the same total amount of internal energy, ΔU . However, if the battery is simply short-circuited with a heavy spanner, as shown in path 1, this energy appears entirely as heat. Path 2 gives part of the total internal energy as heat, but most of the internal energy appears as work done by the motor.

In path 1 of figure 8.9, we simply short-circuit the battery by placing a heavy spanner across the terminals. If you have ever done this, even by accident, you know how violent the result can be. Sparks fly and the spanner becomes very hot as the battery quickly discharges. Lots of heat is given off, but *the system does no work* ($w = 0$). The heat loss to the surroundings is ΔU , the difference in U between the fully discharged and fully charged battery.

In path 2, we discharge the battery more slowly by using it to operate a motor. Along this path, most of the energy represented by ΔU appears as work (running the motor) and only a relatively small amount appears as heat (from the friction within the motor and the electrical resistance of the wires).

Therefore, neither q nor w is a state function. Their values depend *entirely* on the path between the initial and final states.

Heat capacity and specific heat

We saw in section 8.2 that heat is the energy that is transferred as the result of a temperature difference. We cannot measure heat directly, but we can calculate it using the temperature change that occurs when heat flows from one body to another. There is, in fact, a linear relationship between heat and temperature change, described by the following equation.

$$q = C\Delta T$$

In this equation q is heat and C is the **heat capacity** of the object in question. The units of heat capacity (J K^{-1}) help us to understand what it is; it can be thought of as the amount of heat required to increase the temperature of a substance by 1 K.

WORKED EXAMPLE 8.1

Experimental determination of heat capacity

The heat capacity of a solid can be measured by immersing the hot solid in a known volume of water and measuring the temperature rise of the water that occurs. Suppose that a solid having a temperature of 80.4°C is dropped into an insulated flask containing 100.0 g of water at 25.0°C . The temperature of the water rises to 26.7°C . Given that it takes 4.18 J to raise the temperature of 1 g of water by 1 K , what is the heat capacity of the solid?

Analysis

We want to find the heat capacity, C . We can solve $q = C\Delta T$ for C by dividing both sides by the temperature change, ΔT .

$$C = \frac{q}{\Delta T}$$

We must find the temperature change of the solid and the amount of heat, q , that it exchanges with the water in the cup.

Solution

To find q , we can assume that all of the heat lost by the solid will be gained by the water, so we start by calculating the heat gained by the water.

$$\text{heat lost by the solid} = -\text{heat gained by the water}$$

The temperature of the water rises from 25.0°C to 26.7°C , a rise of 1.7 K (recall that a temperature *difference* has the same numerical value in both K and $^\circ\text{C}$). It would take $1.7\text{ K} \times 4.18\text{ J K}^{-1} = 7.1\text{ J}$ of heat to raise the temperature of each gram of water by 1.7 K , so it would

take $100.0 \times 7.1\text{ J} = 7.1 \times 10^2\text{ J}$ to raise the temperature of 100.0 g of water by 1.7 K .

The temperature of the solid drops from 80.4°C to 26.7°C (both the water and the solid will have the same temperature at the end of this process).

$$\begin{aligned}\Delta T &= T_{\text{final}} - T_{\text{initial}} \\ &= 26.7^\circ\text{C} - 80.4^\circ\text{C} \\ &= -53.7^\circ\text{C} \\ &= -53.7\text{ K}\end{aligned}$$

As the heat gained by the water is $7.1 \times 10^2\text{ J}$, the heat lost by the solid must be $-7.1 \times 10^2\text{ J}$ (notice that the negative sign means heat was lost by the solid). Therefore, the heat capacity is as follows.

$$\begin{aligned}C &= \frac{q}{\Delta T} \\ &= \frac{-7.1 \times 10^2\text{ J}}{-53.7\text{ K}} \\ &= 13\text{ J K}^{-1}\end{aligned}$$

Is our answer reasonable?

In any calculation involving energy transfer, we first check to see that all quantities have the correct signs. The water gained about 700 J and warmed up by 1.7 K , so the water's heat capacity is $\frac{700\text{ J}}{1.7\text{ K}}$, or about 400 J K^{-1} . This is about 30 times the calculated heat capacity of the solid. We would expect, then, the temperature rise of the water to be about $\frac{1}{30}$ of the temperature drop of the solid, since it absorbs 30 times as much heat as the solid before its temperature will rise 1 degree. The temperature of the solid dropped by 53.7 K , and the temperature of the water rose by 1.7 K , which agree with this prediction.

PRACTICE EXERCISE 8.1

A ball bearing having a temperature of 200 °C is dropped into an insulated flask containing 125 g of water at a temperature of 25 °C. The final temperature of both the ball bearing and the water is 31.8 °C. Assuming no heat is lost to the surroundings, calculate the heat capacity of the ball bearing, in J K⁻¹.

Heat capacity depends on the size of the sample. If it takes 4.18 J to raise the temperature of 1 g of water by 1 K, it will take twice that amount of energy (8.36 J) to obtain the same temperature rise in 2 g of water. Any property with a value that depends on the size of the sample is called an **extensive property**. Any property with a value that is the same regardless of the size of the sample is called an **intensive property**. For example, the volume of a system is an extensive property, whereas its temperature is an intensive property. We can turn heat capacity, an extensive property, into a new intensive property called **specific heat capacity** (often called **specific heat**) by dividing by the mass of the sample. Specific heat capacity is simply the heat capacity per gram of substance. It has the symbol c and is defined as follows.

$$c = \frac{C}{m}$$

This gives c the units of J g⁻¹ K⁻¹.

The advantage of using the intensive property specific heat is that we can easily compare values for the same mass of different substances by inspection. As we can see in table 8.2, the specific heat of water is approximately nine times that of iron, meaning that it takes nine times as much heat to raise the temperature of water by a specified amount as it does for the same mass of iron. The heat required to raise the temperature of 1 mol of a substance by 1 K is called the **molar heat capacity** and has units of J mol⁻¹ K⁻¹.

TABLE 8.2 Specific heats and molar heat capacities of selected substances at 25 °C

Substance	Specific heat (J g ⁻¹ K ⁻¹)	Molar heat capacity (J mol ⁻¹ K ⁻¹)
lead	0.128	26.5
gold	0.129	25.4
silver	0.235	25.4
copper	0.387	24.6
iron	0.4498	25.1
carbon (graphite)	0.711	8.5
oxygen (gas)	0.920	29.4
neon (gas)	1.03	20.8
nitrogen (gas)	1.04	29.1
ethanol	2.45	113
water (liquid)	4.18	75.3

We can calculate the heat absorbed or emitted by an object given its mass (m), its temperature change (ΔT) and its specific heat (c) by using the following equation.

$$q = cm\Delta T$$

WORKED EXAMPLE 8.2

Relating temperature change, heat, mass and specific heat

Gold is a relatively soft metal, and for this reason, 'gold' jewellery is rarely made of pure gold. The gold content of gold jewellery is often denoted in terms of carats, where 24 carat gold is pure, 18 carat gold is an alloy of 75% gold, 12.5% silver and 12.5% copper, and 9 carat gold contains only 37.5% gold.

In order to determine if a gold ring with a mass of 5.50 g was made of pure gold, it was supplied with 2.1 J of heat. The ring, which was initially at 25.0 °C, increased in temperature to 27.2 °C. Assuming we can measure temperature to a precision of ± 0.1 °C, is the observed temperature rise consistent with the ring being made of pure gold?

Analysis

The question indirectly asks us to calculate the temperature rise that would be observed if the ring was made of pure gold. We will do this using the equation $q = cm\Delta T$. We will need to rearrange the equation to make ΔT the subject.

We are given the mass of the ring (m) and the amount of heat it absorbed (q). We can look up the specific heat of gold in table 8.2 ($c = 0.129 \text{ J g}^{-1} \text{ K}^{-1}$).

If the calculated temperature rise is not 2.2 °C, then we can say that the ring is not made of pure gold.

Solution

$$q = cm\Delta T$$

Therefore:

$$\Delta T = \frac{q}{cm} = \frac{2.1 \text{ J}}{0.129 \text{ J g}^{-1} \text{ K}^{-1} \times 5.50 \text{ g}} = 3.0 \text{ K} = 3.0 \text{ }^{\circ}\text{C}$$

Therefore, if the ring were made of pure gold, we can calculate the final temperature to be $(25.0 \text{ }^{\circ}\text{C} + 3.0 \text{ }^{\circ}\text{C}) = 28.0 \text{ }^{\circ}\text{C}$. As the observed temperature rise is less than this, we can confidently conclude that the ring is not pure (24 carat) gold.

Is our answer reasonable?

Assuming we have made no arithmetic errors, we need to determine if it makes sense for the actual ring to exhibit a lower temperature rise than it would if it were made from pure gold. Note from table 8.2 that gold has the second-lowest specific heat of all the metals listed, and from the introduction to this question that gold is generally alloyed with silver and copper in gold jewellery. Both silver and copper have higher specific heats than gold, meaning that we would expect an alloy of the three metals to have a higher specific heat than pure gold. This would then mean that the bottom line of the equation above would be larger, which would make the value of ΔT smaller than 3.0 °C. Therefore, our answer does make sense.

PRACTICE EXERCISE 8.2

A sample of 400 g of water was cooled from a temperature of 35.0 °C to 17.0 °C. How much heat was lost by the water?

Determination of heat

Now that we know the relationship between temperature change and heat, we can use this to determine the heat lost or gained in a chemical reaction or physical process. We carry out the reaction or process in a **calorimeter**, which is a piece of apparatus especially designed to minimise heat loss between the system and surroundings. There are two main types of calorimeter — those that operate under conditions such that the system remains at constant volume and those that contain the system at constant pressure. While the distinction may appear small, we will see that there are important implications. Let us first consider **combustion reactions** where a substance undergoes reaction with oxygen in a constant volume **bomb calorimeter**, an example of which is shown in figure 8.10.

Because the volume of the system in figure 8.10 cannot change during the reaction, ΔV for the system will be 0. This means that $p\Delta V$ must also be 0. Remember that $w = -p\Delta V$; therefore, no work can be done by or on the system. Recall the following equation.

$$\Delta U = q + w$$

For a reaction carried out under constant volume conditions in a bomb calorimeter where $w = 0$, it follows that:

$$\Delta_{\text{r}}U = q_{\text{v}}$$

where q_{v} is the **heat of reaction at constant volume**.

Food scientists determine the internal energy of foods and food ingredients (figure 8.11) by burning them in a bomb calorimeter. The reactions that break down foods in the body are complex, but they produce the same products as the combustion reaction for the food.

It is important that you use the correct sign of the heat change in any calculations based on calorimetric measurements. Consider, for example, a combustion reaction carried out in a bomb calorimeter of the type shown in figure 8.10. The heat given out by the chemical reaction is absorbed by the calorimeter and the surrounding water, leading to a measured temperature rise of the water. In simple terms, the chemical reaction gives out an amount of heat (q_{reaction}), which is gained by the calorimeter and its surroundings ($q_{\text{calorimeter}}$). These two amounts of heat are numerically equal, but opposite in sign. Regardless of whether the reaction gives out or takes in heat, the following is always true.

$$q_{\text{calorimeter}} = -q_{\text{reaction}}$$

FIGURE 8.10

A bomb calorimeter. The sample is placed in the steel bomb calorimeter which is then filled with $\text{O}_2(\text{g})$. The initial temperature of the stirred water is measured, and the combustion reaction is then initiated electrically. The reaction gives out heat, which is absorbed by the bomb calorimeter and the surrounding water. Measurement of the temperature rise of the water, together with knowledge of the heat capacities of the bomb calorimeter and the water, allow the heat of reaction at constant volume, q_v , and therefore the internal energy of the reaction, $\Delta_r U$, to be calculated.

WORKED EXAMPLE 8.3

Bomb calorimetry

- (a) When 1.000 g of olive oil was completely burned in pure oxygen in a bomb calorimeter like the one shown in figure 8.10, the temperature of the water bath, which contained 0.750 kg of water, increased from 22.000 °C to 22.241 °C. The heat capacity of the bomb calorimeter was 5.896 kJ K⁻¹. How much heat is produced on burning 1.000 g of olive oil?
- (b) Olive oil is almost pure glyceryl trioleate, C₅₇H₁₀₄O₆. The equation for the combustion of glyceryl trioleate is as follows.

What is the change in internal energy, $\Delta_r U$, in kJ for the combustion of 1 mol of glyceryl trioleate? Assume the olive oil burned in (a) was pure glyceryl trioleate.

Analysis

In (a), we are given the heat capacity of the bomb calorimeter, the specific heat and mass of water, and the temperature change observed on burning 1.000 g of olive oil, and we are asked to calculate the heat evolved. Both the bomb calorimeter and the water bath absorb the heat released by the burning olive oil. We can calculate the heat absorbed by both the bomb calorimeter ($q_{\text{calorimeter}}$) and the water bath (q_{water}) from the temperature change, heat capacity of the bomb calorimeter and specific heat and mass of water. The heat released by the oil (q_{reaction}) will be the negative of the sum of these. We will have to take care with units, as the heat capacity of the bomb calorimeter is given in kJ K⁻¹, and the specific heat of water is given in J g⁻¹ K⁻¹.

In (b), we are asked for the change in internal energy, $\Delta_r U$. Bomb calorimetry measures heat at constant volume, q_v , which is equal to the internal energy change for the reaction. Thus, the heat calculated in (a) is equal to $\Delta_r U$ for 1 g of

glyceryl trioleate. We can use the molar mass of glyceryl trioleate to convert $\Delta_r U$ per gram to $\Delta_r U$ per mole.

Solution

- (a) We firstly calculate the heat absorbed by the water bath when 1.000 g of olive oil is burned.

$$\begin{aligned} q_{\text{water}} &= cm\Delta T \\ &= 4.18 \text{ J g}^{-1} \text{ K}^{-1} \times 750 \text{ g} \times (22.241 - 22.000) \text{ K} \\ &= 756 \text{ J} \end{aligned}$$

The heat absorbed by the bomb calorimeter can then be calculated.

$$\begin{aligned} q_{\text{calorimeter}} &= C\Delta T \\ &= 5.896 \text{ kJ K}^{-1} \times (22.241 - 22.000) \text{ K} \\ &= 1.42 \text{ kJ} \end{aligned}$$

The total heat given out in the combustion reaction, q_{reaction} , will be the negative of the sum of these.

$$q_{\text{calorimeter}} + q_{\text{water}} = -q_{\text{reaction}}$$

Therefore, q_{reaction} for burning 1.000 g of olive oil is $-(1.42 + 0.756) \text{ kJ} = -2.17 \text{ kJ}$, and the energy content of the olive oil on a mass basis is thus -2.17 kJ g^{-1} .

- (b) We convert the heat produced per gram to the heat produced per mole, using the molar mass of C₅₇H₁₀₄O₆, 885.4 g mol⁻¹.

$$-2.17 \text{ kJ g}^{-1} \times 885.4 \text{ g mol}^{-1} = -1.92 \times 10^3 \text{ kJ mol}^{-1}$$

Since this is heat at constant volume q_v , we have $\Delta_r U = q_v = -1.92 \times 10^3 \text{ kJ}$ for combustion of 1 mol of C₅₇H₁₀₄O₆.

Is our answer reasonable?

Always check the signs of calculated heats in calorimetry. The combustion reaction releases heat, so the sign must be negative. We appear to have done the numerical calculations correctly, so we can assume our answer is correct.

PRACTICE EXERCISE 8.3

A sample of carbon weighing 1.07 g is completely burned in an atmosphere of excess oxygen in a bomb calorimeter having a heat capacity of 4.504 kJ K⁻¹. The temperature of the 0.655 kg of water surrounding the calorimeter rises from 20.00 °C to 24.84 °C. Use these data to calculate $\Delta_r U$ for the combustion of 1 mol of carbon.

8.4 Enthalpy

LEARNING OBJECTIVE 8.4 Explain the concept of enthalpy and use Hess's law.

In chemistry, we are most often concerned with reactions that occur in solution, and it is more convenient to carry out such reactions in a beaker, flask or test tube open to the atmosphere than inside a metal 'bomb'. In these cases, we are working under conditions of constant atmospheric pressure. Hence, the system is free to expand or contract and this means that it can potentially do pV work. Thus we can see that we will not be able to make the same simplifications as we did under constant volume conditions.

As we have already seen, when a system expands against a constant pressure, p , the pV work done is given by:

$$w = -p\Delta V$$

where:

$$\Delta V = V_{\text{final}} - V_{\text{initial}}$$

Under conditions where the system expands, ΔV is positive and so w is negative, meaning that the system has done work on the surroundings and consequently lowered its internal energy. The opposite is true if the system is compressed. We now rewrite:

$$\Delta U = q + w$$

under conditions of constant pressure as shown below, where q_p is the **heat of reaction at constant pressure**.

$$\Delta U = q_p - p\Delta V$$

However, this equation is inconvenient as we need to know the value of ΔV if we wish to calculate ΔU . We now define a new thermodynamic function called enthalpy, which has the symbol H , as:

$$H = U + pV$$

Thus, under conditions of constant pressure:

$$\Delta H = \Delta U + p\Delta V$$

Substituting $\Delta U = q_p - p\Delta V$ into this gives the following equation.

$$\Delta H = q_p - p\Delta V + p\Delta V$$

Therefore,

$$\Delta H = q_p$$

Thus, the heat of reaction at constant pressure is equal to $\Delta_r H$, in the same way that the heat of reaction at constant volume is equal to $\Delta_r U$. Like $\Delta_r U$, $\Delta_r H$ is a state function, meaning that the enthalpy change for a reaction depends only on the initial and final states of the system. If the final enthalpy of the system is greater than the initial, the system has absorbed heat from its surroundings, so $\Delta_r H$ will be positive and the reaction is said to be **endothermic**. Conversely, if the system has lost heat to the surroundings, the enthalpy of the system has decreased, so $\Delta_r H$ will be negative and the reaction is said to be **exothermic**.

The difference between the enthalpy change and the internal energy change for a reaction is $p\Delta V$. The difference between $\Delta_r U$ and $\Delta_r H$ can be very large for reactions that produce or consume gases, because these reactions can have very large volume changes. If a reaction involves only solids and liquids, though, the values of ΔV are tiny, so $\Delta_r U$ and $\Delta_r H$ for these reactions are nearly identical.

We can obtain values of $\Delta_r H$ using a very simple constant pressure calorimeter, dubbed the coffee cup calorimeter. This comprises two nested and capped cups made of polystyrene, a very good insulator (figure 8.12). A reaction occurring in such a calorimeter exchanges very little heat with the surroundings, particularly if the reaction is fast, under which conditions the temperature change is rapid and easily measured. We can find the heat of reaction if we have determined the heat capacity of the calorimeter and its contents before the reaction. As the polystyrene cup and the thermometer absorb only a tiny amount of heat, we can usually ignore them in our calculations. Therefore, in our calculations of $q_{\text{calorimeter}}$, we need only use the specific heat of the solution.

FIGURE 8.12

A coffee cup calorimeter used to measure heats of reaction at constant pressure

WORKED EXAMPLE 8.4

Constant pressure calorimetry

The reaction of hydrochloric acid and sodium hydroxide is very rapid and exothermic. The balanced chemical equation is as follows.

In one experiment, 50.0 mL of 1.00 mol L⁻¹ HCl at 25.5 °C was placed in a coffee cup calorimeter. To this was added 50.0 mL of 1.00 mol L⁻¹ NaOH solution, also at 25.5 °C. The mixture was stirred, and the temperature quickly increased to a maximum of 32.2 °C. The density of 1.00 mol L⁻¹ HCl is 1.02 g mL⁻¹ and that of 1.00 mol L⁻¹ NaOH is 1.04 g mL⁻¹. What is the heat evolved in joules per mole of HCl? Assume that the specific heats of the solutions are the same as that of water, 4.18 J g⁻¹ K⁻¹. (We will neglect the heat lost to the polystyrene, the thermometer and the surrounding air.)

Analysis

Before we can use $q = cm\Delta T$ to find the heat evolved, we must calculate the system's total mass and the temperature change. The mass here refers to the *total* mass of the combined solutions. However, we were given volumes, so we must use their densities to calculate their masses, using the following equation.

$$\text{mass} = \text{density} \times \text{volume}$$

For the HCl solution, the density is 1.02 g mL⁻¹ so:

$$\text{mass}_{\text{HCl}} = 1.02 \text{ g mL}^{-1} \times 50.0 \text{ mL} = 51.0 \text{ g}$$

For the NaOH solution, the density is 1.04 g mL⁻¹ so:

$$\text{mass}_{\text{NaOH}} = 1.04 \text{ g mL}^{-1} \times 50.0 \text{ mL} = 52.0 \text{ g}$$

Thus:

$$\text{total mass} = 51.0 \text{ g} + 52.0 \text{ g} = 103.0 \text{ g}$$

Solution

The reaction changes the temperature of the calorimeter by $T_{\text{final}} - T_{\text{initial}}$, so:

$$\Delta T = (32.2 - 25.5) \text{ K} = 6.7 \text{ K}$$

Now we can calculate the heat absorbed by the calorimeter, $q_{\text{calorimeter}}$:

$$\begin{aligned} q_{\text{calorimeter}} &= cm\Delta T \\ &= 4.18 \text{ J g}^{-1} \text{ K}^{-1} \times 103.0 \text{ g} \times 6.7 \text{ K} \\ &= 2.9 \times 10^3 \text{ J} \end{aligned}$$

Knowing that $q_{\text{reaction}} = -q_{\text{calorimeter}}$, we obtain:

$$q_{\text{reaction}} = -2.9 \times 10^3 \text{ J.}$$

This is the heat evolved for the specific mixture prepared. However, the problem calls for joules *per mole of HCl*. We calculate the amount of HCl using the following equation.

$$\begin{aligned} n_{\text{HCl}} &= cV \\ &= 1.00 \text{ mol L}^{-1} \times 0.0500 \text{ L} \\ &= 0.0500 \text{ mol} \end{aligned}$$

Neutralising 0.0500 mol of acid gave $q_{\text{reaction}} = -2.9 \times 10^3 \text{ J}$. So, on a per mole basis:

$$\begin{aligned} \text{heat evolved} &= \frac{-2.9 \times 10^3 \text{ J}}{0.0500 \text{ mol}} \\ &= -58 \times 10^3 \text{ J mol}^{-1} = -58 \text{ kJ mol}^{-1} \end{aligned}$$

Thus, the enthalpy change for this reaction is -58 kJ mol^{-1} . (The negative sign shows that the reaction is exothermic.)

Is our answer reasonable?

Let's first review the logic of the steps we used. *Notice how the logic is driven by definitions, which carry specific units.* Working backwards, knowing that we want units of joules per mole in the answer, we must calculate separately the amount of acid neutralised and the amount of heat evolved. The latter will emerge when we multiply the solution's mass (g) and specific heat (J g⁻¹ K⁻¹) by the temperature increase (K).

The step in the calculation that involves the mass of the final sample is straightforward. Because the densities are close to 1 g mL⁻¹, the combined masses are about 50 g per solution or a total of 100 g.

The specific heat is around 4.2 J g⁻¹ K⁻¹, which means that, if the final solution weighed 1 g, its heat capacity would be 4.2 J K⁻¹. If the mass is 100 g, the heat capacity is 100 times as much, or 420 J K⁻¹. The temperature increased by about 7 K so, when we multiply 420 J K⁻¹ by 7, we get the heat absorbed by the calorimeter, about 2940 J or $2.9 \times 10^3 \text{ J}$, which is the same as 2.9 kJ; q_{reaction} is the negative of this. This much heat is associated with neutralising 0.0500 mol HCl, so the heat per mole is -2.9 kJ divided by 0.0500 mol, or -58 kJ mol^{-1} .

PRACTICE EXERCISE 8.4

When pure sulfuric acid dissolves in water, a large amount of heat is given off. To measure it, 175 g of water was placed in a coffee cup calorimeter and chilled to 10.0 °C. Then 4.90 g of sulfuric acid, H₂SO₄, also at 10.0 °C, was added, and the mixture was quickly stirred. The temperature rose rapidly to 14.9 °C. Assume that the value of the specific

heat of the solution is 4.18 J g⁻¹ K⁻¹ and that the solution absorbs all the heat evolved. Calculate the heat evolved in kilojoules on formation of this solution. (Remember to use the *total* mass of the solution: the water plus the acid.) Calculate also the heat evolved *per mole* of sulfuric acid.

Cold fusion — a nuclear reaction at room temperature

On 23 March 1989, an extraordinary press conference was given by two chemists, Professors Martin Fleischmann and Stanley Pons, at the University of Utah, in the USA, in which they announced their discovery of 'cold fusion'. This process, if real, would have solved the energy problems of the world. Fleischmann and Pons (figure 8.13) claimed that they had developed a method by which nuclear fusion, the process that powers our sun, could be carried out in a controlled fashion in a chemistry laboratory, using nothing more than D_2O (water where the protons, ^1_1H , have been replaced by deuterons, ^2_1H), the element palladium, and an electrolysis setup very similar to that shown in figure 8.3.

The reaction to this news was huge. Laboratories around the world set about replicating Pons and Fleischmann's results, and it did not take long for serious doubts about their work to be raised. On the basis of calorimetry measurements, Pons and Fleischmann had claimed that their apparatus produced more energy than it used up. However, two major flaws in their experimental setup were apparent once they published their work. Firstly, they were working with an open system in which matter, in the form of D_2 and O_2 gas, and therefore heat, could escape. Secondly, they did not have a stirrer in their calorimeter, relying instead on the bubbles of D_2 and O_2 gas to stir the solution. This meant that the temperature throughout their solution was not uniform, and the excess heat they apparently measured could simply have come from local hotspots in the solution.

A number of other problems with their results meant that cold fusion was eventually shown to be false, although a few diehard believers can be found on the internet. The driving force for the announcement of cold fusion was not science but money — the potential windfall that would have come the way of Pons, Fleischmann and the University of Utah (not to mention the certain Nobel Prizes) would have been truly mind-boggling, and these riches would only go to the first people to proclaim the discovery — there are no prizes in science for coming second. Sadly, their names will now be forever associated with a scientific fiasco.

FIGURE 8.13

Fleischmann and Pons claimed their cold fusion apparatus produced more energy than it used. Unfortunately, they were wrong.

Standard enthalpy of reaction

The amount of heat a reaction produces or absorbs depends on the amounts of reactants we combine. It makes sense that, if we burn 2 mol of carbon, we will get twice as much heat as if we had burned 1 mol. For heats of reaction to have meaning, we must describe the system completely. Our description must include amounts and concentrations of reactants, amounts and concentrations of products, temperature and pressure, because all of these things can influence heats of reaction.

The **standard enthalpy of reaction** ($\Delta_r H^\ominus$) at temperature T is the value of ΔH for a reaction in which the pure, separated reactants in their standard states are converted to the pure separated products in their standard states, all at temperature T , and in which the stoichiometric coefficients in the balanced chemical equation refer to actual numbers of moles. While the SI unit of $\Delta_r H^\ominus$ is J mol^{-1} , values are usually quoted in kJ mol^{-1} .

To illustrate clearly what we mean by $\Delta_r H^\ominus$, let us use the reaction between gaseous nitrogen and hydrogen that produces gaseous ammonia.

When 1.000 mol of $\text{N}_2(\text{g})$ at 25°C and 10^5 Pa and 3.000 mol of $\text{H}_2(\text{g})$ at 25°C and 10^5 Pa react to form 2.000 mol of $\text{NH}_3(\text{g})$ at 25°C and 10^5 Pa , the reaction releases 92.38 kJ. Hence, for the reaction as given by the preceding equation, $\Delta_r H^\ominus = -92.38\text{ kJ mol}^{-1}$. Often, the enthalpy change is given immediately after the equation, for example:

A chemical equation that also shows the value of $\Delta_r H^\ominus$ is called a **thermochemical equation**. Such equations always specify the physical states of the reactants and products, and their associated $\Delta_r H^\ominus$ value applies to the situation where the stoichiometric coefficients refer to actual numbers of moles. The equation above, for example, shows a release of 92.38 kJ if 2 mol of NH_3 forms. If we were to make twice as much,

or 4.000 mol, of NH_3 (from 2.000 mol of N_2 and 6.000 mol of H_2), then twice as much heat (184.8 kJ) would be released. On the other hand, if only 0.5000 mol of N_2 and 1.500 mol of H_2 were to react to form just 1.000 mol of NH_3 , then only half as much heat (46.19 kJ) would be released. For the various reactions just described, for example, we would have the following thermochemical equations.

Because the coefficients of a thermochemical equation always mean *moles*, not molecules, we may use fractional coefficients.

You must write down physical states for all reactants and products in thermochemical equations. The combustion of 1 mol of methane, for example, has different values of $\Delta_{\text{r}}H^\circ$ if the water produced is in its liquid or its gaseous state.

The difference in $\Delta_{\text{r}}H^\circ$ values for these two reactions is the quantity of energy that would be released by the physical change of 2 mol of water vapour at 25 °C to 2 mol of liquid water at 25 °C.

WORKED EXAMPLE 8.5

Writing a thermochemical equation

The thermochemical equation for the exothermic reaction of hydrogen and oxygen that produces water (figure 8.14) is as follows.

What is the thermochemical equation for the above reaction when it is carried out to produce 1.000 mol H_2O ?

Analysis

The given equation is for the production of 2.000 mol of H_2O , and any changes in the coefficient for water must be made identically to all other coefficients, as well as to the value of $\Delta_{\text{r}}H^\circ$.

Solution

We divide everything in the thermochemical equation by 2 to obtain the following.

Is our answer reasonable?

Compare the equation just found with the initial equation to see that the coefficients and the value of $\Delta_{\text{r}}H^\circ$ are all divided by 2.

FIGURE 8.14

The airship *Hindenburg* used hydrogen, a gas that is lighter than air but also flammable, to provide lift. On 6 May 1937, at Lakehurst, New Jersey, USA, it caught fire while mooring, probably as a result of a build-up of static electricity, and the explosive reaction of hydrogen with oxygen destroyed the airship in minutes.

PRACTICE EXERCISE 8.5

Use the data given in worked example 8.5 to write the thermochemical equation for the formation of 2.800 mol of H_2O .

Once we have the thermochemical equation for a given reaction, we can write the equation for the reverse reaction, regardless of how hard it might actually be to make it happen. For example, the thermochemical equation for the combustion of carbon in oxygen to give carbon dioxide is as follows.

The reverse reaction, which is extremely difficult to carry out, would be the decomposition of carbon dioxide to carbon and oxygen.

Despite the difficulty of carrying out this reaction, we can still determine its value of $\Delta_{\text{r}}H^{\circ}$. This is because ΔH is a state function, and therefore the absolute difference between the enthalpies of the reactants and products does not depend on the direction of the reaction. Therefore, $\Delta_{\text{r}}H^{\circ}$ for the decomposition reaction must be $+393.5 \text{ kJ mol}^{-1}$, that is, equal in size but opposite in sign to $\Delta_{\text{r}}H^{\circ}$ for the reaction written in the opposite direction. The law of conservation of energy requires this remarkable result. If the values of $\Delta_{\text{r}}H^{\circ}$ for the forward and the reverse reactions were not equal, but still opposite in sign, then perpetual-motion machines would be possible. (Despite numerous claims, such machines will always be an unattainable dream.) Thus, regardless of the difficulty of directly decomposing CO_2 into its elements, we can still write a thermochemical equation for it.

To repeat, if we know $\Delta_{\text{r}}H^{\circ}$ for a given reaction, then we also know $\Delta_{\text{r}}H^{\circ}$ for the reverse reaction; it has the same numerical value, but the opposite algebraic sign. This extremely useful fact makes thermochemical data available that would otherwise be impossible to measure.

Hess's law

Hess's law is a method for combining known thermochemical equations in a way that allows us to calculate $\Delta_{\text{r}}H^{\circ}$ for another reaction. This requires experience in other kinds of manipulations of equations. We will illustrate this using the combustion of carbon.

We can imagine two paths leading from 1 mol each of carbon and oxygen to 1 mol of carbon dioxide.

One-step path

Let C and O_2 react to give CO_2 directly.

Two-step path

Let C and O_2 react to give CO, and then let CO react with O_2 to give CO_2 .

Overall, the two-step path consumes 1 mol each of C and O_2 to make 1 mol of CO_2 , just like the one-step path. The initial and final states for the two routes to CO_2 are identical.

If $\Delta_{\text{r}}H^{\circ}$ is a state function dependent only on the initial and final states and independent of path, the values of $\Delta_{\text{r}}H^{\circ}$ for both routes should be identical. We can see that this is true simply by adding the equations for the two-step path and comparing the result with the equation for the one-step path.

Note that we can cancel CO(g) as it appears *identically* on opposite sides of the arrow in both steps 1 and 2. Such a cancellation is permitted only when both the formula and the physical state of a species are identical on opposite sides of the arrow. Therefore, the net thermochemical equation for the two-step process is shown.

The results, chemically and thermochemically, are identical for both routes to CO₂, demonstrating that $\Delta_r H^\ominus$ is a state function.

The above example is a manifestation of **Hess's law**, which states that *the overall enthalpy change for any chemical reaction is constant, regardless of how the reaction is carried out*.

The chief use of Hess's law is to calculate the enthalpy change for a reaction for which such data cannot be determined experimentally or are otherwise unavailable. Because this requires that we manipulate equations, let's restate the few rules that govern these operations.

Rules for manipulating thermochemical equations

1. When an equation is reversed — written in the opposite direction — the sign of $\Delta_r H^\ominus$ must also be reversed. To illustrate, the reverse of the equation:

is as follows.

2. Substances can be cancelled from both sides of an equation only if the substance is in an identical physical state.
3. If all the coefficients of an equation are multiplied or divided by the same factor, the value of $\Delta_r H^\ominus$ must likewise be multiplied or divided by that factor.

WORKED EXAMPLE 8.6

Using Hess's law

Carbon monoxide is often used in metallurgy to remove oxygen from metal oxides to give the free metal. The thermochemical equation for the reaction of CO with iron(III) oxide, Fe₂O₃, is as follows.

Use this equation and the equation for the combustion of CO:

to calculate the value of $\Delta_r H^\ominus$ for the following reaction.

Analysis

We cannot simply add the two given equations, because this will not produce the equation we want. We first have to manipulate these equations so that when we add them, we will obtain the target equation. To do this, it is best to consider reactants or products which appear in only *one* of the equations to be manipulated, as it is then obvious on which side of the equation they need to be.

Solution

We can manipulate the two given equations as follows.

Step 1: We begin with the iron atoms. The target equation must have 2Fe on the left, but the first equation in this worked example has 2Fe to the right of the arrow. To move it to the left, we must reverse the entire equation, remembering also to reverse the sign of $\Delta_r H^\ominus$. This puts Fe₂O₃ to the right of the arrow, which is where it has to be after we add our adjusted equations. After these manipulations, and reversing the sign of $\Delta_r H^\ominus$, we have the following.

Step 2: There must be $\frac{3}{2}\text{O}_2$ on the left, and we must be able to cancel 3CO and 3CO_2 when the equations are added. If we multiply the second equation in this worked example by 3, we will obtain the necessary coefficients. We must also multiply the value of $\Delta_r H^\circ$ for this equation by 3, because three times the amount of substances are now involved in the reaction. When we have done this, we have the following.

We now put our two equations together and find the answer:

Thus, the value of $\Delta_r H^\circ$ for the oxidation of 2 mol Fe(s) to 1 mol $\text{Fe}_2\text{O}_3\text{(s)}$ is $-822.3 \text{ kJ mol}^{-1}$. (The reaction is very exothermic.)

Is our answer reasonable?

There is no shortcut to check that we are right. But, for each step, double-check that you have followed the rules for manipulating thermochemical equations.

PRACTICE EXERCISE 8.6

Ethanol, $\text{C}_2\text{H}_5\text{OH}$, is made industrially by the reaction of water with ethene, C_2H_4 . Calculate the value of $\Delta_r H^\circ$ for the following reaction.

Use the following thermochemical equations.

Standard enthalpy of formation

Enormous databases of thermochemical equations have been compiled to allow the calculation of any enthalpy of reaction using Hess's law. The most frequently tabulated data are those for formation reactions.

The **standard enthalpy of formation** ($\Delta_f H^\circ$) of a substance is the enthalpy change when 1 mol of the substance is formed at 10^5 Pa and the specified temperature from its elements in their standard states. An element is in its standard state when it is in its most stable form and physical state (solid, liquid or gas) at 10^5 Pa and the specified temperature. Oxygen, for example, is in its standard state at a temperature of 25°C only as a gas at 10^5 Pa and only as O_2 molecules, not as O atoms or O_3 (ozone) molecules. Carbon must be in the form of graphite, not diamond, to be in its standard state at a temperature of 25°C because the graphite form of carbon is the most stable form at this temperature under standard conditions (10^5 Pa).

Standard enthalpies of formation for a variety of substances are given in table 8.3, and a more extensive table can be found in appendix A. Notice in particular that all values of $\Delta_f H^\circ$ for the elements in their standard states are 0; forming an element from itself, of course, would yield no change in enthalpy. For this reason, values of $\Delta_f H^\circ$ for the elements are generally not included in tables.

TABLE 8.3 Standard enthalpies of formation of selected substances at 25 °C

Substance	$\Delta_f H^\circ$ (kJ mol ⁻¹)	Substance	$\Delta_f H^\circ$ (kJ mol ⁻¹)	Substance	$\Delta_f H^\circ$ (kJ mol ⁻¹)
Ag(s)	0	CaCl ₂ (s)	-795.0	KCl(s)	-435.89

CaCO ₃ (s)	-1207				

It is important to remember the meaning of the subscript f in the symbol $\Delta_f H^\circ$. It is applied only when 1 mol of the substance is formed *from its elements in their standard states*. Consider, for example, the following four thermochemical equations and their corresponding values of ΔH° .

Only in the first equation is $\Delta_f H^\circ$ given the subscript f. It is the only reaction that satisfies both of the conditions specified for standard enthalpies of formation. The second equation shows the formation of 2 mol of water, rather than 1 mol. The third involves a compound as the reactant. The fourth involves the elements as atoms, which are not standard states for these elements. We can obtain $\Delta_r H^\circ$ for the second equation simply by multiplying the $\Delta_f H^\circ$ value of the first equation by 2.

WORKED EXAMPLE 8.7**Writing an equation for a standard enthalpy of formation**

Write the equation to which $\Delta_f H^\circ_{\text{H}_2\text{SO}_4(\text{l})}$ refers.

Analysis

The equation must show only 1 mol of the product. We begin with the formula of the product and take whatever fractions of moles of the elements are needed to make it. We also remember to include the physical states. Table 8.3 gives the value of $\Delta_f H^\circ$ for $\text{H}_2\text{SO}_4(\text{l})$ as $-811.32 \text{ kJ mol}^{-1}$ at 25.0°C .

Solution

The elements H and O both occur as diatomic molecules in the gaseous state under standard conditions, while S exists as a solid. The following fractions of moles supply exactly enough to make 1 mol of H_2SO_4 .

**Is our answer reasonable?**

The answer correctly shows only 1 mol of H_2SO_4 , and this governs the coefficients for the reactants. Therefore, if the equation is balanced, our answer must be correct.

PRACTICE EXERCISE 8.7

Write the thermochemical equations corresponding to the standard enthalpies of formation of each of the following.

- (a) solid urea, $\text{CO}(\text{NH}_2)_2(\text{s})$
- (b) liquid acetic acid, $\text{CH}_3\text{COOH}(\text{l})$
- (c) gaseous chloromethane, $\text{CH}_3\text{Cl}(\text{g})$

Standard enthalpies of formation are useful because they provide a convenient method for applying Hess's law without having to manipulate thermochemical equations. This is possible because, as we will demonstrate, $\Delta_r H^\circ$ for a reaction equals the sum of the standard enthalpies of formation of the products minus the sum of the standard enthalpies of formation of the reactants, with each $\Delta_f H^\circ$ value multiplied by the appropriate stoichiometric coefficient given by the thermochemical equation. In other words, for the reaction:

$$\Delta_r H^\circ = c\Delta_f H^\circ_C + d\Delta_f H^\circ_D - (a\Delta_f H^\circ_A + b\Delta_f H^\circ_B)$$

The expression above for $\Delta_r H^\circ$ is merely an alternative formulation of the Hess's law equation. It also applies to standard enthalpies of combustion, $\Delta_c H^\circ$ which we shall discuss soon. However, you need to ensure you use only either standard enthalpies of formation or standard enthalpies of combustion when calculating $\Delta_r H^\circ$ using the above equation — you must never mix them.

We will now demonstrate that the Hess's law equation works. Consider the reaction given by the following equation.

We wish to calculate the enthalpy of reaction using standard enthalpies of formation.

If we use the first method we learned, namely the manipulation of thermochemical equations, we would need to imagine a path from the reactant to the products that involves first decomposing $\text{SO}_3(\text{g})$ into its elements in their standard states and then recombining the elements to form the products. This path is shown in figure 8.15.

FIGURE 8.15

Enthalpy diagram for the reaction:

The path of the reaction in this diagram involves the reactant being decomposed into its elements in their standard states (upward blue arrow, $\Delta_r H_1^\ominus$), and then the elements being recombined to form the products (downward blue arrow, $\Delta_r H_2^\ominus$). The difference in the lengths of these two arrows is proportional to the net enthalpy change (upward red arrow $\Delta_r H^\ominus$).

The first step with the enthalpy change indicated as $\Delta_r H_1^\ominus$, corresponds to the decomposition of $\text{SO}_3(\text{g})$ into sulfur and oxygen. This is just the reverse of the equation for the formation of $\text{SO}_3(\text{g})$, so we can write the following.

We use a negative sign because, when we reverse a process, we change the sign of its $\Delta_r H$.

The second step in figure 8.15, with the enthalpy change indicated as $\Delta_r H_2^\ominus$, is the formation of $\text{SO}_2(\text{g})$ plus $\frac{1}{2}$ mol of $\text{O}_2(\text{g})$ from sulfur and oxygen. Therefore, we can write the following.

The sum of these two steps gives the net change we want. Therefore, the sum of $\Delta_r H_1^\ominus$ and $\Delta_r H_2^\ominus$ must equal the desired $\Delta_r H^\ominus$.

$$\Delta_r H^\ominus = \Delta_r H_1^\ominus + \Delta_r H_2^\ominus$$

The expression for $\Delta_r H^\ominus$ can be rewritten as shown.

$$\Delta_r H^\ominus = (\Delta_f H_{\text{SO}_2(\text{g})}^\ominus + \frac{1}{2}\Delta_f H_{\text{O}_2(\text{g})}^\ominus) + (-\Delta_f H_{\text{SO}_3(\text{g})}^\ominus)$$

The change of sign gives the following.

$$\Delta_r H^\ominus = (\Delta_f H_{\text{SO}_2(\text{g})}^\ominus + \frac{1}{2}\Delta_f H_{\text{O}_2(\text{g})}^\ominus) - (\Delta_f H_{\text{SO}_3(\text{g})}^\ominus)$$

Note the net result. $\Delta_r H^\ominus$ for the reaction equals the sum of the enthalpies of formation of the products minus the enthalpy of formation of the reactant, each multiplied by the appropriate coefficient. So, we could have obtained the identical result by using the Hess's law equation directly, instead of by the more laborious method of manipulating thermochemical equations.

WORKED EXAMPLE 8.8

Using Hess's law and standard enthalpies of formation

Some chefs keep baking soda, NaHCO_3 , handy to put out fat and oil fires. When thrown on the fire, baking soda partly smothers the fire and the heat decomposes it to give CO_2 , which further smothers the flame. The equation for the decomposition of NaHCO_3 is shown.

Use the data in table 8.3 to calculate $\Delta_r H^\circ$ for this reaction.

Analysis

The Hess's law equation is now our basic tool for calculating values of $\Delta_r H^\circ$. So we calculate the sum of the $\Delta_f H^\circ$ values for the products (table 8.3), each multiplied by the appropriate stoichiometric coefficient, and do the same for the reactants. Then we subtract the latter from the former to calculate $\Delta_r H^\circ$.

Solution

The Hess's law equation gives us the following.

$$\Delta_r H^\circ = (1 \times \Delta_f H^\circ_{\text{Na}_2\text{CO}_3(\text{s})}) + (1 \times \Delta_f H^\circ_{\text{H}_2\text{O}(\text{g})}) + (1 \times \Delta_f H^\circ_{\text{CO}_2(\text{g})}) - (2 \times \Delta_f H^\circ_{\text{NaHCO}_3(\text{s})})$$

We now use table 8.3 to find the values of $\Delta_f H^\circ$ for each substance in its given physical state.

$$\begin{aligned} \Delta_r H^\circ &= 1 \times (-1131 \text{ kJ mol}^{-1}) + 1 \times (-241.8 \text{ kJ mol}^{-1}) + 1 \times (-393.5 \text{ kJ mol}^{-1}) - 2 \times (-947.7 \text{ kJ mol}^{-1}) \\ &= (-1766 \text{ kJ mol}^{-1}) - (-1895 \text{ kJ mol}^{-1}) \\ &= +129 \text{ kJ mol}^{-1} \end{aligned}$$

Thus, under standard conditions, the reaction is endothermic by 129 kJ mol^{-1} . (Notice that we did not have to manipulate any equations.)

Is our answer reasonable?

It is difficult to know if the answer is reasonable without checking your calculations. Make sure you have multiplied values by the appropriate stoichiometric coefficients, subtracted values for reactants from those for products, and kept track of all signs.

PRACTICE EXERCISE 8.8

Use the data in table 8.3 to calculate $\Delta_r H^\circ$ for the following reactions.

- $\text{C}_2\text{H}_2(\text{g}) + 2\text{H}_2(\text{g}) \longrightarrow \text{C}_2\text{H}_6(\text{g})$
- $\text{CaO}(\text{s}) + 2\text{HCl}(\text{g}) \longrightarrow \text{CaCl}_2(\text{s}) + \text{H}_2\text{O}(\text{l})$

Standard enthalpy of combustion

The **standard enthalpy of combustion** ($\Delta_c H^\circ$) of a substance at temperature T is the enthalpy change when 1 mol of the substance is completely burned in pure oxygen gas, under standard conditions. All carbon in the substance is converted to carbon dioxide gas, and all hydrogen is converted to liquid water. *Combustion reactions are always exothermic*, so $\Delta_c H^\circ$ is always negative. The units of $\Delta_c H^\circ$ are usually kJ mol^{-1} .

WORKED EXAMPLE 8.9

Using standard enthalpies of combustion to obtain a standard enthalpy of formation

The thermochemical equation for the combustion of methane (CH_4) at 25.0°C is as follows.

Use this equation, together with the standard enthalpies of combustion of C and H_2 to determine the standard enthalpy of formation of $\text{CH}_4(\text{g})$ at 25.0°C .

Analysis

We need to write the balanced chemical equation corresponding to the definition of the standard enthalpy of formation of CH_4 . We then carry out a Hess's Law calculation utilising the thermochemical equations for the combustion of C, H, and CH_4 , manipulating these equations so that they sum to give the required enthalpy of formation equation. Notice that the chemical equations for the standard enthalpies of combustion of both C(s) and $\text{H}_2(\text{g})$ are identical to those for the standard enthalpies of formation of CO_2 and H_2O , respectively.

Solution

The balanced chemical equation corresponding to the enthalpy of formation of CH_4 will be the equation showing the formation of 1 mol of CH_4 from its elements in their standard states.

The three combustion reactions are as follows.

Data for reactions 2 and 3 were obtained from table 8.3. Inspection of these reactions shows that reaction 1 should be reversed to put CH_4 on the right-hand side of the arrow. Reaction 2 is correct as is, while reaction 3 requires multiplication by 2 to give the 2 mol of H_2 in the enthalpy of formation reaction. Carrying out these manipulations gives the following.

We can then cancel out the identical species on either side of the arrows as follows.

Adding what remains gives the required enthalpy of formation equation, and therefore adding the standard enthalpies of combustion will give us the standard enthalpy of formation of CH_4 .

Is our answer reasonable?

There is no obvious way of checking if our answer is reasonable. The best that can be done is to make sure that the combustion equations add up to give the required formation equation following manipulation. If they do, then the answer should be correct.

PRACTICE EXERCISE 8.9

A 9 kg cylinder of LPG (liquefied petroleum gas) can hold about 204 mol of propane, C_3H_8 , which has a standard enthalpy of combustion of $-2220 \text{ kJ mol}^{-1}$. How much heat could be produced by burning the propane gas contained in a full cylinder of LPG at atmospheric pressure?

Bond enthalpies

We opened this chapter by asking where the heat comes from when molecules such as hydrocarbons are burned. Chemical reactions generally involve the breaking of chemical bonds in the reactants and the making of chemical bonds in the products. The observed enthalpy change for any chemical reaction is predominantly a result of these bond-breaking and bond-making processes; energy is required to break a chemical bond and energy is liberated on formation of a chemical bond. Therefore, a knowledge of individual bond energies can provide us with a means to estimate the overall enthalpy change in a chemical reaction.

A **bond enthalpy** is the enthalpy change on breaking 1 mol of a particular chemical bond to give electrically neutral fragments in the gas phase at temperature T . You should appreciate that the bond energies we have encountered in previous chapters are associated with ΔU and refer to conditions of constant volume. Bond enthalpies are useful in rationalising chemical reactivity, as they provide a measure of the ease with which a particular chemical bond can be broken. Elemental nitrogen, for example, has a very low degree of reactivity, which is generally attributed to the very strong triple bond in N_2 . Reactions that involve breaking this bond in a single step simply do not occur. When N_2 does react, it is by a stepwise breaking of its three bonds, one at a time.

Bond enthalpies and Hess's law

The bond enthalpies of simple diatomic molecules such as H_2 , O_2 and Cl_2 are usually measured spectroscopically. An electric discharge is used to excite the molecules, causing them to emit electromagnetic radiation. An analysis of the spectrum of the emitted radiation allows calculation of the amount of energy needed to break the bond.

For more complex molecules, thermochemical data can be used to calculate bond enthalpies using Hess's law. We will use the standard enthalpy of formation of methane to illustrate how this is accomplished. However, before we can attempt such a calculation, we must first define a thermochemical quantity called the **atomisation enthalpy** ($\Delta_{\text{at}}H^\circ$). This is the enthalpy change that occurs on breaking all the chemical bonds in 1 mol of gaseous molecules homolytically (the bond breaks so as to give both atoms an equal number of electrons) to give gaseous atoms as products. For example, the equation for the atomisation of methane is as follows.

The enthalpy change for the process is $\Delta_{\text{at}}H^\circ$ under standard conditions. For this particular molecule, $\Delta_{\text{at}}H^\circ$ corresponds to the total enthalpy change on breaking all the C—H bonds in 1 mol of CH_4 under standard conditions; therefore, division of $\Delta_{\text{at}}H^\circ$ by 4 would give the average C—H bond enthalpy in methane.

Figure 8.16 shows how we can use the standard enthalpy of formation, Δ_fH° , to calculate the atomisation enthalpy. Across the bottom we have the chemical equation for the formation of 1 mol of CH_4 from its elements in their standard states. The enthalpy change for this reaction is $\Delta_fH^\circ_{\text{CH}_4(\text{g})}$. In this figure, we also can see an alternative three-step path that leads to $\text{CH}_4(\text{g})$. One step is the breaking of H—H bonds in the H_2 molecules to give 4 mol of gaseous hydrogen atoms; another is the vaporisation of carbon to give 1 mol of gaseous carbon atoms, and the third is the combination of the gaseous atoms to form 1 mol of gaseous CH_4 molecules. These changes are labelled 1, 2 and 3 in the figure.

FIGURE 8.16

Two paths (equations) for the formation of methane from its elements in their standard states. As described in the text, steps 1, 2 and 3 of the upper path are the formation of gaseous atoms of the elements and then the formation of the bonds in CH_4 . The lower path is the direct combination of the elements in their standard states to give CH_4 . Because ΔH is a state function, the sum of the enthalpy changes along the upper path must equal the enthalpy change for the lower path, which is Δ_fH° .

Since enthalpy is a state function, the net enthalpy change from one state to another is the same regardless of the path that we follow. This means that the sum of the enthalpy changes along the upper path must be the same as the enthalpy change along the lower path, which is Δ_fH° . Perhaps this can be seen more easily in Hess's law terms if we write the changes along the upper path in the form of thermochemical equations.

Steps 1 and 2 have enthalpy changes that are standard enthalpies of formation of gaseous atoms. Values for these quantities have been measured for many of the elements, and some are given in table 8.4. Step 3 is the opposite of atomisation, and its enthalpy change will, therefore, be the negative of $\Delta_{\text{at}}H^\circ$. (Recall that if we reverse a reaction, we change the sign of its ΔH .)

TABLE 8.4

Standard enthalpies of formation of selected gaseous atoms from the elements in their standard states at 25 °C

Atom	$\Delta_f H^\ominus$ (kJ mol ⁻¹) ^(a)	Atom	$\Delta_f H^\ominus$ (kJ mol ⁻¹) ^(a)
B	560	I	107.48
Be	324.3	Li	161.5
Br	112.38	N	472.68
C	716.67	O	249.17
Cl	121.47	P	332.2
F	79.14	S	276.98
H	217.89	Si	450

(a) All values are positive because formation of the gaseous atoms from the elements involves bond breaking, which requires an input of energy.

Notice that, by adding the first three equations, we get the equation for the formation of CH₄ from its elements in their standard states.

This means that adding the $\Delta_r H^\ominus$ values of the first three equations should give $\Delta_f H^\ominus$ for CH₄.

$$\Delta_r H_1^\ominus + \Delta_r H_2^\ominus + \Delta_r H_3^\ominus = \Delta_f H_{\text{CH}_4(\text{g})}^\ominus$$

We will substitute for $\Delta_r H_1^\ominus$, $\Delta_r H_2^\ominus$ and $\Delta_r H_3^\ominus$, and then solve for $\Delta_{\text{at}} H^\ominus$. First, we substitute for the $\Delta_r H^\ominus$ quantities.

$$4\Delta_f H_{\text{H}(\text{g})}^\ominus + \Delta_f H_{\text{C}(\text{g})}^\ominus + (-\Delta_{\text{at}} H^\ominus) = \Delta_f H_{\text{CH}_4(\text{g})}^\ominus$$

Next, we solve for $(-\Delta_{\text{at}} H^\ominus)$.

$$-\Delta_{\text{at}} H^\ominus = \Delta_f H_{\text{CH}_4(\text{g})}^\ominus - 4\Delta_f H_{\text{H}(\text{g})}^\ominus - \Delta_f H_{\text{C}(\text{g})}^\ominus$$

Changing signs and rearranging the right-hand side of the equation gives the following.

$$\Delta_{\text{at}} H^\ominus = 4\Delta_f H_{\text{H}(\text{g})}^\ominus + \Delta_f H_{\text{C}(\text{g})}^\ominus - \Delta_f H_{\text{CH}_4(\text{g})}^\ominus$$

Now all we need are the $\Delta_f H^\ominus$ values on the right-hand side. We obtain $\Delta_f H_{\text{H}(\text{g})}^\ominus$ and $\Delta_f H_{\text{C}(\text{g})}^\ominus$ from table 8.4 and $\Delta_f H_{\text{CH}_4(\text{g})}^\ominus$ from table 8.2 and round these to the nearest 0.1 kJ mol⁻¹.

$$\begin{aligned}
 \Delta_f H_{\text{H}(\text{g})}^\ominus &= +217.9 \text{ kJ mol}^{-1} \\
 \Delta_f H_{\text{C}(\text{g})}^\ominus &= +716.7 \text{ kJ mol}^{-1} \\
 \Delta_f H_{\text{CH}_4(\text{g})}^\ominus &= -74.8 \text{ kJ mol}^{-1}
 \end{aligned}$$

Substituting these values gives the following.

$$\Delta_{\text{at}} H^\ominus = 1663.1 \text{ kJ mol}^{-1}$$

Given that each CH₄ molecule contains four C—H bonds, division by 4 gives an estimate of the average C—H bond enthalpy in this molecule.

$$\begin{aligned}
 \text{bond enthalpy} &= \frac{1663.1 \text{ kJ mol}^{-1}}{4} \\
 &= 415.8 \text{ kilojoules per mole of CH bonds}
 \end{aligned}$$

This value is quite close to the one in table 8.5, which is an average of the C—H bond enthalpies in many different compounds. The other bond enthalpies in table 8.5 are also based on thermochemical data and were obtained by similar calculations.

TABLE 8.5 Some average bond enthalpies at 25 °C

Bond	Bond enthalpy (kJ mol ⁻¹)	Bond	Bond enthalpy (kJ mol ⁻¹)	Bond	Bond enthalpy (kJ mol ⁻¹)
C—C	348	C—F	484	H—H	436
C=C	612	C—Cl	338	H—F	565
C≡C	960	C—Br	276	H—Cl	431
C—H	412	C—I	238	H—Br	366
C—N	305			H—I	299
C=N	613			H—N	388
C≡N	890			H—O	463
C—O	360			H—S	338
C=O	743			H—Si	376

A remarkable thing about many covalent bond enthalpies is that they are very nearly the same in many different compounds. This suggests, for example, that a C—H bond is very nearly the same in CH₄ as it is in a large number of other compounds that contain this kind of bond. Also note that, in general, triple bond enthalpies (e.g. C≡C) are greater than double bond enthalpies (C=C), which in turn are greater than single bond enthalpies (C—C).

Because the bond enthalpy does not vary much from compound to compound, we can use tabulated bond enthalpies to estimate the enthalpies of formation of substances. We will illustrate this by calculating the standard enthalpy of formation of gaseous methanol, CH₃OH(g). The structural formula of methanol is shown.

To carry out this calculation, we set up two paths from the elements to the compound, as shown in figure 8.17. The lower path has an enthalpy change corresponding to $\Delta_f H^\circ_{\text{CH}_3\text{OH(g)}}$ while the upper path takes us to the gaseous elements and then through the enthalpy change when the bonds in the molecule are formed. This latter enthalpy can be calculated from the bond enthalpies in table 8.5. As before, the sum of the enthalpy changes along the upper path must be the same as the enthalpy change along the lower path, and this therefore allows us to determine $\Delta_f H^\circ_{\text{CH}_3\text{OH(g)}}$.

FIGURE 8.17

Two paths for the formation of methanol vapour from its elements in their standard states. The numbered steps are discussed in the text.

Steps 1, 2 and 3 in figure 8.17 involve the formation of the gaseous atoms from the elements, and their enthalpy changes are obtained from table 8.4.

$$\begin{aligned}\Delta_f H_1^\ominus &= \Delta_f H_{\text{C(g)}}^\ominus = 1 \times 716.7 \text{ kJ mol}^{-1} = 716.7 \text{ kJ mol}^{-1} \\ \Delta_f H_2^\ominus &= \Delta_f H_{\text{H(g)}}^\ominus = 4 \times 217.9 \text{ kJ mol}^{-1} = 871.6 \text{ kJ mol}^{-1} \\ \Delta_f H_3^\ominus &= \Delta_f H_{\text{O(g)}}^\ominus = 1 \times 716.7 \text{ kJ mol}^{-1} = 249.2 \text{ kJ mol}^{-1}\end{aligned}$$

The sum of these values, $+1837.5 \text{ kJ mol}^{-1}$, is the net $\Delta_r H^\ominus$ for the first three steps.

The formation of the CH_3OH molecule from the gaseous atoms is exothermic because energy is always released when atoms become joined by covalent bonds. In this molecule, we can count three C—H bonds, one C—O bond and one O—H bond. Their formation releases energy equal to the sum of their bond enthalpies, which we obtain from table 8.5.

Bond	Bond enthalpy (kJ mol^{-1})
3(C—H)	$3 \times 412 = 1236$
C—O	360
O—H	463

Adding these gives a total of 2059 kJ mol^{-1} . Therefore, $\Delta_r H_4^\ominus$ is $-2059 \text{ kJ mol}^{-1}$ because it involves bond formation, and so it is exothermic. Now we can calculate the total enthalpy change for the upper path.

$$\begin{aligned}\Delta_r H^\ominus &= (+1837.5 \text{ kJ mol}^{-1}) + (-2059 \text{ kJ mol}^{-1}) \\ &= -222 \text{ kJ mol}^{-1}\end{aligned}$$

The value just calculated should be equal to $\Delta_f H^\ominus$ for $\text{CH}_3\text{OH(g)}$. For comparison, the experimental value of $\Delta_f H^\ominus$ for $\text{CH}_3\text{OH(g)}$ is -201 kJ mol^{-1} . At first glance, the agreement does not seem very good, but on a relative basis the calculated value (-222 kJ) differs from the experimental value by only about 10%.

Lattice enthalpies and Hess's law

Hess's law can be used in combination with particular thermodynamic data to calculate the values of lattice enthalpies for ionic solids. We will illustrate this using NaCl(s) . Recall from the chapter on chemical bonding and molecular structure that the lattice enthalpy (or, as we called it then, lattice energy) of an ionic solid is the enthalpy change for the conversion of 1 mol of the ionic solid into its constituent gaseous ions. For NaCl(s) we would represent this process by the following equation.

We can break this process into smaller steps, each with an associated enthalpy change under standard conditions, as shown in figure 8.18.

FIGURE 8.18

An enthalpy diagram that can be used to calculate the lattice enthalpy of NaCl(s) .

The unknown lattice enthalpy, ΔH_6 , is shown at the bottom of figure 8.18. This is an endothermic process that requires energy to turn NaCl(s) into its gaseous ions $\text{Na}^+(\text{g})$ and $\text{Cl}^-(\text{g})$. From Hess's law, we know that $\Delta H_6 = \Delta H_1 + \Delta H_2 + \Delta H_3 + \Delta H_4 + \Delta H_5$. As each of ΔH_1 to ΔH_5 is a tabulated thermodynamic

quantity, we can calculate ΔH_6 , the lattice enthalpy of NaCl(s). Notice that we have defined ΔH_1 as the enthalpy change for the following process.

This is the reverse of the equation defining the enthalpy of formation of NaCl(s).

So we must use the *negative* of the enthalpy of formation of NaCl(s) in our calculations.

Therefore the calculation is as follows.

$$\begin{aligned}\Delta H_6 &= \Delta_f H^\circ_{\text{NaCl(s)}} + \Delta_f H^\circ_{\text{Na(g)}} + E_{\text{il Na(g)}} + \Delta_f H^\circ_{\text{Cl(g)}} + E_{\text{ea Cl(g)}} \\ &= 411 \text{ kJ mol}^{-1} + 107 \text{ kJ mol}^{-1} + 496 \text{ kJ mol}^{-1} + 121 \text{ kJ mol}^{-1} + (-349 \text{ kJ mol}^{-1}) \\ &= 786 \text{ kJ mol}^{-1}\end{aligned}$$

The lattice enthalpy of NaCl(s) is thus 786 kJ mol^{-1} .

This approach gives values close to the experimentally measured lattice enthalpies for ionic solids containing relatively small ions. As the sizes of the ions increase, the values become less accurate because the bonding in such solids is no longer purely ionic.

Enthalpy of vaporisation and enthalpy of fusion

The enthalpy of vaporisation, $\Delta_{\text{vap}} H$, is the enthalpy change that occurs on conversion of 1 mol of a liquid to its vapour at constant temperature (usually the normal boiling point). The enthalpy of fusion, $\Delta_{\text{fus}} H$, is the enthalpy change that accompanies the melting of 1 mol of solid to give its liquid form at constant temperature (usually the normal melting point). These concepts can be illustrated as follows. If we supply sufficient heat to pure liquid water in an open vessel at atmospheric pressure, the water will eventually reach a temperature of 100°C and boil. If we keep supplying heat, the volume of the liquid water will steadily diminish until it is all converted to water vapour. During this process, the temperature of the boiling water will remain at 100°C . In other words, pure water cannot be heated above 100°C at atmospheric pressure. So where does the added heat go if the temperature of the boiling water remains constant? It enables conversion of liquid water to water vapour. This process, at a temperature of 100°C , requires $40.66 \text{ kJ mol}^{-1}$, and this, under standard conditions, is known as the standard enthalpy of vaporisation, $\Delta_{\text{vap}} H^\circ$, of water. The thermochemical equation for this process is as follows.

The values of all enthalpies of vaporisation are positive. If the above value of $\Delta_{\text{vap}} H^\circ$ is divided by the molar mass of water, we find that it takes 2257 J to convert 1 g of water from the liquid to the gas phase. Compare this with the 4.21 J it takes to raise the temperature of 1 g of water from 99°C to 100°C , and you can see that it takes a *lot* of energy to go from the liquid phase to the gas phase.

Similarly, if we heat a sample of pure ice at atmospheric pressure it will remain at a temperature of 0°C , until it is completely melted; the temperature of the resulting water will then begin to rise. Thus, pure ice cannot be heated above 0°C at atmospheric pressure. The heat added to the ice at 0°C results in melting of the ice to give liquid water. This process, at a temperature of 0°C , requires 6.01 kJ mol^{-1} , and this, under standard conditions, is known as the standard enthalpy of fusion, $\Delta_{\text{fus}} H^\circ$, of water. The thermochemical equation for this process is as follows.

On a mass basis, it takes 334 J to convert 1 g of ice to 1 g of liquid water at 0°C , again, much greater than the 4.22 J required to heat 1 g of water from 0°C to 1°C . Like enthalpies of vaporisation, enthalpies of fusion have positive values.

CHEMICAL CONNECTIONS

The thermodynamics of steam burns

If you have ever been unfortunate enough to accidentally place any of your bare skin over a boiling jug of water, you will know the enormous pain that ensues. In fact, a steam burn causes more damage to the skin than does a burn caused by boiling water. And the reason why this is so can be found in thermodynamics.

Let's consider what happens when we heat up a sample of water at constant pressure. The energy required to increase the temperature of 1 g of water by 1 °C varies slightly with temperature, but we will use the a value of 4.18 J in the following calculations. So if we heat 1 kg of water, initially at 25 °C, it will absorb 4.18 kJ for every degree Celsius by which its temperature increases. By the time the water reaches 100 °C and starts boiling, it will have absorbed $(75 \times 4.18 \text{ kJ}) = 313.5 \text{ kJ}$. Water at this temperature contains a large amount of energy, and will, as you know, cause severe burns.

As we read above, for water at 100 °C, $\Delta_{\text{vap}} H^\circ = 40.66 \text{ kJ mol}^{-1}$. On a mass basis, this means that we would require 2257 kJ to convert our 1 kg of water completely to steam.

Let's now compare the numbers. It takes 313.5 kJ to heat 1 kg of water from 25 °C to 100 °C, and 2257 kJ, or around 7 times as much energy, to convert the boiling water to steam at 100 °C. You can see that steam therefore contains significantly more energy than does the same amount of liquid water at the same temperature. This energy will be rapidly released on contact with skin, and this will therefore lead to substantially more tissue damage than a burn caused by boiling water.

So be careful when making those cappuccinos!

8.5 Entropy

LEARNING OBJECTIVE 8.5 Explain the concept of entropy.

In the previous section, we defined enthalpy, showing how it is related to heat. We will now discuss the thermodynamic function entropy. While there are many different textbook definitions of entropy, here we will concentrate on its statistical basis.

Entropy and probability

Earlier in this chapter, you learned that, when a hot object is placed in contact with a colder one, heat will flow spontaneously from the hot object to the colder one. But why? Energy will be conserved no matter what the direction of the heat flow is. And if we believe that the lowering of energy is the driving force behind spontaneous change, we might wonder why the lowering of the energy of the hot object is favoured over the gain in energy that results for the colder one.

We will build a simple model to explain the direction of heat flow. Imagine that we have two objects made of molecules that have a low-energy ground state and a high-energy excited state. They will actually have many different excited states, but we will keep things simple and assume that the molecules can be either 'low energy' in the ground state or 'high energy' in just one excited state. We will use a blue dot to represent a low-energy cold molecule, and a red dot to represent a high-energy hot molecule. If we place three high-energy molecules in contact with three low-energy molecules, we initially have a configuration like the one shown on the left of figure 8.19, where the three molecules on the top represent an object that is 'hot' and the three on the bottom represent a 'cold' object. After the objects are placed in contact, energy can be transferred between molecules in the two objects. The sum of the energies of the two objects must be the same before and after contact. Because our molecules can have only high-energy (red) or low-energy (blue) states, the total number of red molecules must be the same before and after contact. Figure 8.19 presents all possible distributions of energy among the six molecules after the objects have been placed into contact.

We can see four possible outcomes; 0, 1, 2 or 3 units of energy can be transferred from the hot body to the colder one. Which is most likely to occur?

Notice that some of the outcomes can be produced in a number of different ways. For example, arrangements 2 to 10 represent ways energy can be distributed among the molecules after 1 unit of energy is transferred. The more ways that a state can be produced, the more likely it is to occur. We can use this fact to estimate the probability of the state occurring. There are 20 possible arrangements of energy

among the particles after the hot and cold objects are brought into contact. Let's assume that all of these arrangements are equally probable. The probability of a particular outcome can be calculated as follows.

FIGURE 8.19

Probability model of energy transfer

$$\text{probability of an outcome} = \frac{\text{number of ways the outcome can be produced}}{\text{total number of ways all outcomes can be produced}}$$

For example, there are nine arrangements that correspond to a transfer of 1 energy unit and 20 arrangements in all, so the probability that 1 energy unit will be transferred is $9/20 = 0.45$ or 45%.

Units of energy transferred	Number of equivalent ways to produce the energy transfer	Probability of energy transfer
0	1	$1/20 = 5\%$
1	9	$9/20 = 45\%$
2	9	$9/20 = 45\%$
3	1	$1/20 = 5\%$

In this model system, there is a 19/20 or 95% chance that some amount of energy transfer will occur. This agrees with our expectation that heat should flow spontaneously from the hot object to the colder one.

To show the importance of probability in determining the direction of heat flow, consider the possible outcomes if the initial state of the system was the same as the one shown in outcome 2 in figure 8.19. Here, the hot object contains two high-energy molecules and one low-energy molecule, while the cold object contains two low-energy molecules and one high-energy molecule. If we bring the objects into contact, the final possible states are still given by arrangements 1 to 20 in figure 8.19, although the labels across the bottom would need to change to accurately reflect which outcomes represent which energy transfers. Notice that, if the final state of the system is arrangement 1, in figure 8.19, then this formally involves the 'hot' object getting hotter and the 'cold' object getting colder, something alien to our everyday experience. However, as this is only one of 20 possible final arrangements, the probability of this occurring is only 5%. If we repeat this analysis with objects that contain more and more particles, the probability of energy transfer becomes so high that we can be quite certain that heat will flow from a hot object to a colder one. If we are dealing with hot and cold objects that contain moles of particles, the chance that no energy transfer would occur once they were placed into contact is negligible.

Although our model for heat transfer is very simple, it demonstrates the role of probability in determining the direction of a spontaneous process. *Spontaneous processes tend to proceed from states of low probability to states of higher probability.* The higher probability states are those that allow more options for distributing energy among the molecules, so we can also say that *spontaneous processes tend to disperse energy.*

Entropy and entropy change

Because statistical probability is so important in determining the outcome of chemical and physical events, thermodynamics defines a quantity, called entropy (S), that describes the number of equivalent ways

that energy can be distributed in the system. The larger the value of the entropy, the more energetically equivalent versions there are of the system and, therefore, the higher is its statistical probability. In mathematical terms:

$$S = k \ln W$$

where W is the number of ways of dispersing a fixed amount of energy in a system of fixed size, and k is the Boltzmann constant ($1.380\,65 \times 10^{-23} \text{ J K}^{-1}$).

In chemistry, we usually deal with systems that contain very large numbers of particles. It is usually impractical to count the number of ways that the particles can be arranged to produce a system with a particular energy, as we did in our simple model for energy flow between a hot and cold object. Fortunately, we do not need to do so. The entropy of a system can be related to experimental heat and temperature measurements. We can also recognise increases and decreases in entropy without explicitly counting the number of ways the system can be realised.

Like enthalpy, entropy is a state function. It depends only on the state of the system, so a change in entropy, ΔS , is independent of the path from start to finish. As with other thermodynamic quantities, ΔS is defined as ‘final minus initial’ or ‘products minus reactants’. Thus:

$$\Delta S = S_{\text{final}} - S_{\text{initial}}$$

For a chemical reaction:

$$\Delta_r S = S_{\text{products}} - S_{\text{reactants}}$$

The units of $\Delta_r S$ are $\text{J mol}^{-1} \text{ K}^{-1}$. As you can see, when S_{final} is larger than S_{initial} (or when S_{products} is larger than $S_{\text{reactants}}$), the value of ΔS is positive. A positive value for ΔS means an increase in the number of energy-equivalent ways the system can be produced; we have seen that this kind of change tends to be spontaneous (see figure 8.20). This leads to a general statement about entropy: *Any event that is accompanied by an increase in the entropy of an isolated system has a tendency to occur spontaneously.*

FIGURE 8.20

A positive value for $\Delta_r S$ means an increase in the number of ways energy can be distributed among a system's molecules. Consider the reaction $3A \rightarrow 3B$, where A molecules can take on energies that are multiples of 10 energy units, and B molecules can take on energies that are multiples of 5 units. Suppose that the total energy of the reacting mixture is 20 units. (a) There are two ways to distribute 20 units of energy among three molecules of A . (b) There are four ways to distribute 20 units of energy among three molecules of B . The entropy of B is higher than the entropy of A because there are more ways to distribute the same amount of energy in B than in A . The reaction $3A \rightarrow 3B$ is therefore spontaneous.

Factors that affect entropy

It is often possible to predict whether ΔS is positive or negative for a particular chemical reaction or physical change. This is because several factors influence the magnitude of the entropy in predictable ways.

Volume

For gases, the entropy increases with increasing volume, as illustrated in figure 8.21. At the left we see a gas confined to one side of a container, separated from a vacuum by a removable partition. Let's suppose the partition could be pulled away in an instant, as shown in figure 8.21b. Now we find a situation in which all the molecules of the gas are at one end of a larger container. There are many more possible ways that the total kinetic energy can be distributed if we give the molecules greater freedom of movement and spread them throughout the larger volume. That makes the configuration in figure 8.21b extremely unlikely. Therefore, the gas expands spontaneously to achieve a more probable (higher entropy) particle distribution (figure 8.21c).

FIGURE 8.21

The expansion of a gas into a vacuum: (a) a gas in a container separated from a vacuum by a partition and (b) the gas at the moment the partition is removed. (c) The gas expands to achieve a more probable (higher entropy) particle distribution.

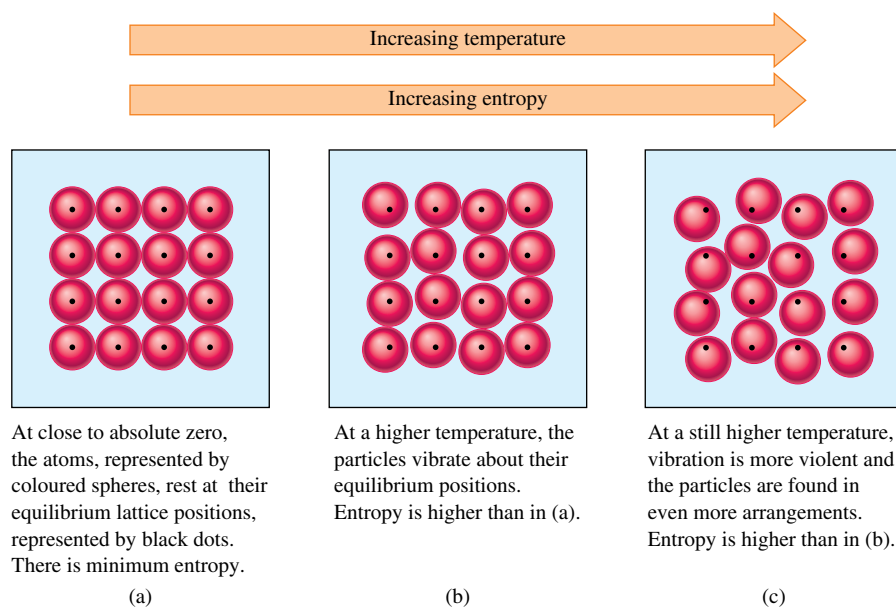

Temperature

Entropy is affected by temperature: the higher the temperature, the higher the entropy. For example, when a substance is a solid at temperatures close to absolute zero, its particles are essentially motionless. There is relatively little kinetic energy; with few ways to distribute kinetic energy among the particles, the entropy of the solid is relatively low (figure 8.22a). If some heat is added to the solid, the kinetic energy of the particles increases along with the temperature. This causes the particles to vibrate within the crystal, so at a particular moment (figure 8.22b) the particles are not found exactly at their equilibrium lattice sites. There is more kinetic energy and more freedom of movement, so there are more ways to distribute the energy among the molecules. At a still higher temperature, there is more kinetic energy and more possible ways to distribute it, so the solid has a still higher entropy (figure 8.22c).

FIGURE 8.22

Variation of entropy with temperature

Physical state

One of the major factors that affects the entropy of a system is its physical state, which is demonstrated in figure 8.23. Suppose that the contents of the three containers are ice, liquid water and water vapour at the same temperature. There is greater freedom of molecular movement in liquid water than in ice at the same temperature, and so there are more ways to distribute kinetic energy among the molecules of liquid water than there are in ice. Water vapour molecules are free to move through the entire container, so there are many more possible ways to distribute the kinetic energy among the gas molecules than there are in

liquid or solid water. In fact, any gas has such a large entropy compared with a liquid or solid that changes which produce gases from liquids or solids are almost always accompanied by increases in entropy.

FIGURE 8.23

Comparison of the entropies of the solid, liquid and gaseous states of water. The crystalline solid has a very low entropy. The liquid has a higher entropy because its molecules can move more freely and, therefore, there are more ways to distribute kinetic energy among them. All the molecules are still found at the bottom of the container. The gas has the highest entropy because the molecules are randomly distributed throughout the entire container, so there are many ways to distribute the kinetic energy.

For reactions that involve gases, we can simply calculate the change in the amount of gas, Δn_{gas} , on going from reactants to products.

$$\Delta n_{\text{gas}} = n_{\text{gaseous products}} - n_{\text{gaseous reactants}}$$

When Δn_{gas} is positive, so is the entropy change.

When a chemical reaction produces or consumes gases, the sign of its entropy change is usually easy to predict. This is because the entropy of a gas is so much larger than that of either a liquid or a solid. For example, the thermal decomposition of sodium bicarbonate produces two gases, CO_2 and H_2O .

Because the amount of gaseous products is larger than the amount of gaseous reactants, we can predict that $\Delta_r S$ for the reaction is positive. On the other hand, the following reaction, which can be used to remove sulfur dioxide, an atmospheric pollutant, from a gas mixture, has a negative entropy change as $\Delta n_{\text{gas}} < 0$.

Number of particles

For chemical reactions, another major factor that affects the sign of $\Delta_r S$ is an increase in the total number of molecules as the reaction proceeds. When more molecules are produced during a reaction, more ways of distributing the energy among the molecules are possible. *When all other things are equal, reactions that increase the number of particles in the system tend to have a positive entropy change*, as shown in figure 8.24. This is particularly true when the products are gases, owing to their inherently large, positive entropies.

FIGURE 8.24

Entropy is affected by the number of particles. Adding particles to a system increases the number of ways that energy can be distributed in the system so, with all other things being equal, a reaction that produces more particles has a positive value of $\Delta_r S$.

WORKED EXAMPLE 8.10**Predicting the sign of $\Delta_r S$**

Predict the algebraic sign of $\Delta_r S$ for the following reactions.

- (a) $2\text{NO}_2(\text{g}) \rightarrow \text{N}_2\text{O}_4(\text{g})$
 (b) $\text{C}_3\text{H}_8(\text{g}) + 5\text{O}_2(\text{g}) \rightarrow 3\text{CO}_2(\text{g}) + 4\text{H}_2\text{O}(\text{g})$
 (c) $\text{CO}(\text{g}) + \text{H}_2\text{O}(\text{g}) \rightarrow \text{H}_2(\text{g}) + \text{CO}_2(\text{g})$

Analysis

As we examine the equations, we look for changes in the number of molecules of gas and changes in the number of particles on going from reactants to products.

Solution

In reaction (a), we are forming one N_2O_4 molecule from the two NO_2 molecules. Since we are forming fewer molecules,

there are fewer ways to distribute energy among them, which means that the entropy must be decreasing. Therefore, $\Delta_r S$ must be negative.

For reaction (b), we can count the number of molecules on both sides. On the left of the equation we have six molecules; on the right there are seven. There are more ways to distribute kinetic energy among seven molecules than among six, so for reaction (b) we expect $\Delta_r S$ to be positive.

For reaction (c), there is the same number of molecules on both sides. We cannot therefore predict the sign of $\Delta_r S$ with confidence, but we expect its magnitude to be small.

PRACTICE EXERCISE 8.10

Predict the sign of the entropy change for the following phase changes.

- (a) the condensation of steam to liquid water
 (b) the sublimation of a solid

8.6 The second law of thermodynamics

LEARNING OBJECTIVE 8.6 State the second law of thermodynamics, and appreciate that any spontaneous process involves an increase in the entropy of the universe.

The **second law of thermodynamics** can help us appreciate the importance of entropy. This law states that, *whenever a spontaneous event takes place in our universe, the total entropy of the universe increases* ($\Delta S_{\text{total}} > 0$). Notice that the increase in entropy referred to here is for the total entropy of the universe (system plus surroundings), not just the system alone. This means that the entropy of a system can decrease, as long as there is a larger increase in the entropy of the surroundings so that the overall entropy change is positive. The consequence of this is that we cannot use the entropy change of the system alone as a criterion for spontaneity of a particular chemical reaction. Because everything that happens relies on spontaneous changes of some sort, the entropy of the universe is constantly increasing.

Now let's examine the entropy change for the universe more closely. As we have suggested, this quantity equals the sum of the entropy change for the system plus the entropy change for the surroundings.

$$\Delta S_{\text{total}} = \Delta S_{\text{system}} + \Delta S_{\text{surroundings}}$$

It can be shown that the entropy change for the surroundings is equal to the heat transferred to the surroundings *from* the system, $q_{\text{surroundings}}$, divided by the thermodynamic temperature, T , at which it is transferred.

$$\Delta S_{\text{surroundings}} = \frac{q_{\text{surroundings}}}{T}$$

The law of conservation of energy requires that the heat gained by the surroundings equals the negative of the heat lost by the system, so we can write the following.

$$q_{\text{surroundings}} = -q_{\text{system}}$$

In our study of the first law of thermodynamics we saw that, for changes at constant temperature and pressure, $q_{\text{system}} = \Delta H$ for the system. By substitution, therefore, we arrive at the following relationship.

$$\Delta S_{\text{surroundings}} = \frac{-\Delta H_{\text{system}}}{T}$$

Our expression for total entropy change therefore becomes the following.

$$\Delta S_{\text{total}} = \Delta S_{\text{system}} - \frac{\Delta H_{\text{system}}}{T}$$

Multiplying through by T gives:

$$T\Delta S_{\text{total}} = T\Delta S_{\text{system}} - \Delta H_{\text{system}}$$

or:

$$T\Delta S_{\text{total}} = -(\Delta H_{\text{system}} - T\Delta S_{\text{system}})$$

We stated above that ΔS_{total} is > 0 for a spontaneous process, and, because T is always positive, the left-hand side of this equation will be positive for a spontaneous process. To make the right-hand side of this equation positive requires that the quantity in parentheses is negative. In other words, for a spontaneous process:

$$\Delta H_{\text{system}} - T\Delta S_{\text{system}} < 0$$

We now formally define the thermodynamic function Gibbs energy (G) as follows.

$$G = H - TS$$

For changes at constant T and p , we can therefore write the equation below where $\Delta G = G_{\text{final}} - G_{\text{initial}}$.

$$\Delta G = \Delta H - T\Delta S$$

We showed above that $\Delta H_{\text{system}} - T\Delta S_{\text{system}} < 0$ for a spontaneous process. As $\Delta G = \Delta H - T\Delta S$, it follows from this that, if $\Delta G < 0$ for a chemical process in a system at constant T and p , that process will be spontaneous. We will investigate this concept further in section 8.8.

8.7 The third law of thermodynamics

LEARNING OBJECTIVE 8.7 State the third law of thermodynamics and calculate entropies of reaction.

Earlier we described how the entropy of a substance depends on temperature, and we noted that at temperatures approaching absolute zero the order within a crystal increases and the entropy decreases. The **third law of thermodynamics** goes one step further by stating that, *at absolute zero, the entropy of a perfectly ordered pure crystalline substance is zero*.

$$S = 0 \quad \text{at} \quad T = 0 \text{ K}$$

Because we know the point at which entropy has a value of 0, it is possible by *experimental measurement* and calculation to determine the entropy of a substance at temperatures above 0 K. If the entropy of 1 mol of a substance is determined under standard conditions, we call it the **standard entropy (S°)**. Table 8.6 lists the standard entropies of a number of substances at 25 °C.

TABLE 8.6 Standard entropies of selected substances at 25 °C

Substance	S° (J mol ⁻¹ K ⁻¹)	Substance	S° (J mol ⁻¹ K ⁻¹)	Substance	S° (J mol ⁻¹ K ⁻¹)
Ag(s)	42.55	CaCl ₂ (s)	114	K ₂ SO ₄ (s)	176
AgCl(s)	96.2	CaO(s)	40	N ₂ (g)	191.5
Al(s)	28.3	Ca(OH) ₂ (s)	76.1	NH ₃ (g)	192.5
Al ₂ O ₃ (s)	51.00	CaSO ₄ (s)	107	NH ₄ Cl(s)	94.6
C(s, diamond)	2.4	CaSO ₄ · $\frac{1}{2}$ H ₂ O(s)	131	NO(g)	210.6
C(s, graphite)	5.69	CaSO ₄ · 2H ₂ O(s)	194.0	NO ₂ (g)	240.5
CH ₃ Cl(g)	234.2	Cl ₂ (g)	223.0	N ₂ O(g)	220.0

CH ₃ OH(l)	126.8	Fe(s)	27	N ₂ O ₄ (g)	304
CH ₃ COOH(l)	160	Fe ₂ O ₃ (s)	90.0	Na(s)	51.0

CO(g)	197.9	Hg(l)	76.1	PbO(s)	67.8
CO ₂ (g)	213.6	Hg(g)	175	S(s, rhombic)	31.9
CO(NH ₂) ₂ (s)	104.6	K(s)	64.18	SO ₂ (g)	248.5
Ca(s)	41.4	KCl(s)	82.59	SO ₃ (g)	256.2
CaCO ₃ (s)	92.9				

Once we have the entropies of a variety of substances, we can calculate the **standard entropy of reaction** ($\Delta_r S^\circ$) for chemical reactions in much the same way as we calculated $\Delta_r H^\circ$ earlier. For the reaction:

$$aA + bB \rightarrow cC + dD$$

$$\Delta_r S^\circ = cS_C^\circ + dS_D^\circ - (aS_A^\circ + bS_B^\circ)$$

If the reaction we are working with corresponds to the formation of 1 mol of a compound from its elements, the $\Delta_r S^\circ$ that we calculate can be referred to as the **standard entropy of formation** ($\Delta_f S^\circ$). Values of $\Delta_r S^\circ$ are not tabulated, however; if we need them for some purpose, we can calculate them from tabulated values of S° .

WORKED EXAMPLE 8.11

Calculating $\Delta_r S^\circ$ from standard entropies

Urea (a compound found in urine) is manufactured commercially from CO₂ and NH₃. One of its uses is as a fertiliser, where it reacts slowly with water in the soil to produce ammonia and carbon dioxide.

The ammonia provides nitrogen for growing plants. What is the standard entropy of reaction when 1 mol of urea reacts with water at 298 K?

Analysis

We can calculate the standard entropy of reaction for the reaction using the standard entropies, S° , of each reactant and product. The data we need can be found in table 8.6 and are listed below.

Substance	S° (J mol ⁻¹ K ⁻¹)
CO(NH ₂) ₂ (s)	104.6
H ₂ O(l)	69.96
CO ₂ (g)	213.6
NH ₃ (g)	192.5

Solution

The standard entropy of reaction can be calculated from the following equation.

$$\begin{aligned}\Delta S^\circ &= \left(S^\circ_{\text{CO}_2(\text{g})} + 2S^\circ_{\text{NH}_3(\text{g})} \right) - \left(S^\circ_{\text{CO}_2(\text{NH}_2)_2(\text{s})} + S^\circ_{\text{H}_2\text{O}(\text{l})} \right) \\ &= (1 \times 213.6 \text{ J mol}^{-1} \text{ K}^{-1}) + (2 \times 192.5 \text{ J mol}^{-1} \text{ K}^{-1}) - [(1 \times 104.6 \text{ J mol}^{-1} \text{ K}^{-1}) + (1 \times 69.96 \text{ J mol}^{-1} \text{ K}^{-1})] \\ &= (598.6 \text{ J mol}^{-1} \text{ K}^{-1}) - (174.6 \text{ J mol}^{-1} \text{ K}^{-1}) \\ &= 424.0 \text{ J mol}^{-1} \text{ K}^{-1}\end{aligned}$$

Thus, the standard entropy of reaction for this reaction is +424.0 J mol⁻¹ K⁻¹.

Is our answer reasonable?

In the reaction, gases are formed from liquid reactants. Since gases have much larger entropies than liquids, we expect $\Delta_r S^\circ$ to be positive, which agrees with our answer.

PRACTICE EXERCISE 8.11

Calculate the standard entropy of reaction, $\Delta_r S^\circ$, for each of the following reactions.

- (a) $\text{CaCO}_3(\text{s}) \rightarrow \text{CaO}(\text{s}) + \text{CO}_2(\text{g})$
- (b) $\text{C}_2\text{H}_2(\text{g}) + 2\text{H}_2(\text{g}) \rightarrow \text{C}_2\text{H}_6(\text{g})$

As there is no standard temperature, the temperature is often specified as a subscript on the symbol for standard thermodynamic quantities: for example, $\Delta S^\circ_{298 \text{ K}}$. As you will see later, there are times when it is desirable to indicate the temperature explicitly.

CHEMICAL CONNECTIONS

Air-conditioning and the second law of thermodynamics

Regardless of where you live, Queensland, Queenstown or beyond, chances are it will be either too hot or too cold inside your house at some time of the year. While it is easy to heat the interior of a house using central heating or a radiant heater, cooling it presents us with a more difficult problem — somehow we need to get rid of unwanted heat, and this is difficult when it's hotter outside than inside. Of course, we all know that the interior of a house can be cooled by using an air conditioner (figure 8.25), but let's stop and think about what actually happens when we do this.

Let's assume that it's a scorching 45 °C outside while the inside temperature of our house is a tropical 35 °C. The normal direction of heat flow will be from the outside to the inside; if we were to open all the windows, the inside temperature would increase and eventually become the same as that outside, a spontaneous process precisely in accord with what we have learned in this chapter. The reverse process, heat flowing from the 35 °C interior of the house (the system) to the 45 °C exterior (the surroundings), is nonspontaneous, and we must therefore use an air conditioner to drive this. In terms of entropy,

we can show, from the equation $\Delta S = \frac{\Delta H}{T}$, that adding heat to, or removing heat from, a cool system gives a greater entropy change than the analogous process with a hotter system. This means that cooling the house will lower the entropy of the inside by more than it will increase the entropy of the outside; it may therefore appear that the overall process leads to a *decrease* in entropy of the universe, violating the second law of thermodynamics. Of course, this is not the case, as we have neglected to include the air conditioner itself in this discussion. It uses electrical energy to do work by compressing and expanding

a fluid that carries the heat from the inside to the outside. In so doing, the air conditioner itself provides an entropy contribution, and the sum of this and the entropy increase of the surroundings is greater than the entropy decrease of the system, thereby ensuring that the overall entropy of the universe increases and that the second law of thermodynamics remains intact.

Heat pumps operate on the same principle but in the opposite direction, taking heat from the chilly outside and delivering it to the warmer inside, and the same arguments concerning the total entropy change apply.

FIGURE 8.25

Air conditioners use electrical energy to compress and expand a fluid that carries heat from the inside of a building to the outside. In doing so, the air conditioner provides an entropy contribution to the system, and the overall entropy of the universe increases.

8.8 Gibbs energy and reaction spontaneity

LEARNING OBJECTIVE 8.8 Determine the spontaneity of a process using the change in Gibbs energy.

Now that we have defined enthalpy and entropy, we are ready to look in detail at Gibbs energy. In section 8.2, we stated that a process is spontaneous if ΔG for the process is negative at constant temperature and pressure. We will begin by looking at the factors that determine the sign of ΔG .

The sign of ΔG

We might expect, as did a number of nineteenth-century scientists, that any chemical process that evolves heat will be spontaneous, as it will lead to a lowering in energy. However, we can show that this is not the case by considering the melting of ice under standard conditions at 25.0 °C, a process that is spontaneous. ΔH° for this process is approximately 6 kJ mol⁻¹, meaning it is endothermic. Given $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$ and remembering that ΔG° must be negative for the process to be spontaneous under standard conditions, we can see that, in this case, if ΔH° is positive, the product of T and ΔS° must be *more* positive to ensure that ΔG° is negative. As T is always positive, ΔS° *must* be positive for the melting of ice to be spontaneous. (We have seen in section 8.5 that liquids generally have larger entropies than solids, so we would expect ΔS° for the melting of ice to be positive.) You can see from this example that the signs of ΔH° and ΔS° are crucial in determining the spontaneity of physical and chemical processes under standard conditions.

The combustion of octane, like all combustion reactions, is exothermic. There is also a large increase in entropy since the number of particles in the system increases. For this change, ΔH is negative and ΔS is positive, both of which favour spontaneity.

$$\begin{aligned}\Delta H &\text{ is negative } (-\text{ve}) \\ \Delta S &\text{ is positive } (+\text{ve}) \\ \Delta G &= \Delta H - T\Delta S \\ &= (-\text{ve}) - (+\text{ve}) \\ &= (-\text{ve})\end{aligned}$$

Notice that, regardless of the thermodynamic temperature, which must have a positive value, ΔG will be negative. This means that such a change must be spontaneous at any temperature. In fact, once started, fires continue to consume all available fuel or oxygen because combustion reactions are always spontaneous (see figure 8.26a).

FIGURE 8.26

Process spontaneity can be predicted if ΔH , ΔS and T are known. (a) When ΔH is negative and ΔS is positive, as in any combustion reaction, the reaction is spontaneous at any temperature. (b) When ΔH is positive and ΔS is negative, the process is not spontaneous. Wood does not spontaneously re-form from ash, carbon dioxide and water. (c) When ΔH and ΔS have the same sign, temperature determines whether the process is spontaneous. Water spontaneously becomes ice below 0°C , and ice spontaneously melts into liquid water above 0°C .

When a change is endothermic and is accompanied by a lowering of the entropy, both factors work against spontaneity.

$$\begin{aligned}\Delta H &\text{ is positive } (+\text{ve}) \\ \Delta S &\text{ is negative } (-\text{ve}) \\ \Delta G &= \Delta H - T\Delta S \\ &= (+\text{ve}) - (-\text{ve}) \\ &= (+\text{ve})\end{aligned}$$

Now, no matter what the temperature is, ΔG will be positive and the change must be nonspontaneous. An example would be carbon dioxide and water recombining to form wood and oxygen after a fire. If you saw such a thing happen in a film, experience would tell you that the film was being played backwards.

When ΔH and ΔS have the same algebraic sign, the temperature becomes the determining factor in controlling spontaneity. If ΔH and ΔS are both positive:

$$\begin{aligned}\Delta G &= (+\text{ve}) - (+\text{ve}) \\ &= (+\text{ve}) \text{ or } (-\text{ve})\end{aligned}$$

ΔG is the difference between two positive quantities, ΔH and $T\Delta S$. This difference will be negative only if the term $T\Delta S$ is larger than ΔH . This will be true only when the temperature is high. (*Note:* We assume that the values of ΔH and ΔS change negligibly with change in temperature.) In other words, when ΔH and ΔS are both positive, the change will be spontaneous at high temperature but not at low temperature. An example we have already seen is the melting of ice.

This is an endothermic change that is accompanied by an increase in entropy. We know that at high temperature (above 0°C) melting is spontaneous, but at low temperature (below 0°C) it is not.

For similar reasons, when ΔH and ΔS are both negative, ΔG will be negative (and the change spontaneous) only at low temperature.

$$\begin{aligned}\Delta G &= (-ve) - (-ve) \\ &= (-ve) \text{ or } (+ve)\end{aligned}$$

Only when the negative value of ΔH is larger than the negative value of $T\Delta S$ will ΔG be negative. Such a change is spontaneous only at low temperature. An example is the freezing of water.

This is an exothermic change that is accompanied by a decrease in entropy; it is spontaneous only at low temperatures (below 0°C).

Figure 8.27 summarises the effects of the signs of ΔH and ΔS on that of ΔG , and hence on the spontaneity of physical and chemical processes. It should be noted at this point that processes having positive values of ΔG are sometimes termed **endergonic**, while those having negative values are called **exergonic**.

FIGURE 8.27

Summary of the effects of the signs of ΔH and ΔS on spontaneity

		ΔH	
		+ve	-ve
ΔS	+ve	spontaneous at high temperatures nonspontaneous at low temperatures	spontaneous at all temperatures
	-ve	nonspontaneous at all temperatures	nonspontaneous at high temperatures spontaneous at low temperatures

Standard Gibbs energy change

When ΔG is determined at 10^5 Pa, we call it the **standard Gibbs energy change ($\Delta_r G^\circ$)**. There are several ways of obtaining $\Delta_r G^\circ$ for a reaction. One is to calculate $\Delta_r G^\circ$ from $\Delta_r H^\circ$ and $\Delta_r S^\circ$.

$$\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ$$

WORKED EXAMPLE 8.12

Calculating $\Delta_r G^\circ$ from $\Delta_r H^\circ$ and $\Delta_r S^\circ$

Calculate $\Delta_r G^\circ$ for the reaction of urea with water at 25.0°C from values of $\Delta_r H^\circ$ and $\Delta_r S^\circ$ at this temperature.

Analysis

We can calculate $\Delta_r G^\circ$ using the equation.

$$\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ$$

The data needed to calculate $\Delta_r H^\circ$ come from table 8.3 and require a Hess's law calculation. To obtain $\Delta_r S^\circ$, we would normally need to do a similar calculation with data from table 8.6. However, we already calculated this in worked example 8.11.

Solution

First we calculate $\Delta_r H^\circ$ from data in table 8.3.

$$\begin{aligned}\Delta_r H^\circ &= (\Delta_f H^\circ_{\text{CO}_2(\text{g})} + 2\Delta_f H^\circ_{\text{NH}_3(\text{g})}) - (\Delta_f H^\circ_{\text{CO(NH}_2)_2(\text{s})} + \Delta_f H^\circ_{\text{H}_2\text{O(l)}}) \\ &= [1 \times (-395.5 \text{ kJ mol}^{-1}) + 2 \times (-46.19 \text{ kJ mol}^{-1})] - [1 \times (-333.19 \text{ kJ mol}^{-1}) + 1 \times (-285.9 \text{ kJ mol}^{-1})] \\ &= (-485.9 \text{ kJ mol}^{-1}) - (-619.1 \text{ kJ mol}^{-1}) \\ &= +132.2 \text{ kJ mol}^{-1}\end{aligned}$$

In worked example 8.11, we found $\Delta_r S^\circ$ to be $+424.0 \text{ J mol}^{-1} \text{ K}^{-1}$. To calculate $\Delta_r G^\circ$, we need to express 25.0°C as a thermodynamic temperature by adding 273 K. Thus, $25.0^\circ\text{C} = 298 \text{ K}$. We must be careful to express $\Delta_r H^\circ$ and $T\Delta_r S^\circ$ in the same energy units, so we change the units of the enthalpy change to J mol^{-1} to give $\Delta_r H^\circ = +133.2 \times 10^3 \text{ J mol}^{-1}$. Substituting into the equation for $\Delta_r G^\circ$:

$$\begin{aligned}\Delta_r G^\circ &= +133.2 \times 10^3 \text{ J mol}^{-1} - [298 \text{ K} \times (+424.0 \text{ J mol}^{-1} \text{ K}^{-1})] \\ &= +133.2 \times 10^3 \text{ J mol}^{-1} - 126 \times 10^3 \text{ J mol}^{-1} \\ &= +7.2 \times 10^3 \text{ J mol}^{-1} = 7.2 \text{ kJ mol}^{-1}\end{aligned}$$

Therefore, for this reaction, $\Delta_r G^\circ = +7.2 \text{ kJ mol}^{-1}$.

Is our answer reasonable?

There's not much we can do to check if the answer is reasonable. We just need to be sure we've done the calculations correctly and that the units are consistent. Note that, instead of changing the units of $\Delta_r H^\circ$ to J mol^{-1} , we could also have changed the units of ΔS° to $\text{kJ mol}^{-1} \text{K}^{-1}$ by dividing by 10^3 . The most common mistake made in calculations like this is forgetting to change the units of either $\Delta_r H^\circ$ or $\Delta_r S^\circ$ to ensure the units are consistent.

PRACTICE EXERCISE 8.12

Use the data in tables 8.3 and 8.6 to calculate $\Delta_r G^\circ$ for the formation of iron(III) oxide (the iron oxide in rust). The equation for the reaction is as follows.

Earlier in this chapter you learned that it is useful to have tabulated standard enthalpies of formation, $\Delta_f H^\circ$, because they can be used with Hess's law to calculate $\Delta_r H^\circ$ for many different reactions. Standard Gibbs energies of formation, $\Delta_f G^\circ$, can be used in similar calculations to obtain $\Delta_r G^\circ$. For the reaction:

$$\Delta_r G^\circ = c\Delta_f G_C^\circ + d\Delta_f G_D^\circ - (a\Delta_f G_A^\circ + b\Delta_f G_B^\circ)$$

The $\Delta_f G^\circ$ values for some typical substances are found in table 8.7. Worked example 8.13 shows how we can use them to calculate $\Delta_r G^\circ$ for a reaction.

TABLE 8.7 Standard Gibbs energies of formation of selected substances at 25 °C

Substance	$\Delta_f G^\circ$ (kJ mol ⁻¹)	Substance	$\Delta_f G^\circ$ (kJ mol ⁻¹)	Substance	$\Delta_f G^\circ$ (kJ mol ⁻¹)

WORKED EXAMPLE 8.13

Calculating from $\Delta_f G^\circ$

Ethanol, C₂H₅OH, is made from grain by fermentation and can be added to petrol to produce a product called gasohol or E10. What is $\Delta_r G^\circ$ of the combustion of liquid ethanol to give CO₂(g) and H₂O(g)?

Analysis

We can calculate the standard Gibbs energy change for the reaction using the following equation.

$$\Delta_r G^\circ = c\Delta_f G_C^\circ + d\Delta_f G_D^\circ - (a\Delta_f G_A^\circ + b\Delta_f G_B^\circ)$$

We will need the standard Gibbs energy changes of formation for each reactant and product. These data can be found in table 8.7.

Solution

First, we need the balanced equation for the following reaction.

$$\Delta_r G^\circ = (2\Delta_f G_{\text{CO}_2(\text{g})}^\circ + 3\Delta_f G_{\text{H}_2\text{O}(\text{g})}^\circ) - (\Delta_f G_{\text{C}_2\text{H}_5\text{OH}(\text{l})}^\circ + 3\Delta_f G_{\text{O}_2(\text{g})}^\circ)$$

As with $\Delta_f H^\circ$, $\Delta_f G^\circ$ for any element in its standard state is 0. Therefore, using the data from table 8.7:

$$\begin{aligned}\Delta_r G^\circ &= [2 \times (-394.4) \text{ kJ mol}^{-1} + (-228.6) \text{ kJ mol}^{-1}] - [1 \times (-174.8) \text{ kJ mol}^{-1} + 3 \times 0 \text{ kJ mol}^{-1}] \\ &= (-1474.6 \text{ kJ mol}^{-1}) - (-174.8 \text{ kJ mol}^{-1}) \\ &= -1299.8 \text{ kJ mol}^{-1}\end{aligned}$$

The standard Gibbs energy change for the reaction is $-1299.8 \text{ kJ mol}^{-1}$.

Is our answer reasonable?

There's no quick way to estimate the answer, although we could calculate $\Delta_r G^\circ$ from $\Delta_r H^\circ$ and $\Delta_r S^\circ$ following the method used in worked example 8.12 for a thorough check. We know that ethanol is quite flammable under standard conditions, so we expect this combustion reaction to proceed spontaneously. The large negative standard Gibbs energy change therefore makes sense.

PRACTICE EXERCISE 8.13

Calculate $\Delta_r G^\circ$ for the following reactions using the data in table 8.7.

Gibbs energy and work

One of the chief uses of spontaneous chemical reactions is the production of useful work. For example, fuels are burned in petrol and diesel engines to power cars and heavy machinery, and chemical reactions in batteries power everything from mobile phones to laptop computers.

When chemical reactions occur, however, their energy is not always harnessed to do work. For instance, if petrol is burned in an open dish, the energy evolved is lost entirely as heat and no useful work is accomplished. Engineers, therefore, seek ways to capture as much energy as possible in the form of work. One of their primary goals is to maximise the efficiency with which chemical energy is converted to work and to minimise the amount of energy transferred unproductively to the surroundings as heat.

The maximum conversion of chemical energy to work occurs if a reaction is carried out under conditions that are said to be thermodynamically reversible. A process is defined as thermodynamically reversible if its driving force is opposed by another force that is just slightly weaker, so that the slightest increase in the opposing force will cause the direction of the change to be reversed. An example of a nearly reversible process is illustrated in figure 8.28, where we have a compressed gas in a cylinder pushing against a piston that is held in place by liquid water above it. If a water molecule evaporates, the external pressure drops slightly and the gas can expand just a bit. Gradually, as one water molecule after another evaporates, the gas inside the cylinder slowly expands. At any time, however, the process can be reversed by the condensation of a water molecule.

FIGURE 8.28

A reversible expansion of a gas. As water molecules evaporate one at a time, the external pressure gradually decreases and the gas slowly expands. The process would be reversed if a molecule of water were to condense into the liquid. The ability of the expansion to be reversed by the slightest increase in the opposing pressure is what makes this a reversible process.

As we will see in the chapter on chemical equilibrium, thermodynamic reversibility implies that the system is very close to equilibrium (a state in which there is no driving force for chemical or physical change) at every stage of a process. While we sometimes say that a reaction such as dissociation of a weak acid in water (see the chapter on acids and bases) is ‘reversible’, simply because it runs in both the forward and reverse directions, we cannot say the reaction is *thermodynamically reversible* unless the concentrations are only infinitesimally different from their equilibrium values as the reaction occurs.

Although we could obtain the maximum work by carrying out a change reversibly, a thermodynamically reversible process requires so many steps that it proceeds at an extremely slow speed. If the work cannot be done at a reasonable rate, it is of little value to us. Our goal, then, is to approach thermodynamic reversibility for maximum efficiency, but to carry out the change at a pace that will deliver work at acceptable rates. Note that, irrespective of the rate that we carry out the process shown in figure 8.28, we will always lose some energy as heat, due to the friction between the piston and the cylinder. In fact, it is impossible to extract all the energy from any chemical or physical process as work, and therefore there is no such thing as a truly thermodynamically reversible process.

The relationship of useful work to thermodynamic reversibility was illustrated earlier (section 8.3) in our discussion of the discharge of a car battery. Recall that, when the battery is short-circuited with a heavy spanner, no work is done and all the energy appears as heat. In this case, there is nothing opposing the discharge, and it occurs in the most thermodynamically irreversible manner possible. However, when the current is passed through a small electric motor, the motor itself offers resistance to the passage of the electricity and the discharge takes place slowly. In this instance, the discharge occurs in a more nearly thermodynamically reversible manner because of the opposition provided by the motor, and a relatively large amount of the available energy appears in the form of work accomplished by the motor.

The preceding discussion leads naturally to the question, ‘Is there a limit to the amount of the available energy in a reaction that can be harnessed as useful (i.e. non- pV) work?’ The answer to this question is yes. The limit is the Gibbs energy for the reaction.

The maximum amount of energy produced by a chemical reaction that can be *theoretically* harnessed as non- pV work is equal to $\Delta_r G$. This is the energy that need not be lost to the surroundings as heat and is, therefore, available to be used for work. Thus, by determining the value of $\Delta_r G$, we can find out whether a given reaction will be an effective source of useful energy. Also, by comparing the actual amount of

non- pV work derived from a given system with the $\Delta_r G$ values for the reactions involved, we can measure the efficiency of the system.

WORKED EXAMPLE 8.14

Calculating maximum non- pV work

Calculate the maximum non- pV work available from the oxidation of 1 mol of octane, $\text{C}_8\text{H}_{18}(\text{l})$, by oxygen to give $\text{CO}_2(\text{g})$ and $\text{H}_2\text{O}(\text{l})$ at 25°C and 10^5 Pa .

Analysis

The maximum non- pV work is equal to $\Delta_r G$ for the reaction. Standard thermodynamic conditions are specified, so we need to calculate $\Delta_r G^\circ$.

Solution

First we need a balanced equation for the reaction. For the combustion of 1 mol of C_8H_{18} we have the following.

$$\Delta_r G^\circ = (8\Delta_f G^\circ_{\text{CO}_2(\text{g})} + 9\Delta_f G^\circ_{\text{H}_2\text{O}(\text{l})}) - (\Delta_f G^\circ_{\text{C}_8\text{H}_{18}(\text{l})} + 12\frac{1}{2}\Delta_f G^\circ_{\text{O}_2(\text{g})})$$

Referring to table 8.7:

$$\begin{aligned}\Delta_r G^\circ &= 8 \times (-394.4 \text{ kJ mol}^{-1}) + 9 \times (-237.2 \text{ kJ mol}^{-1}) - [1 \times (-17.3 \text{ kJ mol}^{-1}) + 12\frac{1}{2} \times 0 \text{ kJ mol}^{-1}] \\ &= (-5290 \text{ kJ mol}^{-1}) - (+17.3 \text{ kJ mol}^{-1}) \\ &= -5307 \text{ kJ mol}^{-1}\end{aligned}$$

Thus, at 25°C and 10^5 Pa , we can expect no more than 5307 kJ of non- pV work from the oxidation of 1 mol of C_8H_{18} .

Is our answer reasonable?

Be sure to check the algebraic signs of each of the terms in the calculation. This is a combustion reaction, so we would expect it to be spontaneous and hence have a negative $\Delta_r G$ value, which it does.

PRACTICE EXERCISE 8.14

Calculate the maximum non- pV work that could be obtained at 25°C and 10^5 Pa from the oxidation of 1.00 mol of aluminium by $\text{O}_2(\text{g})$ to give $\text{Al}_2\text{O}_3(\text{s})$. (Aluminium was

one of the components of the booster rocket that was used to launch the world's first successful scramjet flight in Australia.)

Gibbs energy and equilibrium

We have seen that, when the value of ΔG for a given change is negative, the change occurs spontaneously. We have also seen that a change is nonspontaneous when ΔG is positive. However, when ΔG is neither positive nor negative, the change is neither spontaneous nor nonspontaneous — the system is in a state of equilibrium. This occurs when ΔG is equal to 0. When a system is in a state of equilibrium in which two opposing physical processes or chemical reactions are occurring at the same rate (we call this a dynamic equilibrium) at constant temperature and pressure.

$$G_{\text{products}} = G_{\text{reactants}} \quad \text{and} \quad \Delta G = 0$$

Let's again consider the freezing of water at $p = 1.013 \times 10^5\text{ Pa}$.

Below 0°C , ΔG for this change is negative and freezing is spontaneous, that is, we would write $\text{H}_2\text{O}(\text{l}) \rightarrow \text{H}_2\text{O}(\text{s})$. On the other hand, above 0°C we find that ΔG is positive and freezing is nonspontaneous, that is, we would write $\text{H}_2\text{O}(\text{s}) \rightarrow \text{H}_2\text{O}(\text{l})$. When the temperature is exactly 0°C , $\Delta G = 0$ and an ice–water mixture exists in a condition of equilibrium. As long as heat is not added or removed from the system, neither overall freezing nor melting is spontaneous and the ice and liquid water

can exist together indefinitely. In this state of dynamic equilibrium, the rate at which liquid water freezes to give ice is exactly equal to the rate at which ice melts to give liquid water.

We have identified ΔG as a quantity that specifies the amount of non- pV work available from a system. Since $\Delta G = 0$ at equilibrium, the amount of non- pV work available is 0 also. Therefore, when a system is at equilibrium, no non- pV work can be extracted from it. As an example, we will consider again the common lead storage battery that we use to start a car.

When a battery is fully charged, there are virtually no products of the discharge reaction present. The chemical reactants, however, are present in large amounts. Therefore, the total Gibbs energy of the reactants far exceeds the total Gibbs energy of products and, since $\Delta_r G = G_{\text{products}} - G_{\text{reactants}}$, the $\Delta_r G$ of the system has a large negative value. This means that a lot of energy is available to do non- pV work. As the battery discharges, the reactants are converted to products and G_{products} gets larger while $G_{\text{reactants}}$ gets smaller, so $\Delta_r G$ becomes less negative, and less energy is available to do non- pV work. Finally, the battery reaches equilibrium. The total free energies of the reactants and the products have become equal, so:

$$G_{\text{products}} - G_{\text{reactants}} = 0 \quad \text{and} \quad \Delta_r G = 0$$

No further non- pV work can be extracted and we say the battery is flat.

When we have equilibrium in any system, $\Delta G = 0$. For a phase change such as $\text{H}_2\text{O}(\text{l}) \rightarrow \text{H}_2\text{O}(\text{s})$, equilibrium can be established only at one particular temperature at atmospheric pressure. In this instance, that temperature is 0°C . Above 0°C , only liquid water can exist, and below 0°C all the liquid will freeze to give ice. This yields an interesting relationship between ΔH and ΔS that applies not only to phase changes but also to chemical reactions. Since at equilibrium, $\Delta G = 0$:

$$\Delta G = 0 = \Delta H - T\Delta S$$

Therefore:

$$\Delta H = T\Delta S$$

and:

$$\Delta S = \frac{\Delta H}{T}$$

Thus, if we know ΔH for a chemical reaction or phase change and the temperature at which equilibrium is established, we can calculate ΔS . We can also rearrange the above equation to give the following.

$$T = \frac{\Delta H}{\Delta S}$$

Thus, if we know ΔH and ΔS , we can calculate the temperature at which equilibrium will be established.

WORKED EXAMPLE 8.15

Calculating the equilibrium temperature for a phase change

For the phase change $\text{Br}_2(\text{l}) \rightarrow \text{Br}_2(\text{g})$, $\Delta H^\circ = +30.9 \text{ kJ mol}^{-1}$ and $\Delta S^\circ = 93.2 \text{ J mol}^{-1} \text{ K}^{-1}$ at 25°C . Assuming that ΔH and ΔS are temperature independent, calculate the approximate temperature at which $\text{Br}_2(\text{l})$ will be in equilibrium with $\text{Br}_2(\text{g})$ at 10^5 Pa (i.e. the normal boiling point of liquid Br_2).

Analysis

The temperature at which equilibrium exists is given by the following equation.

$$T = \frac{\Delta H}{\Delta S}$$

We are working under standard conditions (10^5 Pa), so we can use ΔH° and ΔS° in this equation. That is:

$$T = \frac{\Delta H^\circ}{\Delta S^\circ}$$

Solution

We now substitute the data given in the problem.

$$\begin{aligned} T &= \frac{30.9 \times 10^3 \text{ J mol}^{-1}}{93.2 \text{ J mol}^{-1} \text{ K}^{-1}} \\ &= 332 \text{ K} \\ &= (332 - 273)^\circ\text{C} = 59^\circ\text{C} \end{aligned}$$

Notice that we must express ΔH° in J mol^{-1} , not kJ mol^{-1} , so the units cancel correctly. It is also interesting that the boiling point we calculate is quite close to the measured normal boiling point of 58.8°C .

Is our answer reasonable?

ΔH° equals 30 900 and ΔS° equals approximately 100, which means the temperature should be about 310 K. Our value, 332 K, is not far from that, so the answer is reasonable.

PRACTICE EXERCISE 8.15

The standard enthalpy of vaporisation of silicon tetrachloride, SiCl_4 , is 28.7 kJ mol^{-1} . For $\text{SiCl}_4(\text{l})$, $S_{298\text{K}}^\circ = 239.3 \text{ J mol}^{-1} \text{ K}^{-1}$ and for $\text{SiCl}_4(\text{g})$, $S_{298\text{K}}^\circ = 331.4 \text{ J mol}^{-1} \text{ K}^{-1}$. Estimate the normal boiling point of liquid SiCl_4 .

We can also use the equation $T = \frac{\Delta H}{\Delta S}$ to determine the temperature at which a nonspontaneous reaction first becomes spontaneous. To illustrate this, consider the decomposition of calcium carbonate under standard conditions at 25°C , which occurs according to the following equation.

Using the $\Delta_f H^\circ$ and S° data in tables 8.3 and 8.6, or the $\Delta_f G^\circ$ data in table 8.7, we can calculate that $\Delta_r G^\circ = 130 \text{ kJ mol}^{-1}$ for this reaction at 25°C . Therefore, the reaction is nonspontaneous at this temperature under standard conditions. However, we showed earlier that the spontaneity of reactions with positive ΔH and ΔS values depends on the temperature, and that such reactions are generally spontaneous at high temperature. We can substitute the values of $\Delta_r H^\circ = +178 \text{ kJ mol}^{-1}$ and $\Delta_r S^\circ = 160.7 \text{ J mol}^{-1} \text{ K}^{-1}$ for this reaction into the following equation.

$$\begin{aligned} T &= \frac{\Delta_r H^\circ}{\Delta_r S^\circ} \\ &= \frac{178 \times 10^3 \text{ J mol}^{-1}}{160.7 \text{ J mol}^{-1} \text{ K}^{-1}} \\ &= 1.11 \times 10^3 \text{ K} \end{aligned}$$

This shows that the system will be in equilibrium at 1110 K under standard conditions (assuming that $\Delta_r H^\circ$ and $\Delta_r S^\circ$ are independent of temperature) and that the forward reaction will be spontaneous at any temperature greater than this. We summarise this in figure 8.29.

FIGURE 8.29

Diagram showing the relative values of $\Delta_r H^\circ$ and $T\Delta_r S^\circ$ for the decomposition of calcium carbonate. At low temperatures, $\Delta_r H^\circ$ (blue line) is greater than $T\Delta_r S^\circ$ (red line). This means that $\Delta_r G^\circ$ will be positive under these conditions and the reaction will be nonspontaneous. As the temperature increases, the value of $T\Delta_r S^\circ$ increases and eventually, at $T = 1.11 \times 10^3 \text{ K}$, $\Delta_r H^\circ = T\Delta_r S^\circ$ and the system is at equilibrium. At any temperature greater than $1.11 \times 10^3 \text{ K}$, $\Delta_r H^\circ$ is less than $T\Delta_r S^\circ$. Under these conditions, $\Delta_r G^\circ$ will be negative and the decomposition reaction will be spontaneous.

In this chapter, we have shown that ΔG can be used as the criterion for spontaneity of a chemical reaction or phase change. Furthermore, we have shown that the sign of ΔG depends on the signs of both ΔH and ΔS and that, when $\Delta G = 0$, there is no driving force for chemical or physical change and the system is at equilibrium. In the chapter on chemical equilibrium, we will see how the value of $\Delta_r G$ measured under standard conditions, $\Delta_r G^\ominus$, is related to the extent of reaction.

SUMMARY

8.1 Explain the difference between spontaneous and non-spontaneous chemical processes.

A spontaneous change occurs without outside assistance, whereas a nonspontaneous change requires continuous help and can occur only if it is accompanied by, and linked to, some other spontaneous event.

The science of chemical thermodynamics allows us to predict both the direction and extent of spontaneous chemical and physical change under particular conditions.

8.2 Use the terminology and units of chemical thermodynamics.

We call the object we are interested in the 'system', which is enclosed by a 'boundary'. Everything else in the 'universe' is the system's 'surroundings'.

Chemical thermodynamics uses the SI unit of energy, work and heat, the joule (J) or the kilojoule (kJ). Many thermodynamic equations require the temperature to be expressed in kelvin. Standard states for chemical substances depend on the phase of the substance, all standard states involve $p^\circ (1 \times 10^5 \text{ Pa})$. Standard thermodynamic functions refer to conversion of unmixed reactants in their standard states to unmixed products in their standard states. Such functions are denoted by a superscript plimsoll, $^\circ$, and are said to be determined under standard conditions. Note there is no standard temperature.

Gibbs energy, G , is defined by the equation $G = H - TS$, where H is the enthalpy of the system, S is the entropy of the system and T is the thermodynamic temperature. We use ΔG to symbolise the change in Gibbs energy that occurs when a chemical system changes from one state to another due to a reaction or physical change at constant temperature and pressure. The sign of ΔG allows us to determine whether a particular chemical reaction or physical change is spontaneous.

8.3 Carry out calculations related to the first law of thermodynamics.

The first law of thermodynamics states that energy cannot be created or destroyed; it can, however, be transferred as either heat or work. This is summarised by the following equation.

$$\Delta U = q + w$$

The internal energy U , is the sum of all the nuclear, electronic, vibrational, rotational, translational and interaction energies of all of the individual particles in a sample of matter. It is an extensive property, and the change in internal energy, $\Delta_r U$, for a chemical reaction is given by the following equation.

$$\Delta_r U = U_{\text{products}} - U_{\text{reactants}}$$

The value of the state function internal energy depends only on the current condition or state of the system. Temperature is an intensive property that determines the direction of spontaneous heat flow. Heat, q , is a transfer of energy from an object at a high temperature to one at a lower temperature and can be determined by measuring temperature changes, ΔT , using the following equation where C is the heat capacity of the system; that is, the heat needed to change the temperature of the system by 1 kelvin.

$$q = C\Delta T$$

The specific heat (c) of a pure substance is defined as follows.

$$c = \frac{C}{m}$$

Heat capacity is specific heat multiplied by mass. Heat capacity calculated on a per mole basis is called molar heat capacity.

When the mass and specific heat of an object are known, heat can be calculated using the following equation.

$$q = cm\Delta T$$

Heats of reaction are measured at constant volume or at constant pressure. When a gas evolves and pushes against the atmosphere or causes a piston to move in a cylinder, pressure-volume work is being done. When the volume change, ΔV , occurs at constant opposing pressure, p , the associated pressure-volume work is given by $w = -p\Delta V$. The energy expended in doing this pressure-volume work causes heats of reaction measured at constant volume, q_v , to differ numerically from heats measured at constant pressure, q_p .

In the equation $\Delta U = q + w$ the algebraic signs for q and w are negative when the system gives heat to or does work on the surroundings. The signs are positive when the system absorbs heat or has work done to it. When a closed system has rigid and immovable walls, no pressure-volume work can be done to or by the system so $\Delta U = q_v$. Values of q_v are determined using a bomb calorimeter.

8.4 Explain the concept of enthalpy and use Hess's law.

When a system is under constant pressure (e.g. open to the atmosphere), pressure-volume work is possible and a new thermodynamic property called enthalpy, H , can be defined.

$$H = U + pV$$

Like U , absolute values of H cannot be easily measured or calculated, but the difference in enthalpy between reactants and products can be determined. The heat of reaction is now called the enthalpy change, ΔH . Under constant pressure:

$$\Delta H = \Delta U + p\Delta V = q_p$$

While ΔH is a state function, its value differs from that of ΔU by the work involved in interacting with the surroundings when the change occurs at constant pressure. In general, the difference between ΔU and ΔH is quite small.

Exothermic reactions have negative values of $\Delta_r H$; endothermic changes have positive values. A balanced chemical equation that includes both the enthalpy change and the physical states of the substances is called a thermochemical equation. These can be added, reversed (reversing also the sign of the enthalpy change) or multiplied by a constant multiplier (doing the same to the enthalpy change). If substances are cancelled or added, they must be in identical physical states.

Thermochemical equations can be added because enthalpy is a state function. Values of $\Delta_r H^\circ$ can be determined by the manipulation of any combination of thermochemical equations that add up to the final net equation.

An enthalpy change measured under standard conditions at the specified temperature T is called the standard enthalpy of reaction, $\Delta_r H^\circ$. The value of $\Delta_r H^\circ$ is a function of the amounts of substances involved in the reaction. If the amount of reactants is doubled, the standard enthalpy of the reaction doubles.

The enthalpy change for the formation of 1 mol of a substance under standard conditions from its elements in their standard states is called the standard enthalpy of formation, $\Delta_f H^\circ$, and it is generally given in units of kJ mol^{-1} . Hess's law is possible because enthalpy is a state function. The value of $\Delta_r H^\circ$ for a reaction can be calculated as the sum of the $\Delta_f H^\circ$ values of the products minus the sum of the $\Delta_f H^\circ$ values of the reactants, each multiplied by the corresponding stoichiometric coefficient in the equation.

The enthalpy change for the complete combustion of 1 mol of a pure substance under standard conditions is called the standard enthalpy of combustion, $\Delta_c H^\circ$.

The bond enthalpy is the enthalpy change on breaking 1 mol of a particular chemical bond to give electrically neutral fragments. The sum of all the bond enthalpies in a molecule is the atomisation enthalpy, $\Delta_{at} H$, and, on a mole basis, it corresponds to the energy needed to break 1 mol of molecules into individual atoms.

8.5 Explain the concept of entropy.

Spontaneity is associated with statistical probability; spontaneous processes tend to proceed from lower probability to higher probability states. The thermodynamic quantity associated with the probability of a state is entropy, S . Entropy measures the number of energetically equivalent ways a state can be realised.

8.6 State the second law of thermodynamics, and appreciate that any spontaneous process involves an increase in the entropy of the universe.

The second law of thermodynamics states that the entropy of the universe increases whenever a spontaneous change occurs.

In general, gases have much higher entropies than liquids, which have somewhat higher entropies than solids. Entropy increases with volume for a gas and with the temperature. During a chemical reaction, the entropy tends to increase if the number of molecules increases on going from reactants to products.

8.7 State the third law of thermodynamics and calculate entropies of reaction.

The third law of thermodynamics states that the entropy of a pure crystalline substance is equal to 0 at absolute zero (0 K).

Because we know where the zero point is on the entropy scale, it is possible to measure absolute entropies. Standard entropies, S° , are calculated at 10^5 Pa (table 8.6) and can be used to calculate ΔS° for chemical reactions.

8.8 Determine the spontaneity of a process using the change in Gibbs energy.

Gibbs energy is defined as $G = H - TS$. A chemical or physical change at constant temperature and pressure is spontaneous only if the Gibbs energy of the system decreases (ΔG is negative). When ΔH and ΔS have the same algebraic sign, the temperature becomes the critical factor in determining spontaneity.

When ΔG is measured under standard conditions, it is the standard Gibbs energy change, ΔG° . As with enthalpy changes, the standard Gibbs energies of formation, $\Delta_f G^\circ$, (table 8.7) can be used to obtain $\Delta_r H^\circ$ for chemical reactions by a Hess's law type of calculation.

For any system, the value of ΔG is equal to the maximum amount of energy that can be obtained in the form of useful non- pV work. This maximum work can be obtained only if the change takes place reversibly. All real changes are irreversible and we always obtain less work than is theoretically available; the rest is lost as heat.

When a system reaches equilibrium, $\Delta G = 0$ and no useful work can be obtained from it. At any particular pressure, an equilibrium between two phases of a substance (e.g. liquid–solid or solid–vapour) can occur at only one temperature. The entropy change can be calculated as $\Delta S = \frac{\Delta H}{T}$. The temperature at which the equilibrium occurs can be calculated from $T = \frac{\Delta H}{\Delta S}$.

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation
Heat capacity and specific heat	8.3	The equation: $q = C\Delta T$ (q = heat, C = heat capacity, ΔT = temperature change) can be used to calculate the heat of a reaction. Specific heat (c) is defined as follows. $c = \frac{C}{m}$
Thermochemical equations	8.4	We can use thermochemical equations for one set of reactions to write a thermochemical equation for some net reaction.
Hess's law	8.4	Hess's law states that the overall enthalpy change for a reaction is the same regardless of how it is carried out. This enables us to use standard enthalpies of formation to calculate the enthalpy of a reaction.
$\Delta_f H^\circ$ and S°	8.4, 8.7	Standard enthalpies of formation and standard entropies can be used to calculate, respectively, $\Delta_r H^\circ$ and $\Delta_r S^\circ$ for a reaction.
ΔG as a predictor of spontaneity	8.8	If $\Delta_r G$ for a reaction is negative, the reaction is spontaneous under the defined conditions.
Calculating ΔG° from ΔH° and ΔS°	8.8	ΔG° values can be calculated from values of ΔH° , ΔS° and T through the following equation. $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$
Using $\Delta_f G^\circ$ values	8.8	Standard Gibbs energy of formation values can be used to calculate $\Delta_r G^\circ$ for a reaction.

KEY TERMS

atomisation enthalpy ($\Delta_{\text{at}}H$) The enthalpy change on rupturing all of the bonds in 1 mol of a substance in the gas phase to produce its atoms, also in the gas phase.

bomb calorimeter Apparatus used in the determination of the heat of a reaction under constant volume conditions.

bond enthalpy The enthalpy change on breaking 1 mol of a particular bond to give electrically neutral fragments.

boundary The interface between a system and its surroundings across which energy or matter might pass.

calorimeter A device for measuring the heat evolved or absorbed in a chemical reaction.

chemical thermodynamics The study of the role of energy in chemical change and in determining the behaviour of materials.

combustion reaction The reaction of a chemical substance with oxygen.

endergonic A process for which ΔG is positive.

endothermic Describes a change in which energy enters a system from the surroundings.

enthalpy (H) The heat content of a system measured under constant pressure conditions.

entropy (S) A thermodynamic quantity related to the number of equivalent ways the energy of a system can be distributed. The greater this number, the more probable is the state and the higher is the entropy.

exergonic A process in which ΔG is negative.

exothermic Describes a change in which energy leaves a system and enters the surroundings.

extensive property A property of an object that is described by a physical quantity (such as mass and volume) that is proportional to the size or amount of the object.

first law of thermodynamics A formal statement of the law of conservation of energy; $\Delta U = q + w$.

Gibbs energy (G) A thermodynamic quantity that relates enthalpy (H), entropy (S) and temperature (T) by the equation $G = H - TS$.

heat (q) A transfer of energy due to a temperature difference.

heat capacity (C) The quantity of heat needed to raise the temperature of an object by 1 K.

heat of reaction at constant pressure (q_p) The heat of a reaction in an open system.

heat of reaction at constant volume (q_v) The heat of a reaction in a sealed vessel, such as a bomb calorimeter.

Hess's law For any reaction that can be written in steps, the standard enthalpy of reaction is the same as the sum of the standard enthalpies of reaction for the steps.

intensive property A property of an object that is described by a physical quantity (such as density and temperature) that is independent of the size of the sample.

internal energy (U) The sum of all of the kinetic energies and potential energies of the particles within a system.

joule (J) The SI unit of energy; $1 J = 1 \text{ kg m}^2 \text{ s}^{-2}$.

kilojoule (kJ) 1000 J

molar heat capacity The heat capacity of 1 mol of a substance.

second law of thermodynamics Whenever a spontaneous event takes place in our universe, the total entropy of the universe increases ($\Delta S_{\text{total}} > 0$).

specific heat (c) See *specific heat capacity*.

specific heat capacity (c) The quantity of heat that will raise the temperature of 1 g of a substance by 1 K, usually in units of $\text{J g}^{-1} \text{ K}^{-1}$; also called specific heat.

spontaneous Describes a process that, once started, proceeds by itself without outside assistance.

standard enthalpy of combustion ($\Delta_c H^\circ$) The enthalpy change for the combustion of 1 mol of a compound under standard conditions.

standard enthalpy of formation ($\Delta_f H^\circ$) The enthalpy change when 1 mol of a compound is formed from its elements in their standard states.

standard enthalpy of reaction ($\Delta_r H^\circ$) The enthalpy change of a reaction when determined with reactants and products at 10^5 Pa and on the scale of the mole quantities given by the coefficients of the balanced equation.

standard entropy (S°) The entropy of a substance measured under standard conditions.

standard entropy of formation ($\Delta_f S^\circ$) The entropy change when 1 mol of a substance is formed from its elements in their standard states.

standard entropy of reaction ($\Delta_r S^\circ$) The entropy change of a reaction when determined with reactants and products at 10^5 Pa and on the scale of the mole quantities given by the coefficients of the balanced equation.

standard Gibbs energy change (ΔG°) $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$

state function A quantity that depends only on the initial and final states of the system and not on the path taken by the system to get from the initial to the final state; p , V , T , H , S and G are all state functions.

surroundings That part of the universe other than the system being studied and separated from the system by a real or an imaginary boundary.

system That part of the universe under study and separated from the surroundings by a real or an imaginary boundary. A system may be open, closed or isolated.

thermochemical equation A balanced chemical equation accompanied by the value of ΔH° that corresponds to the mole quantities specified by the coefficients.

thermodynamic temperature A temperature scale in which temperature is measured in kelvin.

third law of thermodynamics At absolute zero, the entropy of a perfectly ordered pure crystalline substance is 0.

universe A system and its surroundings taken together.

work (w) The energy expended in moving an opposing force through a particular distance. Work has units of force $\times$ distance.

REVIEW QUESTIONS

Introduction to chemical thermodynamics

LO1

8.1 The chemical reaction below is nonspontaneous, as we found in section 8.1.

This means that the reverse reaction must be spontaneous.

However, a gaseous mixture of H_2 and O_2 is stable indefinitely in the absence of any ignition source. Why is it therefore still correct to say that the reaction of H_2 with O_2 to give water is spontaneous?

Thermodynamic concepts

LO2

8.2 Define the terms *system*, *surroundings* and *universe* as they are used in thermodynamics.

8.3 What is a state function? Give two examples.

The first law of thermodynamics**LO3**

- 8.4** What kinds of energies contribute to the internal energy of a system?
- 8.5** Write the equation for the first law of thermodynamics. To what type of systems does this equation apply? What are the only two ways in which energy can be transferred between these systems and their surroundings?
- 8.6** Define heat capacity in words.
- 8.7** If the same amount of heat is applied to 1 kg of water and 1 kg of iron, which are initially at the same temperature, for the same amount of time, will they still have the same temperature after the heat has been applied? If not, which will have the higher temperature? Explain your answer in terms of specific heat.
- 8.8** Why is heat capacity an extensive property, while the closely related property specific heat is an intensive property?
- 8.9** If the specific heat values in table 8.2 were in units of $\text{kJ kg}^{-1} \text{K}^{-1}$, would the values be numerically different? Explain.
- 8.10** An endothermic chemical reaction absorbs heat from the surroundings and, as a result, the reaction vessel gets colder. What happens to the heat absorbed by the reaction?
- 8.11** Why can no pV work be done in a bomb calorimeter?

Enthalpy**LO4**

- 8.12** Give the equation that defines ΔH in terms of internal energy, pressure and volume.
- 8.13** Why does the calorimeter in figure 8.12 consist of polystyrene cups rather than, for instance, a glass beaker?
- 8.14** What is the sign of ΔH for an endothermic change?
- 8.15** In numerical terms, what is the major difference between $\Delta_r H$ and $\Delta_r H^\circ$ for a particular chemical reaction at temperature T ?
- 8.16** How do enthalpy and internal energy differ?
- 8.17** What fundamental property of $\Delta_r H$ makes Hess's law possible?
- 8.18** If $\Delta_r H^\circ$ for a particular chemical reaction is $x \text{ kJ mol}^{-1}$, what will be the value of $\Delta_r H^\circ$ if the balanced chemical equation is reversed and the stoichiometric coefficients are multiplied by 3?
- 8.19** Define the term 'standard enthalpy of formation'.
- 8.20** How can Hess's law be expressed in terms of standard enthalpies of formation?
- 8.21** Write Hess's law in terms of standard enthalpies of combustion.
- 8.22** Define atomisation enthalpy, $\Delta_{\text{at}} H$.
- 8.23** Why are lattice enthalpies always positive?

Entropy**LO5**

- 8.24** Give a definition of entropy in terms of the distribution of energy in a system.

- 8.25** Will the entropy change for each of the following be positive or negative?

- (a) Moisture condenses on the outside of a cold glass.
- (b) Raindrops form in a cloud.
- (c) Air is pumped into a tyre.
- (d) Frost forms on the windscreen of your car.
- (e) Sugar dissolves in coffee.

- 8.26** Why should an increase in the temperature of a system lead to an increase in entropy of the system?

- 8.27** Consider two systems, one of which comprises 1 mol of ice, and the other 1 mol of liquid water, both at exactly 0°C . Would you expect the entropies of the two systems to be the same? Explain your answer.

The second law of thermodynamics**LO6**

- 8.28** State the second law of thermodynamics.
- 8.29** How can a chemical or physical process lead to a negative entropy change for the system under study and still be spontaneous?

The third law of thermodynamics**LO7**

- 8.30** State the third law of thermodynamics.
- 8.31** Would you expect the entropy of an alloy (a solution of two metals) to be 0 at 0 K? Explain your answer.
- 8.32** Glass is classified as an amorphous solid, rather than a crystalline solid. This means that there is no long-range order in the structure of glass. Should the entropy of glass at 0 K be zero? Explain your answer.

Gibbs energy and reaction spontaneity**LO8**

- 8.33** What is the equation expressing the change in the Gibbs energy for a reaction occurring at constant temperature and pressure?
- 8.34** For each of the following conditions, state in terms of the algebraic signs of ΔH and ΔS the circumstances under which a change will be spontaneous.
- (a) at all temperatures
 - (b) at low temperatures but not at high temperatures
 - (c) at high temperatures but not at low temperatures
- 8.35** Under what circumstances will a change be nonspontaneous regardless of the temperature?
- 8.36** Define the terms *exergonic* and *endergonic*.
- 8.37** How is Gibbs energy related to useful work?
- 8.38** $\Delta_r G$ for the combustion of 1 mol of octane in an open beaker is the same as that for combustion in a car engine (assuming T and p are the same in both cases). With reference to your answer for question 8.37, explain how the amount of work obtained in the two processes is so significantly different.
- 8.39** What is a dynamic equilibrium?
- 8.40** What is the numerical difference in the values of Gibbs energy for reactants and products when a chemical process is at equilibrium?

REVIEW PROBLEMS

Note: Unless otherwise stated, a temperature of 25°C is assumed in all problems requiring calculations. Thermodynamic data required for calculations can be found in the appropriate tables in this chapter or in the appendices.

- 8.41** Consider a system undergoing a process for which the value of ΔU was -1047 J . During the process the system did 523 J work on the surroundings. Was heat evolved from, or absorbed by, the system? How much heat was involved in the process? **LO3**
- 8.42** If a sample of 580 g of water had its temperature lowered from 45.2°C to 22.7°C , how much heat did the sample lose? **LO3**
- 8.43** How much heat is needed to increase the temperature of 1.00 kg of water from 25.0°C to 100.0°C ? This amount of heat would be comparable to making four cups of coffee. **LO3**
- 8.44** 750 J of heat is added to samples of 100.0 g of copper and 100.0 g of water, with both samples having an initial temperature of 22.0°C . What are the final temperatures of the copper and the water? **LO3**
- 8.45** A small silver ingot was heated to 150°C and then immediately plunged into an insulated vessel containing 150 g of water at 25.00°C . The final temperature of both the water and the silver ingot was 27.40°C . **LO3**
- (a) How much heat was absorbed by the water?

(b) How much heat was lost by the silver ingot?

(c) What was the mass of the silver ingot?

8.46 Use the value of the specific heat of silver in table 8.2 to calculate its molar heat capacity.

L03

8.47 Nitric acid, HNO_3 , reacts with potassium hydroxide, KOH , according to the equation:

L03,4

A student poured 72.0 mL of $1.0 \text{ mol L}^{-1} \text{HNO}_3$ into a coffee cup calorimeter, noted that the temperature was 25.0°C and added 72.0 mL of $1.0 \text{ mol L}^{-1} \text{KOH}$, also at 25.0°C . The mixture was stirred quickly with a thermometer, and its temperature rose to 31.3°C . Assuming that the specific heats of all solutions are $4.18 \text{ J g}^{-1} \text{K}^{-1}$ and that all densities are 1.00 g mL^{-1} , calculate both the enthalpy of reaction, and the enthalpy of reaction per mole of acid.

8.48 A 0.100 mol sample of propane, a gas used in portable gas cookers, was placed in a bomb calorimeter where it was burned in the presence of excess oxygen. The reaction was as follows.

L03,4

The water bath surrounding the bomb calorimeter contained 1.000 kg of water at an initial temperature of 25.000°C . The heat capacity of the bomb calorimeter was 93.1 kJ K^{-1} . The reaction raised the temperature of the water bath to 27.282°C . The specific heat of water is $4.18 \text{ J g}^{-1} \text{K}^{-1}$.

(a) How much heat was liberated in this reaction?

(b) What is the enthalpy of reaction of propane with oxygen?

8.49 Toluene, C_7H_8 , is used in the manufacture of explosives such as TNT (trinitrotoluene). A 1.500 g sample of liquid toluene was placed in a bomb calorimeter along with excess oxygen. When the combustion of the toluene was initiated, the temperature of the 2.500 kg of water in the water bath surrounding the bomb calorimeter rose from 25.000°C to 26.413°C . The products of the combustion were $\text{CO}_2(\text{g})$ and $\text{H}_2\text{O}(\text{l})$, and the heat capacity of the calorimeter was 34.61 kJ K^{-1} . The reaction was as follows.

L03,4

(a) How much heat was liberated by the reaction?

(b) How much heat would be liberated under similar conditions if 1.00 mol of toluene was burned?

8.50 With the exception of chemical equations which define thermodynamic functions such as the standard enthalpies of formation and combustion, thermochemical equations generally do not refer to the consumption or production of specific amounts of reactants or products. For example, we can write the thermochemical equation for the high temperature reaction of iron with steam as follows.

L04

(a) What would be the thermochemical equation for the reaction of iron with steam that uses 2 mol of Fe as the reactant?

(b) Determine $\Delta_r H$ for the formation of 6 mol of $\text{Fe}_3\text{O}_4(\text{s})$ from the reaction of iron with steam.

8.51 Ammonia reacts with oxygen as follows.

L04

(a) Calculate the enthalpy change for the combustion of 1 mol of NH_3 .

(b) Write the thermochemical equation for the reaction in which 1 mol of H_2O is formed.

8.52 Aluminium and iron(III) oxide, Fe_2O_3 , react to form aluminium oxide, Al_2O_3 , and iron. For each mole of aluminium used, 426.9 kJ of energy is released under standard conditions. Write the thermochemical equation that shows the consumption of 4 mol of Al. (All of the substances are solids.)

L04

8.53 Strontium is an element that is responsible for the red colour observed in fireworks displays. The thermochemical equation for the reaction of strontium with oxygen is as follows.

L04

What is the enthalpy change for the combustion of 8.42 g of strontium under standard conditions?

8.54 Use the thermochemical equations:

L04

to calculate $\Delta_r H^\circ$ for the following reaction.

8.55 Hydrogen chloride can be generated by heating a mixture of sulfuric acid and potassium chloride according to the following equation.

L04

Calculate $\Delta_r H^\circ$ for this reaction from the following thermochemical equations.

8.56 Calculate $\Delta_r H^\circ$ for the below reaction, using the thermochemical equations provided.

L04

Use the following thermochemical equations.

- 8.57** Barium oxide reacts with sulfuric acid according to the following equation.

L04

Calculate $\Delta_r H^\circ$ for this reaction. The following thermochemical equations can be used.

- 8.58** Use the thermochemical equations below to calculate the standard enthalpy of formation of $\text{Ag}_2\text{O}_2\text{(s)}$.

L04

- 8.59** Use the following thermochemical equations to calculate the standard enthalpy of formation of $\text{Mg(NO}_3)_2\text{(s)}$.

L04

- 8.60** Which of the following equations has a value of $\Delta_r H^\circ$ that would correctly be labelled $\Delta_f H^\circ$?

L04

- $\text{CaCO}_3\text{(s)} \rightarrow \text{CaO(s)} + \text{CO}_2\text{(g)}$
- $\text{Ca(s)} + \frac{1}{2}\text{O}_2\text{(g)} \rightarrow \text{CaO(s)}$
- $2\text{Cu(s)} + \text{O}_2\text{(g)} \rightarrow 2\text{CuO(s)}$
- $2\text{Fe(s)} + \text{O}_2\text{(g)} \rightarrow 2\text{FeO(s)}$
- $\text{SO}_2\text{(g)} + \frac{1}{2}\text{O}_2\text{(g)} \rightarrow \text{SO}_3\text{(g)}$
- $\text{N}_2\text{(g)} + \frac{5}{2}\text{O}_2\text{(g)} \rightarrow \text{N}_2\text{O}_5\text{(g)}$

- 8.61** Write the thermochemical equations for the standard enthalpy of formation of the following substances at 25 °C.

L04

- C(s, diamond)
- $\text{CHBr}_3\text{(g)}$
- $\text{SO}_2\text{Cl}_2\text{(l)}$
- $\text{Fe(NO}_3)_3 \cdot 9\text{H}_2\text{O(s)}$
- $\text{Mg}_3\text{N}_2\text{(s)}$
- $\text{O}_3\text{(g)}$

- 8.62** Using the data in table 8.3, calculate $\Delta_r H^\circ$ for each of the following reactions.

L04

- $2\text{H}_2\text{O}_2\text{(l)} \rightarrow 2\text{H}_2\text{O(l)} + \text{O}_2\text{(g)}$
- $\text{HCl(g)} + \text{NaOH(s)} \rightarrow \text{NaCl(s)} + \text{H}_2\text{O(l)}$
- $\text{CH}_4\text{(g)} + \text{Cl}_2\text{(g)} \rightarrow \text{CH}_3\text{Cl(g)} + \text{HCl(g)}$
- $2\text{NH}_3\text{(g)} + \text{CO}_2\text{(g)} \rightarrow \text{CO(NH}_2)_2\text{(s)} + \text{H}_2\text{O(l)}$

- 8.63** Lactose is the most abundant sugar in both human and cow milk. The standard enthalpy of combustion ($\Delta_c H^\circ$) of lactose, $\text{C}_{12}\text{H}_{22}\text{O}_{11}$, is $-5.63 \times 10^3 \text{ kJ mol}^{-1}$. The products of the combustion of lactose are $\text{CO}_2\text{(g)}$ and $\text{H}_2\text{O(l)}$. Write the thermochemical equation for the combustion of 1 mol of lactose and calculate $\Delta_r H^\circ$ for this compound.

L04

- 8.64** The thermochemical equation for the combustion of ethyne (acetylene) gas, $\text{C}_2\text{H}_2\text{(g)}$, is as follows.

L04

Using the data in table 8.3, determine the value of $\Delta_f H^\circ$ for ethyne (acetylene) gas.

- 8.65** Use the data in tables 8.3 and 8.4 to calculate the approximate atomisation enthalpy of CO_2 . Use your answer to obtain an approximate value for a C = O bond enthalpy.

L04

- 8.66** The standard enthalpy of formation of ethanol vapour, $\text{C}_2\text{H}_5\text{OH(g)}$, is $-235.3 \text{ kJ mol}^{-1}$. Use the data in table 8.4 and the average bond enthalpies for C—C, C—H and O—H bonds to estimate the C—O bond enthalpy in this molecule. The structure of the molecule is shown.

L04

- 8.67** Gaseous hydrogen sulfide, $\text{H}_2\text{S(g)}$, has $\Delta_f H^\circ = -20.15 \text{ kJ mol}^{-1}$. Use the data in table 8.4 to calculate the average S—H bond enthalpy in this molecule.

L04

- 8.68** For $\text{SF}_6\text{(g)}$, $\Delta_f H^\circ = -1209 \text{ kJ mol}^{-1}$. Use the data in table 8.4 to calculate the average S—F bond enthalpy in this molecule.

L04

- 8.69** Use the results of problem 8.68 and the data in table 8.3 to calculate the standard enthalpy of formation of $\text{SF}_4(\text{g})$. The measured value of $\Delta_f H^\circ$ for $\text{SF}_4(\text{g})$ is $-718.4 \text{ kJ mol}^{-1}$. What is the percentage difference between your calculated value of $\Delta_f H^\circ$ and the experimentally determined value? **L04**
- 8.70** Use tables 8.4 and 8.5 to estimate the standard enthalpy of formation of $\text{C}_2\text{H}_4(\text{g})$. **L04**
- 8.71** Calculate the approximate enthalpy of formation of CCl_4 vapour at 25°C and 10^5 Pa . **L04**
- 8.72** 5.00 kg of water was heated from an initial temperature of 25°C to boiling. **L04**
- (a) How much heat did this process require?
- (b) How much more energy would be required to convert the boiling water to water vapour at 100°C ?
- 8.73** Use the data from table 8.3 to calculate $\Delta_r H^\circ$ for each of the following reactions. **L04**
- (a) $\text{CaO}(\text{s}) + \text{CO}_2(\text{g}) \rightarrow \text{CaCO}_3(\text{s})$
- (b) $\text{C}_2\text{H}_2(\text{g}) + 2\text{H}_2(\text{g}) \rightarrow \text{C}_2\text{H}_6(\text{g})$
- (c) $3\text{CaO}(\text{s}) + 2\text{Fe}(\text{s}) \rightarrow 3\text{Ca}(\text{s}) + \text{Fe}_2\text{O}_3(\text{s})$
- (d) $\text{Ca}(\text{OH})_2(\text{s}) \rightarrow \text{CaO}(\text{s}) + \text{H}_2\text{O}(\text{l})$
- (e) $2\text{NaCl}(\text{s}) + \text{H}_2\text{SO}_4(\text{l}) \rightarrow \text{Na}_2\text{SO}_4(\text{s}) + 2\text{HCl}(\text{g})$
- (f) $2\text{C}_2\text{H}_2(\text{g}) + 5\text{O}_2(\text{g}) \rightarrow 4\text{CO}_2(\text{g}) + 2\text{H}_2\text{O}(\text{g})$
- (g) $\text{C}_2\text{H}_2(\text{g}) + 5\text{N}_2\text{O}(\text{g}) \rightarrow 2\text{CO}_2(\text{g}) + \text{H}_2\text{O}(\text{g}) + 5\text{N}_2(\text{g})$
- (h) $\text{Fe}_2\text{O}_3(\text{s}) + 2\text{Al}(\text{s}) \rightarrow \text{Al}_2\text{O}_3(\text{s}) + 2\text{Fe}(\text{s})$
- (i) $\text{NH}_4\text{Cl}(\text{s}) \rightarrow \text{NH}_3(\text{g}) + \text{HCl}(\text{g})$
- (j) $\text{Ag}(\text{s}) + \text{KCl}(\text{s}) \rightarrow \text{AgCl}(\text{s}) + \text{K}(\text{s})$
- 8.74** By considering the number of moles and the physical states of the reactants and products in the following chemical reactions, predict the sign of the entropy change for each reaction. **L05**
- (a) $2\text{SO}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2\text{SO}_3(\text{g})$
- (b) $\text{PF}_3(\text{g}) + \text{F}_2(\text{g}) \rightarrow \text{PF}_5(\text{g})$
- (c) $\text{NH}_3(\text{g}) + \text{HBr}(\text{g}) \rightarrow \text{NH}_4\text{Br}(\text{s})$
- (d) $\text{Na}_2\text{CO}_3(\text{s}) + 2\text{HCl}(\text{aq}) \rightarrow \text{CO}_2(\text{g}) + \text{H}_2\text{O}(\text{l}) + 2\text{NaCl}(\text{aq})$
- (e) $\text{N}_2(\text{g}) + \frac{1}{2}\text{O}_2(\text{g}) \rightarrow \text{N}_2\text{O}(\text{g})$
- (f) $\text{C}_5\text{H}_{12}(\text{l}) + 8\text{O}_2(\text{g}) \rightarrow 5\text{CO}_2(\text{g}) + 6\text{H}_2\text{O}(\text{g})$
- (g) $2\text{O}_3(\text{g}) \rightarrow 3\text{O}_2(\text{g})$
- (h) $4\text{H}_3\text{PO}_3(\text{s}) \rightarrow \text{PH}_3(\text{g}) + 3\text{H}_3\text{PO}_4(\text{s})$
- 8.75** Calculate $\Delta_r S^\circ$ for each of the following reactions from the data in table 8.6. **L07**
- (a) $\text{N}_2(\text{g}) + 3\text{H}_2(\text{g}) \rightarrow 2\text{NH}_3(\text{g})$
- (b) $\text{CO}(\text{g}) + 2\text{H}_2(\text{g}) \rightarrow \text{CH}_3\text{OH}(\text{l})$
- (c) $2\text{C}_2\text{H}_6(\text{g}) + 7\text{O}_2(\text{g}) \rightarrow 4\text{CO}_2(\text{g}) + 6\text{H}_2\text{O}(\text{g})$
- (d) $\text{Ca}(\text{OH})_2(\text{s}) + \text{H}_2\text{SO}_4(\text{l}) \rightarrow \text{CaSO}_4(\text{s}) + 2\text{H}_2\text{O}(\text{l})$
- (e) $\text{S}(\text{s}) + 2\text{N}_2\text{O}(\text{g}) \rightarrow \text{SO}_2(\text{g}) + 2\text{N}_2(\text{g})$
- (f) $\text{Ag}(\text{s}) + \frac{1}{2}\text{Cl}_2(\text{g}) \rightarrow \text{AgCl}(\text{s})$
- (g) $\text{H}_2(\text{g}) + \frac{1}{2}\text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{g})$
- (h) $\text{H}_2(\text{g}) + \frac{1}{2}\text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})$
- (i) $\text{CaCO}_3(\text{s}) + \text{H}_2\text{SO}_4(\text{l}) \rightarrow \text{CaSO}_4(\text{s}) + \text{H}_2\text{O}(\text{g}) + \text{CO}_2(\text{g})$

- (i) $2\text{AgCl}(\text{s}) + \text{Ca}(\text{s}) \rightarrow \text{CaCl}_2(\text{s}) + 2\text{Ag}(\text{s})$
- (j) $\text{NH}_3(\text{g}) + \text{HCl}(\text{g}) \rightarrow \text{NH}_4\text{Cl}(\text{s})$

8.79 Given the following information:

L08

calculate $\Delta_r G^\circ$ for the following reaction.

8.80 Given the following reactions and their $\Delta_r G^\circ$ values:

L08

calculate the value of $\Delta_r G^\circ$ for the following reaction.

8.81 What is the maximum amount of useful work that could theoretically be obtained at 25 °C and 10^5 Pa from the combustion of 62.0 g of ethane, $\text{C}_2\text{H}_6\text{(g)}$, to give $\text{CO}_2\text{(g)}$ and $\text{H}_2\text{O(g)}$? **L08**

8.82 In 1846, diethyl ether, $\text{C}_2\text{H}_5\text{OC}_2\text{H}_5$, became the first anaesthetic to be used in a surgical procedure. The enthalpy of vaporisation ($\Delta_{\text{vap}}H$) of liquid diethyl ether is 27.0 kJ mol^{-1} , and $\Delta S^\circ = 87.8 \text{ J mol}^{-1} \text{ K}^{-1}$ for the conversion of the liquid to the gas. At what temperature will diethyl ether boil (i.e. at what temperature will the liquid and vapour be in equilibrium at 10^5 Pa)? **L08**

8.83 Isooctane, an important constituent of petrol, has a boiling point of 99.3 °C and an enthalpy of vaporisation of 37.7 kJ mol^{-1} . What is ΔS for the vaporisation of 1 mol of isooctane? **L07,8**

8.84 Acetone, $(\text{CH}_3)_2\text{CO}$, has a boiling point of 56.2 °C. The change $(\text{CH}_3)_2\text{CO(l)} \rightarrow (\text{CH}_3)_2\text{CO(g)}$ has $\Delta H^\circ = 31.9 \text{ kJ mol}^{-1}$. What is ΔS° for this change? **L07,8**

8.85 Which of the following equations (which are not necessarily balanced) represent a reaction that would be expected to be spontaneous at 25 °C and 10^5 Pa? **L08**

- (a) $\text{PbO(s)} + \text{NH}_3\text{(g)} \rightarrow \text{Pb(s)} + \text{N}_2\text{(g)} + \text{H}_2\text{O(g)}$
- (b) $\text{NaOH(s)} + \text{HCl(g)} \rightarrow \text{NaCl(s)} + \text{H}_2\text{O(l)}$
- (c) $\text{Al}_2\text{O}_3\text{(s)} + \text{Fe(s)} \rightarrow \text{Fe}_2\text{O}_3\text{(s)} + \text{Al(s)}$
- (d) $2\text{CH}_4\text{(g)} \rightarrow \text{C}_2\text{H}_6\text{(g)} + \text{H}_2\text{(g)}$

8.86 How much work is accomplished by the following chemical reaction if it occurs inside a bomb calorimeter? **L03**

What is the maximum amount of work that could be done if the reaction is carried out at 10^5 Pa, with all reactants and products at 25 °C? (For $\text{C}_6\text{H}_{14}\text{(l)}$, $\Delta_r H^\circ = -199 \text{ kJ mol}^{-1}$ and $\Delta S^\circ = 295 \text{ J mol}^{-1} \text{ K}^{-1}$.)

ADDITIONAL EXERCISES

8.87 A cylinder fitted with a piston contains 5.00 L of a gas at a pressure of 4×10^5 Pa. The entire apparatus is maintained at a constant temperature of 25 °C. The piston is released and the gas expands until the pressure inside the cylinder equals the atmospheric pressure outside, which is 10^5 Pa. Assume ideal gas behaviour and calculate the amount of work done by the gas as it expands at constant temperature. **L03**

8.88 The experiment described in exercise 8.87 is repeated, but this time a weight, which exerts a pressure of 2×10^5 Pa, is placed on the piston. When the gas expands, its pressure drops to this 2×10^5 Pa pressure. Then the weight is removed and the gas is allowed to expand again to a final pressure of 10^5 Pa. Throughout both expansions, the temperature of the apparatus was held at a constant 25 °C. Calculate the amount of work done by the gas in each step. How does the combined total amount of work in this two-step expansion compare with the amount of work done by the gas in the one-step expansion described in exercise 8.87? **L03**

8.89 The statement of the first law of thermodynamics in this chapter says that energy cannot be created or destroyed; it can, however, be transferred as either heat or work. Remarkably, energy and matter can be interconverted, as shown by Einstein's famous equation, $E = mc^2$, with an example of this being the conversion of mass to energy in nuclear reactions. What mass would have to be converted to energy in order to turn all of the water in an Olympic-sized swimming pool, initially at 25.0 °C, to steam at 100 °C? Assume the pool has dimensions of $50.0 \text{ m} \times 25.0 \text{ m} \times 2.00 \text{ m}$ and that the density of the water in the pool is 1.00 g mL^{-1} . **L03**

8.90 1.000 kg of gold at a temperature of 120.00 °C was plunged into an insulated vat of water. The mass of the water was 2.000 kg, and its initial temperature was 25.00 °C. What was the temperature of the resulting system when it stabilised? **L03**

8.91 A dilute solution of hydrochloric acid with a mass of 610.29 g and containing 0.331 83 mol of HCl was exactly neutralised in a calorimeter by the sodium hydroxide in 615.31 g of a comparably dilute solution. The temperature increased from 16.784 °C to 20.610 °C. The specific heat of the HCl solution was $4.031 \text{ J g}^{-1} \text{ K}^{-1}$ and that of the NaOH solution was $4.046 \text{ J g}^{-1} \text{ K}^{-1}$. The heat capacity of the calorimeter was 77.99 J K^{-1} . Use this information to calculate the enthalpy change for the following reaction. **L04**

What is the enthalpy of neutralisation per mole of HCl? Assume that the original solutions made independent contributions to the total heat capacity of the system following their mixing.

- 8.92** In the recovery of iron from iron ore, the reduction of the ore is actually accomplished by reactions involving carbon monoxide. Use the following thermochemical equations: **LO4**

to calculate $\Delta_r H^\circ$ for the following reaction.

- 8.93** Use the results from exercise 8.92 as well as the data in table 8.3 to calculate the value of $\Delta_f H^\circ$ for FeO. **LO4**

- 8.94** Phosphorus burns in air to give tetraphosphorus decaoxide, P_4O_{10} . **LO4**

The product combines with water to give phosphoric acid, H_3PO_4 .

Using these equations (and any others in the chapter, as needed), write the thermochemical equation for the formation of 1 mol of $\text{H}_3\text{PO}_4(\text{l})$ from the elements, and calculate $\Delta_f H^\circ$.

- 8.95** There is a significant amount of current research into the use of molten salts as both energy storage and production media. The salts are melted through the focusing of sunlight using huge banks of mirrors, and the molten salts can then be used directly to convert water to steam for electricity production, or be stored in insulated containers for later use. Commercial plants currently operate in the USA, China, Morocco, the UAE, and Chile. One material used is called solar salt, a mixture of 60% NaNO_3 /40% KNO_3 , which can be used at temperatures up to 565°C . What mass of water could be heated from 25.0°C to boiling using 1 kg of solar salt at a temperature of 550°C ? The specific heat of solar salt at this temperature is $1538 \text{ J kg}^{-1} \text{ K}^{-1}$.

- 8.96** The value of $\Delta_f H^\circ$ for $\text{HBr}(\text{g})$ was first evaluated using the following standard enthalpy values obtained experimentally. **LO4**

Use this information to calculate the value of $\Delta_f H^\circ$ for $\text{HBr}(\text{g})$.

- 8.97** The reaction for the metabolism of sucrose, $\text{C}_{12}\text{H}_{22}\text{O}_{11}$, in the body is the same as for its combustion in oxygen to yield $\text{CO}_2(\text{g})$ and $\text{H}_2\text{O}(\text{l})$. The standard enthalpy of formation of sucrose is $-2230 \text{ kJ mol}^{-1}$. Use data in table 8.3 to calculate the amount of energy released by metabolising 50.0 g of sucrose. **LO4**

- 8.98** Consider the following thermochemical equations.

Suppose equation 1 is reversed and divided by 2, equations 2 and 3 are multiplied by $\frac{1}{2}$, and then the three adjusted equations are added. What is the net reaction, and what is the value of $\Delta_r H^\circ$ for the net reaction?

- 8.99** The radioactive ^{238}Pu isotope is being used to provide electricity for operation of the Perseverance Mars Rover. This isotope is used because it has a very high decay heat of 560 W kg^{-1} . This heat is then converted to electricity using a thermocouple. Given that $1 \text{ W} = 1 \text{ J s}^{-1}$, calculate the mass of water that could be heated from 25.0°C to 100.0°C using the heat produced from the radioactive decay of 1.00 kg of ^{238}Pu over 1 day.

- 8.100** Tartaric acid, $\text{C}_4\text{H}_6\text{O}_6$, is a carboxylic acid that occurs naturally in many fruits. The standard enthalpy of combustion, $\Delta_c H^\circ$, of tartaric acid at 25.0°C is $-1141 \text{ kJ mol}^{-1}$. Use the data provided in the table (all at 25°C) to complete the tasks below. **LO4,7,8**

- Write the balanced thermochemical equation for the combustion of 1 mol of tartaric acid.
- Write the balanced thermochemical equation for the formation of 1 mol of tartaric acid from its elements in their standard states at 25°C .
- Use the information in the table and your equations in (a) and (b) to calculate $\Delta_f H^\circ$ for tartaric acid.
- Calculate $\Delta_f S^\circ$ for tartaric acid and $\Delta_r S^\circ$ for the combustion of 1 mol of tartaric acid.
- Calculate $\Delta_f G^\circ$ for tartaric acid and $\Delta_r G^\circ$ for the combustion of 1 mol of tartaric acid at 25°C .

Substance	$\Delta_f H^\circ$ (kJ mol ⁻¹)	S° (J mol ⁻¹ K ⁻¹)
C(s, graphite)	0	5.69
CO ₂ (g)	-393.5	213.6
H ₂ (g)	0	130.6
H ₂ O(l)	-285.9	69.96
O ₂ (g)	0	205.0
C ₄ H ₆ O ₆ (s)	?	120.1

- 8.101** Many biochemical reactions have positive values for $\Delta_r G$ under biological conditions and so should not be expected to be spontaneous. They occur, however, because they are chemically coupled with other reactions that have negative values of $\Delta_r G$. An example is the set of reactions that begins the sequence of reactions involved in the metabolism of glucose, a sugar. Given these reactions and their corresponding $\Delta_r G$ values under biological conditions:

LO8

calculate $\Delta_r G$ for the coupled reaction:

- 8.102** The burning of all hydrocarbons results in the formation of CO₂, which leads to atmospheric warming. On a molar basis, the lower the number of C atoms in the hydrocarbon, the smaller the amount of CO₂ released per mole of hydrocarbon burned. However, on a molar basis, the more C atoms in a hydrocarbon, the greater the energy released when 1 mol of it is burned. The enthalpy data for the combustion of methane, CH₄, and 2,2,4-trimethylpentane, C₈H₁₈, (also called isooctane, a major constituent of petrol) are as follows.

LO4

- (a) What mass of CO₂ is produced upon complete burning of (i) 1.00 mol of CH₄ and (ii) 1.00 mol of C₈H₁₈?
 (b) How much heat is produced upon complete burning of (i) 1.00 mol of CH₄ and (ii) 1.00 mol of C₈H₁₈?
 (c) What mass of CO₂ is produced upon complete burning of (i) 1.00 kg of CH₄ and (ii) 1.00 kg of C₈H₁₈?
 (d) How much heat is produced upon complete burning of (i) 1.00 mol of CH₄ and (ii) 1.00 mol of C₈H₁₈?
 (e) Which is the best fuel on a molar basis?
 (f) Which is the best fuel on a mass basis?
 (g) Which fuel gives the lowest CO₂ emissions on a mass basis?
- 8.103** Ethanol, C₂H₅OH, has been suggested as a potential alternative to petrol as a fuel. In worked example 8.13, we calculated $\Delta_r G^\circ$ for combustion of 1 mol of C₂H₅OH; in worked example 8.14, we calculated $\Delta_r G^\circ$ for combustion of 1 mol of octane. We will assume that petrol has the same properties as octane (one of its constituents). The density of C₂H₅OH is 0.7893 g mL⁻¹; the density of octane, C₈H₁₈, is 0.7025 g mL⁻¹. Calculate the maximum work that could be obtained by burning 1 L each of C₂H₅OH and C₈H₁₈. On a volume basis, which is a better fuel? Explain your answer.
- 8.104** Use the data in table 8.4 to calculate the bond enthalpy of the single F—F bond in the gaseous F₂ molecule and the single Cl—Cl bond in the gaseous Cl₂ molecule.
- 8.105** The enthalpy of vaporisation of carbon tetrachloride, CCl₄, is 29.9 kJ mol⁻¹. Using this information and the data in tables 8.4 and 8.5, estimate the standard enthalpy of formation of liquid CCl₄.
- 8.106** Ammonium nitrate, NH₄NO₃, is a white, crystalline substance manufactured on an enormous scale, for use as a fertiliser, from the reaction of anhydrous ammonia with concentrated nitric acid. However, ammonium nitrate must be handled with care as it is potentially explosive.
- (a) The standard enthalpy of formation ($\Delta_f H^\circ$) of NH₄NO₃(s) is -365.56 kJ mol⁻¹. Write the balanced chemical equation to which this value refers. Specify the standard state for each species in this reaction.
 (b) Write the balanced chemical equation for the formation of NH₄NO₃(s) from NH₃(g) and HNO₃(l). Calculate $\Delta_r H^\circ$ for this reaction.
 (c) When gently heated, NH₄NO₃(s) can decompose according to the following equation.

Calculate $\Delta_r H^\circ$ for this reaction.

- (d) When vigorously heated, NH₄NO₃ can decompose explosively according to the following equation.

Calculate the enthalpy change if 5.000 kg of NH₄NO₃ decomposes completely according to this equation under standard conditions.

- (e) If the energy released from the reaction in (d) was used to heat 50.0 kg of water, initially at 25.0 °C, what would be the final temperature of the water?

8.107 Carbon reacts with oxygen to form carbon dioxide according to the following balanced chemical equation.

Use the following standard enthalpy data to calculate the standard enthalpy change, $\Delta_r H^\circ$ for the above reaction.

Chemical equilibrium

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 9.1** define chemical equilibrium
 - 9.2** use the equilibrium constant, K , and the reaction quotient, Q
 - 9.3** show how equilibrium and Gibbs energy are related
 - 9.4** predict how an equilibrium will respond to change
 - 9.5** carry out calculations involving equilibria.
-

The Earth's oceans are extremely complex chemical systems, comprising vast quantities of dissolved inorganic salts, dissolved organic matter and dissolved gases. Of the gases, carbon dioxide is very important because it provides a source of carbonate ions for the growth and maintenance of the calcium carbonate exoskeletons of marine organisms, such as coral and clams (figure 9.1). The rate at which coral reefs grow, therefore, depends critically on the amount of dissolved carbon dioxide in the ocean, and any process that alters this amount will affect coral reefs.

FIGURE 9.1

The ability of coral and shelled marine life to grow and maintain their exoskeletons depends on the oceans' concentration of dissolved CO_2 , which is directly related to water temperature.

We know that carbon dioxide levels in the Earth's atmosphere are currently increasing and the pH of the Earth's oceans is decreasing. It is also becoming ever more apparent that the Earth's average temperature is rising. All of these factors can influence the chemical equilibrium between solid and dissolved calcium carbonate in the oceans, thereby potentially putting coral reefs, such as Australia's Great Barrier Reef, at risk.

This chapter will introduce the concept of chemical equilibrium, the factors that can affect the behaviour of chemical systems at equilibrium and how a system in which equilibrium has been perturbed must respond to re-establish equilibrium. An understanding of chemical equilibrium is necessary in all forms of chemistry, and we will study important applications of chemical equilibrium in detail later in the text.

9.1 Chemical equilibrium

LEARNING OBJECTIVE 9.1 Define chemical equilibrium.

In the chapter on chemical thermodynamics, we learned how to use the value of ΔG to predict whether a particular chemical reaction or physical change would be spontaneous under the specified conditions. We also briefly introduced the concept of equilibrium and showed that a system is at equilibrium when $\Delta G = 0$; under these conditions, no non- pV work can be extracted from the system, and there is no driving force for chemical or physical change. In this chapter, we will develop the idea of equilibrium further; most importantly, we will show that equilibria in chemical reactions can be quantified using the equilibrium constant, K , and that this is related to the thermodynamic functions we encountered in the chapter on chemical thermodynamics.

We start by considering the Haber–Bosch process, the chemical reaction between nitrogen and hydrogen to give ammonia, which occurs according to the following balanced chemical equation.

Using the data in table 8.7, we can determine that $\Delta_r G^\circ = -33.4 \text{ kJ mol}^{-1}$ for this reaction. We can therefore say with certainty that we would expect the forward reaction to be spontaneous under standard conditions. However, it is very important to recognise that a negative value of $\Delta_r G^\circ$ does not imply that the reaction will proceed to completion. In other words, mixing 1 mol of $\text{N}_2(\text{g})$ with 3 mol of $\text{H}_2(\text{g})$ under standard conditions will not result in formation of 2 mol of $\text{NH}_3(\text{g})$. This may seem to be at odds with what we learned in the chapter on chemical reactions and stoichiometry, so let's revisit what information we can obtain from a balanced chemical equation. For the above equation, the stoichiometric coefficients tell us that:

- $\text{N}_2(\text{g})$ always reacts with $\text{H}_2(\text{g})$ in a 1 : 3 mole ratio
- the amount of $\text{NH}_3(\text{g})$ formed in this reaction is twice the amount of $\text{N}_2(\text{g})$ and two-thirds the amount of $\text{H}_2(\text{g})$ that has reacted.

If we mixed 1 mol of N_2 with 3 mol of H_2 under standard conditions and monitored the composition of the reaction mixture over time, we would (very slowly) see the concentration of $\text{NH}_3(\text{g})$ increase and the concentrations of $\text{N}_2(\text{g})$ and $\text{H}_2(\text{g})$ decrease; eventually, however, the concentrations of $\text{N}_2(\text{g})$, $\text{H}_2(\text{g})$ and $\text{NH}_3(\text{g})$ would stop changing, and we would end up not with pure $\text{NH}_3(\text{g})$ but with a mixture of reactants and products. We say that the reaction mixture has come to **chemical equilibrium** and we distinguish this by using a double-headed arrow $\rightleftharpoons$ (called an equilibrium arrow).

The equilibrium arrow highlights a very important point — a chemical reaction can proceed in both the forward and reverse directions at the same time. At equilibrium, N_2 and H_2 are still reacting to give NH_3 , and NH_3 is also reacting to give N_2 and H_2 , but *the rates of the forward and reverse reactions are equal*. This means that the concentrations of the reactants and products in the reaction mixture remain constant and there is *no net change in the overall composition of the reaction mixture*. Since both the forward and reverse reactions are still occurring, we say that the system is in a state of **dynamic equilibrium**.

In a chemical equilibrium, the terms 'reactants' and 'products' do not have the usual significance because the reaction is proceeding in both directions simultaneously. Instead, we use 'reactants' and 'products' simply to identify the substances on the left- and right-hand sides, respectively, of the equation for the equilibrium.

9.2 The equilibrium constant, K , and the reaction quotient, Q

LEARNING OBJECTIVE 9.2 Use the equilibrium constant, K , and the reaction quotient, Q .

A classic experiment that demonstrates many important concepts of equilibrium is the decomposition of $\text{N}_2\text{O}_4(\text{g})$ (dinitrogen tetroxide) to give $\text{NO}_2(\text{g})$ (nitrogen dioxide) (figure 9.2).

This reaction is easily monitored by observing the colour of the reaction mixture. Pure $\text{N}_2\text{O}_4(\text{g})$ is colourless, while pure $\text{NO}_2(\text{g})$ is dark brown; as N_2O_4 decomposes, the mixture becomes more and more brown. Figure 9.3 shows how the concentrations of the two gases change over time as pure $\text{N}_2\text{O}_4(\text{g})$ is converted to an equilibrium mixture of $\text{N}_2\text{O}_4(\text{g})$ and $\text{NO}_2(\text{g})$.

Suppose we set up an experiment to study the equilibrium: at constant temperature. We begin by putting 0.0350 mol N_2O_4 in a 1-litre flask. Since no NO_2 is present, some N_2O_4 must decompose for the system to reach equilibrium, so the forward reaction in the equilibrium equation will predominate (i.e. from left to right) until equilibrium is reached. At this point, we find the concentration of N_2O_4 has dropped to $0.0292 \text{ mol L}^{-1}$ and the concentration of NO_2 has become $0.0116 \text{ mol L}^{-1}$. We then put 0.0700 mol of NO_2 (*precisely* the amount of NO_2 that would form if 0.0350 mol of N_2O_4 — the amount placed in the first flask — decomposed completely) in a second 1-litre flask. As there is no N_2O_4 present initially in this second flask, the reverse reaction in the equilibrium equation will predominate (right to left), with NO_2 molecules combining to give N_2O_4 until equilibrium is reached. When we measure the concentrations at equilibrium in the second flask, we find, once again, that the concentration of N_2O_4 is $0.0292 \text{ mol L}^{-1}$ and that of NO_2 is $0.0116 \text{ mol L}^{-1}$. (In practice, these experiments are difficult, if not impossible, to carry out, because $\text{N}_2\text{O}_4(\text{g})$ and $\text{NO}_2(\text{g})$ are always in equilibrium with each other, so they cannot be obtained absolutely pure.) We see here that the same equilibrium composition is reached, whether we begin with pure NO_2 or pure N_2O_4 , as long as the *total* amount of N and O to be divided between these two substances is the same. Similar observations apply to other chemical systems as well, which leads to the following generalisation: for a given *overall* system composition at constant temperature, we always reach the same equilibrium concentrations regardless of the direction from which equilibrium is approached.

Consider the general equilibrium equation in which a mol of substance A and b mol of substance B are in equilibrium with c mol of substance C and d mol of substance D .

FIGURE 9.2

Equilibrium mixtures of $\text{N}_2\text{O}_4(\text{g})$ and $\text{NO}_2(\text{g})$ at different temperatures. In ice (right), colourless N_2O_4 predominates and the mixture is pale. At high temperature (left), dark brown NO_2 predominates. At room temperature (middle), both gases are present in appreciable amounts, with N_2O_4 in a slight excess. It is important to recognise that all tubes contain both NO_2 and N_2O_4 .

FIGURE 9.3

The approach to equilibrium. In the decomposition of $\text{N}_2\text{O}_4(\text{g})$ into $\text{NO}_2(\text{g})$, $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2\text{NO}_2(\text{g})$, the concentrations of N_2O_4 and NO_2 change relatively quickly at first. As time passes, the concentrations change more and more slowly. When equilibrium is reached, the concentrations of N_2O_4 and NO_2 no longer change with time; they remain constant. Note that the concentration change of NO_2 over the course of the reaction is twice the concentration change of N_2O_4 .

Provided that A , B , C and D are all either gases or species in solution (usually aqueous), then the following holds when equilibrium is established.

$$K_c = \frac{\left(\frac{[C]_e}{c^\ominus}\right)^c \left(\frac{[D]_e}{c^\ominus}\right)^d}{\left(\frac{[A]_e}{c^\ominus}\right)^a \left(\frac{[B]_e}{c^\ominus}\right)^b}$$

K_c is called the **equilibrium constant** (or, occasionally, the concentration-based equilibrium constant) and the above expression is called the **equilibrium constant expression**. The square brackets refer to concentrations in mol L^{-1} , and $c^\ominus$, the standard concentration, equals 1 mol L^{-1} . Because each concentration term is divided by 1 mol L^{-1} , each term in parentheses is dimensionless, and this means that K_c has no units. Although the K_c expression we have presented looks rather daunting, you will be pleased to know that, in practice, it is usually simplified. Because they are numerically equal to 1, the $c^\ominus$ terms are often omitted; however, it is still understood that each term is dimensionless. The subscript 'e' is also generally omitted, as it is implicit that the concentrations used in an equilibrium constant expression must be equilibrium concentrations. Having made these simplifications, we obtain the more common version of the equilibrium constant expression.

$$K_c = \frac{[C]^c [D]^d}{[A]^a [B]^b}$$

Note that we will use this form throughout the text, and all equilibrium constants will be dimensionless. This expression is derived from the balanced chemical equation as follows.

Notice that the products (the species to the right of the equilibrium arrow) always appear on the top line of the expression (the numerator), and the reactants always appear on the bottom (the denominator). Each reactant and product is raised to the power of the appropriate stoichiometric coefficient (a , b , c or d) from the balanced equilibrium equation (i.e. the coefficients become the exponents). Note that we are not restricted to reactions involving two products and two reactants; we simply include all gaseous

or aqueous reactants and products in the equilibrium constant expression. For example, the equilibrium constant expression for the reaction we described earlier, $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2\text{NO}_2(\text{g})$, is as follows.

$$K_c = \frac{[\text{NO}_2]^2}{[\text{N}_2\text{O}_4]}$$

The value of K_c for a particular reaction depends on the temperature, so it is important that the temperature is always specified when K_c is reported. Tabulated values of K_c generally refer to 25.0 °C and concentrations in mol L^{-1} .

Returning to the previous example, table 9.1 gives the results of four further experiments using differing initial concentrations of $\text{N}_2\text{O}_4(\text{g})$ and $\text{NO}_2(\text{g})$. The final column shows that the value of K_c is constant (within experimental error). We can, therefore, say that the equilibrium constant for the equilibrium $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2\text{NO}_2(\text{g})$ is as follows.

$$K_c = \frac{[\text{NO}_2]^2}{[\text{N}_2\text{O}_4]} = 4.61 \times 10^{-3} \text{ at } 25.0^\circ\text{C}$$

TABLE 9.1 Equilibrium mixture compositions for various initial concentrations of $\text{NO}_2(\text{g})$ and $\text{N}_2\text{O}_4(\text{g})$

Initial concentration		Equilibrium concentration		$K_c = \frac{[\text{NO}_2]^2}{[\text{N}_2\text{O}_4]}$
$[\text{N}_2\text{O}_4] \text{ (mol L}^{-1}\text{)}$	$[\text{NO}_2] \text{ (mol L}^{-1}\text{)}$	$[\text{N}_2\text{O}_4] \text{ (mol L}^{-1}\text{)}$	$[\text{NO}_2] \text{ (mol L}^{-1}\text{)}$	
0.0450	0	0.0384	0.013 3	$\frac{(0.0133)^2}{0.0384} = 4.61 \times 10^{-3}$
0.0150	0	0.0114	0.007 24	$\frac{(0.00724)^2}{0.0114} = 4.60 \times 10^{-3}$
0	0.0600	0.0248	0.010 7	$\frac{(0.0107)^2}{0.0247} = 4.62 \times 10^{-3}$
0	0.0500	0.0202	0.009 64	$\frac{(0.00964)^2}{0.0202} = 4.60 \times 10^{-3}$

Note: The values of K_c are equal within experimental error.

Similarly, consider the following equilibrium.

If we were to study this equilibrium using different initial concentrations of $\text{H}_2(\text{g})$, $\text{I}_2(\text{g})$ and $\text{HI}(\text{g})$ at 400 °C, we would find that, when the system came to equilibrium:

$$K_c = \frac{[\text{HI}]^2}{[\text{H}_2][\text{I}_2]} = 49.5 \text{ at } 400^\circ\text{C}$$

We can apply the equilibrium constant expression to any system at equilibrium.

We can also write an expression for systems that are not at equilibrium. We call this the **reaction quotient (Q)**. For:

we can write the **reaction quotient expression**:

$$Q_c = \frac{[\text{C}]^c[\text{D}]^d}{[\text{A}]^a[\text{B}]^b}$$

(A quotient is the number obtained from a division.) The expression takes a similar form to that for K_c , and we have made the same simplifications for Q_c as for K_c . It is essential that you appreciate the following points concerning Q_c , K_c and equilibrium.

- K_c involves equilibrium concentrations and so refers to a system *at equilibrium*.
- Q_c refers to systems that are not necessarily at equilibrium.

- K_c can have only one positive value at a particular temperature.
- Q_c can have any positive value at a particular temperature.
- All chemical systems will eventually come to equilibrium.
- When equilibrium is established, $Q_c = K_c$.

In systems where $Q_c \neq K_c$, a comparison of their values can tell us how a system must change to establish equilibrium, as shown in figure 9.4.

FIGURE 9.4 How a system must change to establish equilibrium

$Q_c < K_c$ equilibrium shifts to the right 	$aA + bB \rightleftharpoons cC + dD$ $Q_c = \frac{[C]^c [D]^d}{[A]^a [B]^b}$ $Q_c = K_c$ equilibrium	$Q_c > K_c$ equilibrium shifts to the left 
• If $Q_c < K_c$, the value of Q_c must be made larger so that $Q_c = K_c$. • The value of Q_c is made larger by either increasing the value of the top line or decreasing the value of the bottom line of the expression for Q_c. • The value of the top line is increased if more products are formed. • The value of the bottom line is decreased if more reactants are used up. • Therefore, the reaction mixture composition will move to the right, towards products.		• If $Q_c > K_c$, the value of Q_c must be made smaller so that $Q_c = K_c$. • The value of Q_c is made smaller by either decreasing the value of the top line or increasing the value of the bottom line of the expression for Q_c. • The value of the top line is decreased if more products are used up. • The value of the bottom line is increased if more reactants are formed. • Therefore, the reaction mixture composition will move to the left, towards reactants.

If $Q_c > K_c$, the system reacts to use up products and generate more reactants, thereby decreasing Q_c to the point where it equals K_c ; that is, the system is at equilibrium. If $Q_c < K_c$, the opposite occurs; the system reacts to use up reactants and form more products, thereby increasing Q_c to the point where it equals K_c , again meaning the system is at equilibrium (see section 9.4).

The subscript 'c' in both Q_c and K_c refers to the fact that we are expressing the composition of the reaction mixtures in terms of concentration. For equilibria involving gases, we can also express the composition of the equilibrium mixture in terms of partial pressure, rather than concentration. When we do this, the equilibrium constant expression takes the following form.

$$K_p = \frac{\left(\frac{p_C}{p^\ominus}\right)^c \left(\frac{p_D}{p^\ominus}\right)^d}{\left(\frac{p_A}{p^\ominus}\right)^a \left(\frac{p_B}{p^\ominus}\right)^b}$$

In this expression, p_A , p_B , p_C and p_D are the equilibrium partial pressures of A, B, C and D, respectively, and $p^\ominus$ is the standard pressure.

Because $p^\ominus = 1 \times 10^5$ Pa, we cannot make the simplification that we made earlier for K_c as, in this case, the $p^\ominus$ terms affect the actual value of K_p . Therefore, expressions for K_p must be written in full, including the $p^\ominus$ terms when pressures are measured in Pa. Like K_c , K_p has no units.

WORKED EXAMPLE 9.1

Writing expressions for K_c

Interest is growing in the potential use of hydrogen as an alternative fuel to replace fossil fuels. Ironically, much of the hydrogen produced in the world is derived from the reaction of methane, CH_4 , in natural gas with water, using the forward reaction of the following equilibrium.

Write the expression for K_c for this equilibrium.

Analysis

To write the equilibrium constant expression, we place the concentrations of the products in the numerator and the concentrations of the reactants in the denominator, each raised to the value of the appropriate stoichiometric coefficient. As stated earlier, it is usual to ignore the c° terms as these do not affect the value of K_c .

Solution

The equilibrium constant expression is as follows.

$$K_c = \frac{[\text{CO}][\text{H}_2]^3}{[\text{CH}_4][\text{H}_2\text{O}]}$$

Is our answer reasonable?

Check to see that products are on the top line and that reactants are on the bottom. Also check the superscripts and be sure that they are the same as those in the balanced chemical equation. Notice that we omit the exponent when it is equal to 1.

PRACTICE EXERCISE 9.1

Write the equilibrium constant expression K_c for each of the following equilibria.

- (a) $2\text{NH}_3(\text{g}) \rightleftharpoons \text{N}_2(\text{g}) + 3\text{H}_2(\text{g})$
 (b) $2\text{H}_2(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons 2\text{H}_2\text{O}(\text{g})$

WORKED EXAMPLE 9.2

Writing expressions for K_p

Ethene, C_2H_4 , is a gas that is produced on a massive scale for use in the preparation of polyethene (otherwise known as polyethylene), a plastic that makes up about one-third of the plastics market worldwide. The majority of ethene is prepared from the gas ethane, C_2H_6 , which, when treated with steam at high temperature, reacts as follows.

Write the expression for K_p for this equilibrium.

Analysis

Whenever we write an expression for K_p , we use partial pressures throughout. The equilibrium partial pressures of the products are in the numerator and the equilibrium partial pressures of the reactants are in the denominator.

The coefficients in the equation become exponents of the pressures. Because we are working in SI units, in which $p^\circ = 1 \times 10^5 \text{ Pa}$, we must explicitly divide each term by p° to calculate K_p .

Solution

The expression for K_p for this reaction is as follows.

$$K_p = \frac{\left(\frac{p_{\text{C}_2\text{H}_4}}{p^\circ}\right)\left(\frac{p_{\text{H}_2}}{p^\circ}\right)}{\left(\frac{p_{\text{C}_2\text{H}_6}}{p^\circ}\right)}$$

Is our answer reasonable?

Check to make sure you have written the expression in terms of products over reactants, and not the other way around. Check each superscript against the coefficients in the balanced chemical equation.

PRACTICE EXERCISE 9.2

Using partial pressures, write the equilibrium constant expression for the following equilibrium.

The values of K_p and K_c are related through the following equation.

$$K_p = K_c \left(\frac{1000 RT}{p^\ominus} \right)^{\Delta n_{\text{gas}}}$$

In this equation, Δn_{gas} is the change in the *number of moles of gas* in going from the reactants to the products:

$$\Delta n_{\text{gas}} = (\text{number of moles of gaseous products}) - (\text{number of moles of gaseous reactants})$$

For example, the reaction:

has:

$$\Delta n_{\text{gas}} = 2 - 4 = -2$$

The exact thermodynamic treatment of equilibrium uses **activities**, rather than concentrations or pressures, in the equilibrium expression. Activities are dimensionless quantities that take account of the fact that neither gases in gas mixtures nor species in solution behave ideally; atoms, molecules and ions in the gas or solution phase tend to interact with each other, with the magnitude of the interaction increasing as the concentration increases. Activities can, therefore, be thought of as ‘effective’ concentrations and, as they are dimensionless, this leads to equilibrium constants having no units. Providing that we work at low gas pressures or with dilute solutions, activities approximate concentrations to an acceptable degree. Equilibrium constants obtained using activities, rather than pressures or concentrations, are often called **thermodynamic equilibrium constants**.

Manipulating equilibrium constant expressions

In the chapter on chemical thermodynamics, we manipulated thermochemical equations involving ΔH , ΔS and ΔG values to carry out Hess’s law calculations. These manipulations involved reversing an equation, multiplying the coefficients by some factor, and adding equations. We can carry out similar manipulations of equilibrium equations, which then affect the resulting equilibrium constant expressions. The rules for these are explained below.

Changing the direction of an equilibrium equation

When the direction of an equilibrium equation is reversed, the new equilibrium constant is the reciprocal of the original. As an example, when we reverse the equilibrium:

we obtain:

The equilibrium constant expression for the second reaction is the reciprocal of that for the first, so:

$$K_c' = \frac{1}{K_c}$$

Multiplying the coefficients by a factor

When the coefficients in an equation are multiplied by a factor, the equilibrium constant is raised to a power equal to that factor. For example, if we multiply the coefficients of the equation:

by 2, this gives:

Comparing equilibrium constant expressions, we see that $K_c'' = K_c^2$.

Adding chemical equilibria

When chemical equilibria are added, their equilibrium constants are multiplied. For example, consider the following.

We have numbered the equilibrium constants just to distinguish between them. If we multiply the equilibrium constant expression for K_{c1} by that for K_{c2} , we obtain the equilibrium constant expression for K_{c3} .

$$\frac{\cancel{[\text{N}_2\text{O}]^2}}{[\text{N}_2]^2[\text{O}_2]} \times \frac{[\text{NO}_2]^4}{\cancel{[\text{N}_2\text{O}]^2}[\text{O}_2]^3} = \frac{[\text{NO}_2]^4}{[\text{N}_2]^2[\text{O}_2]^4}$$

Therefore, $K_{c3} = K_{c1} \times K_{c2}$.

PRACTICE EXERCISE 9.3

Under particular conditions of temperature, $K_c = 8.7 \times 10^4$ for the following equilibrium.

Under these conditions what is the value of K_c for the equilibrium below?

PRACTICE EXERCISE 9.4

At 25 °C, the equilibrium constants for the following equilibria are as shown.

Use these data to calculate K_c for the following reaction.

The magnitude of the equilibrium constant

Because the concentrations of the products are always on the top line of the equilibrium constant expression K_c , the value of the equilibrium constant gives us a measure of how far the reaction has proceeded towards completion when equilibrium is reached. For example, the equilibrium:

has:

$$K_c = 9.1 \times 10^{80} \text{ at } 25^\circ\text{C}$$

This means that when there is an equilibrium between these gases:

$$K_c = \frac{[\text{H}_2\text{O}]^2}{[\text{H}_2]^2[\text{O}_2]} = 9.1 \times 10^{80} = \frac{9.1 \times 10^{80}}{1}$$

By writing K_c as a fraction, $\frac{9.1 \times 10^{80}}{1}$, we see that the top line (numerator) of the equilibrium constant expression is enormous compared with the bottom line (denominator), which means that, at equilibrium, the concentration of H_2O has to be enormous compared with the concentrations of H_2 and O_2 . At equilibrium, therefore, most of the hydrogen and oxygen atoms in the system are found in H_2O and very few are present in H_2 and O_2 . The enormous value of K_c tells us that the reaction between H_2 and O_2 goes essentially to completion and that the products are strongly favoured at equilibrium.

The reaction between N_2 and O_2 to give NO :

has a very small equilibrium constant:

$$K_c = 4.8 \times 10^{-31} \text{ at } 25^\circ\text{C}$$

The equilibrium constant expression for this reaction is as follows.

$$K_c = \frac{[\text{NO}]^2}{[\text{N}_2][\text{O}_2]} = 4.8 \times 10^{-31}$$

Since:

$$10^{-31} = \frac{1}{10^{31}}$$

we can write this as:

$$K_c = \frac{[\text{NO}]^2}{[\text{N}_2][\text{O}_2]} = 4.8 \times \frac{1}{10^{31}} = \frac{4.8}{10^{31}}$$

Here the bottom line is huge compared with the top line, so the concentrations of N_2 and O_2 must be very much larger than the concentration of NO at equilibrium. This means that, in a mixture of N_2 and O_2 at this temperature, the amount of NO that is formed is negligible. The reaction hardly proceeds at all towards completion before equilibrium is reached, so the reactants are favoured at equilibrium. This fact is reflected in the composition of the Earth's atmosphere, which consists almost entirely of N_2 and O_2 .

The relationship between the equilibrium constant and the position of equilibrium is summarised in figure 9.5.

FIGURE 9.5 The relationship between the magnitude of K_c and the position of equilibrium

Consider the following equilibrium.

- When K_c is very large ($K_c \gg 1$), there is a large amount of product and very little reactant in the reaction mixture at equilibrium, so we say *the position of equilibrium lies to the right*.
- When $K_c \approx 1$, similar amounts of reactant and product are present at equilibrium.
- When $K_c \ll 1$, the reaction mixture contains a large amount of reactant at equilibrium and very little product, so we say *the position of equilibrium lies to the left*.

One of the ways that we can use equilibrium constants is to compare the extents to which two or more reactions proceed to completion. Take care in making such comparisons, however, because, unless the K values are greatly different, the comparison is valid *only if both reactions have the same number of reactant and product molecules appearing in their balanced chemical equations*. Note also that the magnitude of the equilibrium constant tells us nothing about how rapidly a system reaches equilibrium. For example, we saw previously that K_c for the formation of water from H_2 and O_2 is enormous, yet a mixture of H_2 and O_2 is stable almost indefinitely at room temperature. However, once initiated by a spark, the reaction proceeds rapidly to completion with explosive force.

PRACTICE EXERCISE 9.5

Values of the equilibrium constant for the following reaction at different temperatures are shown in the table below.

T(K)	K_c
300	2.06×10^8
400	1.34×10^5
500	1.73×10^3

If we begin with a closed flask containing $\text{NO}(\text{g})$, $\text{Cl}_2(\text{g})$ and $\text{NOCl}(\text{g})$ at equilibrium at room temperature and heat it, at which temperature — 300 K, 400 K or 500 K — will the greatest amount of NOCl be present in the equilibrium mixture?

Equilibrium constant expressions for heterogeneous systems

In a **homogeneous reaction** — or a **homogeneous equilibrium** — all of the reactants and products are in the same phase. Equilibria among gases are homogeneous because all gases mix freely with each other, so a single phase exists. There are also many equilibria in which reactants and products are dissolved in the same liquid phase.

When more than one phase exists in a reaction mixture, we call it a **heterogeneous reaction**. A common example is the combustion of wood, in which a solid fuel reacts with gaseous oxygen. Another is the thermal decomposition of sodium bicarbonate (baking soda), which occurs when the compound is sprinkled on a fire.

Heterogeneous reactions reach equilibrium just as homogeneous reactions do. If NaHCO_3 is placed in a sealed container so that no CO_2 or H_2O can escape, the gases and solids come to a **heterogeneous equilibrium**.

When we write the equilibrium constant expression for this, and in fact any heterogeneous equilibrium, *we do not include concentrations of pure solids or pure liquids*. Therefore, the equilibrium constant expression becomes:

$$K_c = [\text{H}_2\text{O}(\text{g})][\text{CO}_2(\text{g})]$$

Consider the reverse reaction.

Following the rules we learned earlier about changing the direction of an equilibrium, we write the equilibrium constant expression as follows.

$$K_c = \frac{1}{[\text{H}_2\text{O}(\text{g})][\text{CO}_2(\text{g})]}$$

The reason we do not include pure solids and pure liquids is that the concentration of a pure liquid or solid is unchangeable at a given temperature. In other words, *for any pure liquid or solid at constant temperature, the ratio of amount of substance to volume of substance is constant.* For example, at 25.0 °C and 1.013×10^5 Pa, 1 mol of NaHCO₃ will occupy a volume of 38.9 mL and 2 mol of NaHCO₃ will occupy twice this volume, 77.8 mL, but the *ratio* of the amount to volume (i.e. the molar concentration) remains the same (figure 9.6).

FIGURE 9.6

The concentration of a substance in the solid state is constant. Doubling the amount also doubles the volume, but the ratio of amount to volume remains the same.

For NaHCO₃, the concentration of the solid at 25.0 °C is:

$$c = \frac{n}{V} = \frac{1 \text{ mol}}{0.0389 \text{ L}} = \frac{2 \text{ mol}}{0.0778 \text{ L}} = 25.7 \text{ mol L}^{-1}$$

This is the concentration of NaHCO₃ in the solid, regardless of the size of the solid sample. In other words, the concentration of NaHCO₃(s) is constant at constant temperature, provided there is some of it present in the reaction mixture. Even though neither NaHCO₃(s) nor Na₂CO₃(s) appears in the equilibrium constant expression for the following reaction.

it is important to realise that some NaHCO₃(s) and Na₂CO₃(s) *must* be present in the reaction mixture in order for equilibrium to be established. In any equilibrium, the presence of *all* reactants and products in the balanced chemical equation is necessary at all times after the reaction is initiated in order for the system to reach equilibrium.

WORKED EXAMPLE 9.3

Writing the equilibrium constant expression for a heterogeneous reaction

The air pollutant sulfur dioxide can be removed from a gas mixture by passing it over calcium oxide. The equation for this reaction is as follows.

Write the equilibrium constant expression for K_c for this reaction.

Analysis

The concentrations of the two solids, CaO and CaSO₃, are incorporated into the equilibrium constant, K_c , for the reaction. The only concentration that should appear in the equilibrium constant expression is that of SO₂(g).

Solution

The equilibrium constant expression is simply:

$$K_c = \frac{1}{[\text{SO}_2]}$$

Is our answer reasonable?

The only gaseous component in the reaction mixture is a reactant, and must therefore appear on the bottom line of the expression for K_c , which it does.

PRACTICE EXERCISE 9.6

Write the equilibrium constant expression K_c for each of the following heterogeneous equilibria.

- (a) $\text{S(s)} + \text{Cl}_2(\text{g}) \rightleftharpoons \text{SCl}_2(\text{l})$
- (b) $2\text{NH}_3(\text{g}) + \text{CO}_2(\text{g}) \rightleftharpoons (\text{NH}_2)_2\text{CO(s)} + \text{H}_2\text{O(l)}$
- (c) $3\text{Mg(s)} + \text{N}_2(\text{g}) \rightleftharpoons \text{Mg}_3\text{N}_2(\text{s})$
- (d) $\text{C(s)} + 2\text{H}_2(\text{g}) \rightleftharpoons \text{CH}_4(\text{g})$
- (e) $\text{Ag}^+(\text{aq}) + \text{Cl}^-(\text{aq}) \rightleftharpoons \text{AgCl(s)}$

9.3 Equilibrium and Gibbs energy

LEARNING OBJECTIVE 9.3 Show how equilibrium and Gibbs energy are related.

We introduced the concept of Gibbs energy in the chapter on chemical thermodynamics. In this section, we will outline the relationship between Gibbs energy and chemical equilibrium.

Gibbs energy diagrams

We have seen in the chapter on chemical thermodynamics that the sign of ΔG tells us the direction of spontaneous change in a chemical or physical system, and in this chapter we have seen that the equilibrium constant, K , gives us a measure of how far a spontaneous process will proceed towards completion. Is there then a relationship between Gibbs energy and K ? To answer this question, we will first consider phase changes and then look at chemical reactions.

Phase changes

The freezing of water is an example of a phase change. As liquid water freezes to give ice at atmospheric pressure ($1.013 \times 10^5 \text{ Pa}$), there is only a single temperature at which both water and ice can coexist in equilibrium; that temperature is 0°C , the normal freezing point of water. At any other temperature, the system will consist entirely of either water or ice. One way to gain a better understanding of this is by studying **Gibbs energy diagrams**, which depict how the Gibbs energy changes as we proceed from the 'reactants' to the 'products'.

Let us consider the following phase change at three different temperatures: below 0°C , at 0°C and above 0°C .

We know, from experience that below 0°C the freezing of water will occur spontaneously, while above 0°C water will not freeze — in fact, the reverse process, the melting of ice, will be spontaneous. At 0°C , we will obtain an equilibrium mixture of ice and water. Why is this? Inspection of the three Gibbs energy diagrams in figure 9.7, which correspond to these three situations, provides an answer. Each diagram shows how the Gibbs energy, G , of the system varies with the composition of the system, from pure liquid water on the left of each diagram to pure solid water (ice) on the right. In each case, ΔG for the phase change $\text{H}_2\text{O(l)} \rightarrow \text{H}_2\text{O(s)}$ is equal to $G(\text{H}_2\text{O, s}) - G(\text{H}_2\text{O, l})$.

Below 0°C , we see that the Gibbs energy of the liquid is higher than that of the solid. You have learned that a spontaneous change occurs if the Gibbs energy can decrease. Therefore, the first diagram tells us that the liquid phase, or any mixture of liquid or solid, below 0°C freezes until only the solid is present. This is because the Gibbs energy decreases continuously until all the liquid has frozen. At this point, G is minimised. In other words, ΔG for the phase change $\text{H}_2\text{O(l)} \rightarrow \text{H}_2\text{O(s)}$ is negative at this temperature.

FIGURE 9.7

Gibbs energy diagrams (not to scale) for the phase change between liquid H_2O and solid H_2O at $1.013 \times 10^5 \text{ Pa}$. The horizontal axis represents the amount of $\text{H}_2\text{O(l)}$ and $\text{H}_2\text{O(s)}$ present. At the left of each diagram the system consists entirely of $\text{H}_2\text{O(l)}$, while at the right of each diagram only $\text{H}_2\text{O(s)}$ is present. The green line shows the direction of decreasing G , and hence spontaneous change, in each case.

Above 0°C , we have the opposite situation. The Gibbs energy of the solid is greater than that of the liquid. It therefore decreases in the direction $\text{H}_2\text{O(s)} \rightarrow \text{H}_2\text{O(l)}$, and it continues to decrease until all the solid has melted. This means that ice, or any mixture of ice and liquid water, above 0°C continues to melt until only the liquid is present. ΔG for the melting of ice at this temperature is therefore negative.

Above or below 0°C , the system is unable to establish an equilibrium mixture of liquid and solid. Melting or freezing occurs spontaneously until only one phase is present. However, at 0°C , the Gibbs energies of both $\text{H}_2\text{O(l)}$ and $\text{H}_2\text{O(s)}$ are the same. Therefore, there is no change in Gibbs energy if either melting or freezing occurs, so there is no driving force for either change. Therefore, as long as a system of ice and liquid water is insulated from warmer or colder surroundings, any particular mixture of the two phases is stable and a state of equilibrium exists. Remember that this is a dynamic equilibrium; the ice melts and the water freezes, but both processes occur at the same rate, so no overall change is observed.

Chemical reactions

The Gibbs energy changes that occur in most chemical reactions are more complex than those in phase changes. As an example, let's study a reaction you've seen before — the decomposition of N_2O_4 into NO_2 .

In our previous discussion of chemical equilibrium, we noted that equilibrium in this system can be approached from *either* direction, with the same equilibrium concentrations being achieved provided we begin with the same overall system composition.

Figure 9.8 shows the Gibbs energy diagram for the reaction. Notice that, in going from reactant to product, the Gibbs energy has a minimum, in contrast to the diagrams in figure 9.7; it drops below that of both pure N_2O_4 and pure NO_2 .

FIGURE 9.8

Gibbs energy diagram for the decomposition of $\text{N}_2\text{O}_4(\text{g})$. The minimum on the curve indicates the composition of the reaction mixture at equilibrium. Because $\Delta_r G^\circ$ is positive, the position of equilibrium lies close to the reactants. Not much product forms by the time the system reaches equilibrium.

Why is this? Let's suppose we start with pure $\text{N}_2\text{O}_4(\text{g})$ and allow the reaction to come to equilibrium. As the reaction proceeds, $\text{NO}_2(\text{g})$ molecules start to form, and they mix spontaneously with the remaining $\text{N}_2\text{O}_4(\text{g})$ molecules so that the reaction mixture is homogeneous at all times. This spontaneous mixing has an associated Gibbs energy change, $\Delta_{\text{mix}}G$, that is *negative* at all possible reaction mixture compositions — this simply means that, no matter what the proportions of NO_2 and N_2O_4 are in the reaction mixture, the two gases *always* mix spontaneously as this leads to an increase in entropy of the system relative to the unmixed gases. Hence, the total Gibbs energy change for this gaseous system becomes the Gibbs energy change for the chemical reaction *plus* the Gibbs energy change of mixing. Surprisingly, it is the contribution from $\Delta_{\text{mix}}G$ that leads to the minimum in the Gibbs energy diagram (figure 9.9).

FIGURE 9.9

Gibbs energy diagram for mixing $A(\text{g})$ and $B(\text{g})$ in the hypothetical reaction $A(\text{g}) \rightarrow B(\text{g})$. The minimum corresponds to an equimolar mixture of $A(\text{g})$ and $B(\text{g})$.

If the $\text{NO}_2(\text{g})$ molecules formed in the reaction did not mix with the $\text{N}_2\text{O}_4(\text{g})$ molecules, we would find that the Gibbs energy diagram would simply be a straight line joining $G_{\text{N}_2\text{O}_4(\text{g})}^\ominus$ with $G_{\text{NO}_2(\text{g})}^\ominus$, similar to that shown on the right of figure 9.7. ($\text{H}_2\text{O}(\text{l})$ and $\text{H}_2\text{O}(\text{s})$ are different phases and hence cannot mix.) However, when we add the contribution from $\Delta_{\text{mix}}G$, we always find that a minimum exists in the Gibbs energy curve, with its position depending primarily on the sign and magnitude of $\Delta_r G^\ominus$, the standard Gibbs energy change for the reaction.

We said in the chapter on chemical thermodynamics that $\Delta G = 0$ at equilibrium. Let's now look at this statement with reference to figure 9.10.

FIGURE 9.10

Gibbs energy diagram for the decomposition of $\text{N}_2\text{O}_4(\text{g})$. ΔG for any change in composition of the reaction mixture is given by $G_{\text{final}} - G_{\text{initial}}$.

Again, let us imagine a reaction mixture having the composition indicated by point 1 on the curve and see what happens when the system changes to the composition indicated by point 2. $\Delta_r G$ for this change is $G_2 - G_1$ and is negative — thus, we expect the system at point 1 to undergo a spontaneous change to use up $\text{N}_2\text{O}_4(\text{g})$ and give more $\text{NO}_2(\text{g})$. The reverse change, where the system at point 2 changes to give the system at point 1, does not occur as $\Delta_r G$ for this change, $G_1 - G_2$, is positive. Similarly, we can see that the system at point 3 will change spontaneously to point 4 as $\Delta_r G$ for this change, $G_4 - G_3$, is negative — in other words, $\text{NO}_2(\text{g})$ is consumed and $\text{N}_2\text{O}_4(\text{g})$ is produced. As we approach the minimum in the curve from either direction, $\Delta_r G$ for any small change in composition of the reaction mixture starts becoming less negative, until, when we reach the minimum, $\Delta_r G$ for any infinitesimally small change in composition of the reaction mixture becomes 0, so the system is at equilibrium. Obviously, when the

system has a composition corresponding to the minimum in the Gibbs energy diagram, $\Delta_r G$ for *any* change in composition is positive, so no change in composition occurs.

It is very important that you appreciate the difference between $\Delta_r G$ and $\Delta_r G^\circ$. You will notice from figure 9.8 that $\Delta_r G^\circ$ for the reaction $\text{N}_2\text{O}_4(\text{g}) \rightarrow 2\text{NO}_2(\text{g})$ is positive so you might ask why the reaction proceeds in the forward direction at all. To answer this question, we need to remember that $\Delta_r G^\circ$ is the Gibbs energy change for the conversion of reactants *in their standard states* to products *in their standard states* — in this case, the standard state is the pure gas, each at p° . A sample of $\text{N}_2\text{O}_4(\text{g})$ at p° reacts spontaneously to give a small amount of $\text{NO}_2(\text{g})$; however, the pressure of $\text{NO}_2(\text{g})$ at equilibrium is much less than p° so $\text{N}_2\text{O}_4(\text{g})$ predominates in the equilibrium mixture. A more familiar example is the vaporisation of water, for which ΔG° is $+8.6 \text{ kJ mol}^{-1}$ at 25.0°C . You know from experience that water evaporates spontaneously at 25.0°C ; in this case, the positive value of ΔG° simply means that the partial pressure of water never reaches p° under these conditions when the system is at equilibrium. Similarly, a negative value of ΔG° simply means that the products are present in a large amount at equilibrium, but there are also some reactants in the equilibrium mixture. Hence, we can see that the sign of $\Delta_r G^\circ$ tells us about *the composition of the reaction mixture at equilibrium*. It is the sign of $\Delta_r G$ that tells us whether a particular change in composition of the reaction mixture is spontaneous. Under standard conditions, $\Delta_r G$ and $\Delta_r G^\circ$ are equivalent, but $\Delta_r G$ must be used as the criterion of spontaneity in all other situations. That is, $\Delta_r G^\circ$ should not be used as a criterion of spontaneity *except in the very rare case when the reaction is carried out under standard conditions*.

You might also ask why both the forward and reverse reactions occur spontaneously at equilibrium when the fact that $\Delta_r G = 0$ might suggest that no spontaneous reaction should occur. This apparent contradiction is possibly more a matter of semantics than anything else. Although it is customary to talk of the value of $\Delta_r G$ for a particular reaction, it is more correct, and indeed probably more instructive, to talk of $\Delta_r G$ for a particular *change in the composition of the reaction mixture*. When $\Delta_r G$ is negative, it means that the reaction mixture undergoes a spontaneous change such that reactants are used up and more products are formed in order to minimise the Gibbs energy of the system. Likewise, the term ‘spontaneous reaction’ can be confusing — when any system is at dynamic equilibrium, the forward and reverse reactions both occur spontaneously, with their rates being governed by both their respective activation energies and the temperature, as we will see in the chapter on reaction kinetics. However, there is no spontaneous change in the *composition of the reaction mixture* at equilibrium, and we are referring to this when we talk about whether a particular ‘reaction’ is spontaneous.

The extent to which a reaction proceeds is very sensitive to the magnitude of $\Delta_r G^\circ$. If the $\Delta_r G^\circ$ value for a reaction is reasonably large — about 20 kJ mol^{-1} or more — and positive, almost no reaction will occur at room temperature. On the other hand, the reaction will eventually go almost to completion under the same conditions if $\Delta_r G^\circ$ is both large and negative. From a practical standpoint, then, *the magnitude and sign of $\Delta_r G^\circ$ indicate the extent to which the forward reaction will occur*. However, even a large negative value of $\Delta_r G^\circ$ is no guarantee that the predicted spontaneous reaction will actually be observed. Consider, for example the following equilibrium, which has $\Delta_r G^\circ = -394 \text{ kJ mol}^{-1}$ at 25°C .

The fact that the lead in pencils (which is graphite) can exist in air, which is 21% $\text{O}_2(\text{g})$, suggests that another factor is important in determining whether or not a spontaneous reaction will be observed. That factor is kinetics, the focus of a later chapter.

WORKED EXAMPLE 9.4

Using $\Delta_r G^\circ$ as a predictor of the position of equilibrium

The reaction of SO_2 with O_2 to give SO_3 proceeds according to the following balanced equilibrium equation.

If a mixture of SO_2 and O_2 was allowed to react at 25°C , would the equilibrium position favour reactants or products?

Analysis

To answer this question it is necessary to calculate the magnitude and sign of $\Delta_r G^\circ$ for the reaction. If $\Delta_r G^\circ$ is reasonably large and positive, the reaction will proceed negligibly in the forward direction and only a tiny amount of product will be formed. If it is reasonably large and negative, we can expect to see the reaction go nearly to completion.

Solution

We can calculate $\Delta_r G^\circ$ for the reaction using the data in table 8.7. We sum the $\Delta_f G^\circ$ values of the products, each multiplied by their stoichiometric coefficients, and subtract the $\Delta_f G^\circ$ values of the reactants, each multiplied by their stoichiometric coefficients.

$$\begin{aligned}\Delta_r G^\circ &= (\Delta_f G^\circ_{\text{SO}_3(\text{g})}) - (\Delta_f G^\circ_{\text{SO}_2(\text{g})} + \frac{1}{2} \Delta_f G^\circ_{\text{O}_2(\text{g})}) \\ &= [1 \times (-370.4 \text{ kJ mol}^{-1})] - [(1 \times (-300.4 \text{ kJ mol}^{-1}) + \frac{1}{2} \times (0 \text{ kJ mol}^{-1}))] \\ &= -70.0 \text{ kJ mol}^{-1}\end{aligned}$$

Because $\Delta_r G^\circ$ is large and negative, we expect the reaction to proceed essentially to completion at this temperature.

PRACTICE EXERCISE 9.7

Use the data in table 8.7 to show that the following equilibrium should favour products at 25 °C.

Given that $\text{NO}_2(\text{g})$ is red-brown in colour, why do you think that bottles of aqueous ammonia ($\text{NH}_3(\text{g})$ dissolved in water) do not show a red-brown colour above the liquid?

The relationship between $\Delta_r G^\circ$ and K

In the preceding discussion, we learned that the position of equilibrium is determined by the sign and magnitude of $\Delta_r G^\circ$. We also learned that the direction of spontaneous change in a reaction mixture depends on where the system composition stands relative to the minimum on the Gibbs energy curve. Thus, spontaneous change in the forward direction only occurs if it lowers the Gibbs energy (i.e. if $\Delta_r G$ for the change in question is negative).

Quantitatively, the relationship between $\Delta_r G$ and $\Delta_r G^\circ$ is expressed by the following equation, which is derived from the ideal gas equation (see the chapter on gases) where R is the gas constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$), T is the temperature in kelvin and $\ln Q$ is the natural logarithm of the reaction quotient.

$$\Delta_r G = \Delta_r G^\circ + RT \ln Q$$

For gaseous reactions, Q_p is calculated using partial pressures expressed in Pa, while, for reactions in solution, Q_c is calculated from molar concentrations. This equation is extremely powerful, as it allows us to predict the direction of the spontaneous change in a reaction mixture if we know $\Delta_r G^\circ$ and the composition of the mixture. This is illustrated in worked example 9.5.

WORKED EXAMPLE 9.5

Determining the direction of spontaneous change

The forward reaction of the equilibrium $2\text{NO}_2(\text{g}) \rightleftharpoons \text{N}_2\text{O}_4(\text{g})$ has $\Delta_r G^\circ = -5.40 \text{ kJ mol}^{-1}$ at 298 K. A mixture of the two gases was prepared such that, at the instant of mixing, the partial pressure of both gases was $5.70 \times 10^4 \text{ Pa}$. Is the system at equilibrium under these conditions? If not, how must the composition of the reaction mixture change to reach equilibrium?

Analysis

We are first asked if the system is at equilibrium. We can determine this by calculating the value of $\Delta_r G$ using the equation $\Delta_r G = \Delta_r G^\circ + RT \ln Q$. This will involve us calculating the value of Q and we will therefore need to use the expression for Q_p . If the value of $\Delta_r G$ is zero, then the system will be at equilibrium. If the system is not at equilibrium, we know that, if the value of $\Delta_r G$ is negative, the forward reaction will be spontaneous, and if the value of $\Delta_r G$ is positive, the reverse reaction will be spontaneous.

Solution

First, we need the correct form for the reaction quotient expression. Expressed in terms of partial pressures in Pa, this is:

$$Q_p = \frac{\frac{p_{\text{N}_2\text{O}_4}}{p^\ominus}}{\left(\frac{p_{\text{NO}_2}}{p^\ominus}\right)^2}$$

Therefore, the equation we use is as follows.

$$\Delta_r G = \Delta_r G^\ominus + RT \ln \left(\frac{\frac{p_{\text{N}_2\text{O}_4}}{p^\ominus}}{\left(\frac{p_{\text{NO}_2}}{p^\ominus}\right)^2} \right)$$

Now we list the data that we will substitute into this equation, remembering to use SI units throughout.

$$\begin{array}{lll} \Delta_r G^\ominus = -5.40 \text{ kJ mol}^{-1} = -5.40 \times 10^3 \text{ J mol}^{-1} & R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1} \\ T = 298 \text{ K} & p_{\text{N}_2\text{O}_4} = p_{\text{NO}_2} = 5.70 \times 10^4 \text{ Pa} & p_{\text{O}_2} = 1 \times 10^5 \text{ Pa} \end{array}$$

Substituting quantities gives the following.

$$\begin{aligned} \Delta_r G &= -5.40 \times 10^3 \text{ J mol}^{-1} + (8.314 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K}) \ln \left(\frac{\frac{5.70 \times 10^4}{1 \times 10^5}}{\left(\frac{5.70 \times 10^4}{1 \times 10^5}\right)^2} \right) \\ &= -5.40 \times 10^3 \text{ J mol}^{-1} + (8.314 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K})(0.562) \\ &= -5.40 \times 10^3 \text{ J mol}^{-1} + 1.39 \times 10^3 \text{ J mol}^{-1} \\ &= -4.01 \times 10^3 \text{ J mol}^{-1} \end{aligned}$$

Since $\Delta_r G$ is negative, change in the forward direction will be spontaneous and this will occur until the system reaches equilibrium. The composition of the reaction mixture changes to decrease the amount of NO_2 and increase the amount of N_2O_4 .

Is our answer reasonable?

There is no simple check other than ensuring you have carried out the arithmetic correctly. Remember also to use SI units throughout so that your final answer is in units of J mol^{-1} .

PRACTICE EXERCISE 9.8

For the forward reaction of the equilibrium $2\text{HI} \rightleftharpoons \text{H}_2 + \text{I}_2$:

$$\Delta_r G_{298\text{K}}^\ominus = 15 \text{ kJ mol}^{-1}$$

The partial pressures of HI , H_2 and I_2 in a mixture of the gases were $1.00 \times 10^4 \text{ Pa}$, $6.50 \times 10^4 \text{ Pa}$ and $4.25 \times 10^4 \text{ Pa}$, respectively. In which direction would you expect spontaneous change to occur in this system?

At this point, we have two seemingly separate criteria for determining whether or not a system is at equilibrium. We know that, when $\Delta_r G = 0$ for an infinitesimal change in composition of a reaction mixture, or when $Q = K$ for a particular set of reaction conditions, the system is at equilibrium. We will now substitute these conditions into the following equation.

$$\Delta_r G = \Delta_r G^\ominus + RT \ln Q$$

If $\Delta_r G = 0$, $Q = K$, and thus:

$$0 = \Delta_r G^\ominus + RT \ln K$$

and therefore:

$$\Delta_r G^\ominus = -RT \ln K$$

This is one of the most important equations in thermodynamics, if not all of chemistry. It allows us to use tabulated values of $\Delta_r G^\circ$ to calculate the equilibrium constant for a particular reaction, and, conversely, we can use measured values of the equilibrium constant to determine $\Delta_r G^\circ$ for the forward reaction of the equilibrium. *K in the equation $\Delta_r G^\circ = -RT \ln K$ corresponds to K_p for reactions involving gases and K_c for reactions involving species in solution.*

From this equation you can see that, if $\Delta_r G^\circ$ for a reaction is large and negative, $\ln K$ must be large and positive, and hence K is large — the equilibrium position lies towards products. Similarly, if $\Delta_r G^\circ$ is large and positive, $\ln K$ must be negative, and hence K is small — the equilibrium position lies towards reactants.

WORKED EXAMPLE 9.6

Equilibrium constants

The brownish haze associated with air pollution is caused by nitrogen dioxide, NO_2 , a red-brown gas (figure 9.11). Nitric oxide, NO , is formed in car engines and some of it escapes into the air, where it is oxidised to NO_2 by oxygen.

The value of K_p for this equilibrium is 1.7×10^{12} at 25°C . What is $\Delta_r G^\circ$ for the forward reaction at this temperature?

FIGURE 9.11

The atmospheric pollutant nitrogen dioxide, NO_2 , produces a characteristic brown haze.

Analysis

We can calculate $\Delta_r G^\circ$ from the given value of K_p using the following relationship.

$$\Delta_r G^\circ = -RT \ln K_p$$

We'll need the following data.

$$R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1} \quad T = 298 \text{ K} \quad K_p = 1.7 \times 10^{12}$$

Solution

Substituting these values into the equation, we obtain the following.

$$\begin{aligned} \Delta_r G^\circ &= -(8.314 \text{ J mol}^{-1} \text{ K}^{-1} \times 298 \text{ K}) \ln(1.7 \times 10^{12}) \\ &= -(8.314 \text{ J mol}^{-1} \text{ K}^{-1} \times 298 \text{ K})(28.16) \\ &= -7.0 \times 10^4 \text{ J mol}^{-1} \end{aligned}$$

In kilojoules per mole, $\Delta_r G^\circ = -7.0 \times 10^1 \text{ kJ mol}^{-1}$.

Is our answer reasonable?

The large value of K_p tells us that the position of equilibrium lies far to the right, which means $\Delta_r G^\circ$ must be large and negative. Therefore, the answer, -70 kJ mol^{-1} , seems reasonable.

PRACTICE EXERCISE 9.9

The equilibrium $\text{N}_2(\text{g}) + 3\text{H}_2(\text{g}) \rightleftharpoons 2\text{NH}_3(\text{g})$ has $K_p = 6.9 \times 10^5$ at 25.0°C . Calculate $\Delta_r G^\circ$ for the forward reaction.

WORKED EXAMPLE 9.7

Equilibrium constants

Sulfur dioxide, which is sometimes present in polluted air, reacts with oxygen when it passes over the catalyst in a car's catalytic converter, producing the acidic oxide SO_3 .

$\Delta_r G^\circ = -1.40 \times 10^2 \text{ kJ mol}^{-1}$ for the forward reaction at 25°C . What is the value of K_p at this temperature?

Analysis

As in worked example 9.6, we use the equation below.

$$\Delta_r G^\circ = -RT \ln K_p$$

Our data are:

$$R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1} \quad T = 298 \text{ K} \quad \Delta_r G^\circ = -1.40 \times 10^2 \text{ kJ mol}^{-1} = -1.40 \times 10^5 \text{ J mol}^{-1}$$

To calculate K_p , it is easiest to rearrange the equation and solve for $\ln K_p$.

$$\ln K_p = \frac{-\Delta_r G^\circ}{RT}$$

Solution

Substituting values gives the following.

$$\ln K_p = \frac{-(-1.40 \times 10^5 \text{ J mol}^{-1})}{(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K})} = +56.5$$

To calculate K_p , we take the antilogarithm:

$$K_p = e^{56.5} = 3 \times 10^{24}$$

Notice that we have expressed the answer to only one significant figure. This is because, as we saw in the chapter on the language of chemistry, when taking a logarithm, the number of digits written after the decimal place equals the number of significant figures in the number. Conversely, the number of significant figures in the antilogarithm equals the number of digits after the decimal in the logarithm.

Is our answer reasonable?

The value of $\Delta_r G^\circ$ is large and negative, so the position of equilibrium should favour the products. The large value of K_p is therefore reasonable.

PRACTICE EXERCISE 9.10

The forward reaction in the equilibrium:

has $\Delta_r G^\circ_{298 \text{ K}} = -257.1 \text{ kJ mol}^{-1}$. What is the value of K_p at this temperature?

We can use thermodynamic data collected at 25 °C to calculate good approximations of the values of equilibrium constants at temperatures other than 25 °C. This is because the values of $\Delta_r H^\circ$ and $\Delta_r S^\circ$ do not change much with temperature, so we can use these to calculate $\Delta_r G^\circ$ and, hence, K at the new temperature.

WORKED EXAMPLE 9.8

Calculating K at temperatures other than 25 °C

Nitrous oxide, N_2O , is an anaesthetic known as laughing gas because it sometimes relieves patients of their inhibitions. The decomposition of nitrous oxide has $K_p = 1.8 \times 10^{36}$ at 25 °C. The equation is:

For this reaction, $\Delta_r H^\circ = -163 \text{ kJ mol}^{-1}$ and $\Delta_r S^\circ = +148 \text{ J mol}^{-1} \text{ K}^{-1}$. What is the approximate value of K_p for this reaction at 40 °C?

Analysis

We need a value of $\Delta_r G^\circ$ at 40 °C (313 K), which we can represent as $\Delta_r G^\circ_{313 \text{ K}}$. We can estimate $\Delta_r G^\circ_{313 \text{ K}}$ using the values of $\Delta_r H^\circ$ and $\Delta_r S^\circ$ measured at 25 °C and the equation $\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ$.

Hence:

$$\Delta_r G_{313\text{ K}}^\circ \approx \Delta_r H_{298\text{ K}}^\circ - (313\text{ K})\Delta_r S_{298\text{ K}}^\circ$$

Solution

Substituting the values of $\Delta_r H^\circ$ and $\Delta_r S^\circ$ provided in the question gives the following.

$$\Delta_r G_{313\text{ K}}^\circ \approx -1.63 \times 10^5 \text{ J mol}^{-1} - (313\text{ K})(+148 \text{ J mol}^{-1} \text{ K}^{-1})$$

Notice that we have converted kJ mol^{-1} to J mol^{-1} . Performing the arithmetic gives the following.

$$\Delta_r G_{313\text{ K}}^\circ \approx -2.09 \times 10^5 \text{ J mol}^{-1}$$

The next step is to use this value of $\Delta_r G_{313\text{ K}}^\circ$ to calculate K_p . First, let's solve for $\ln K_p$.

$$\ln K_p = \frac{-\Delta_r G_{313\text{ K}}^\circ}{RT}$$

Inserting the values $R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1}$ and $T = 313 \text{ K}$ gives the following.

$$\ln K_p = \frac{2.09 \times 10^5 \text{ J mol}^{-1}}{(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(313 \text{ K})} = +80.3$$

Taking the antilogarithm:

$$K_p = e^{80.3} = 7 \times 10^{34}$$

Notice that, at this higher temperature, $\text{N}_2\text{O}(\text{g})$ is actually slightly more stable with respect to dissociation into its elements than at 25°C , as reflected in the slightly smaller value for the equilibrium constant for its decomposition.

Is our answer reasonable?

As we will learn in the next section, the equilibrium constant for an exothermic reaction decreases with increasing temperature. Therefore, the answer is reasonable.

PRACTICE EXERCISE 9.11

The forward reaction in the equilibrium below has a standard enthalpy of reaction of $-92.4 \text{ kJ mol}^{-1}$ and a standard entropy of reaction of $-198.3 \text{ J mol}^{-1} \text{ K}^{-1}$ at 25°C .

Estimate the value of K_p for this equilibrium at 50°C .

9.4 How systems at equilibrium respond to change

LEARNING OBJECTIVE 9.4 Predict how an equilibrium will respond to change.

We have seen that the composition of a reaction mixture changes in the direction of decreasing Gibbs energy until it reaches equilibrium. What we have not yet discussed is how a system at equilibrium behaves when a change is made that perturbs the system. Such a change might be a change in temperature, volume or pressure of the system, addition or removal of chemical species to or from the system, or addition of a catalyst. Such knowledge is important as it may allow us to optimise reaction conditions to obtain the maximum amount of a desired product.

Le Châtelier's principle

One of the first to study in detail the effect of change on a system at equilibrium was the French chemist Henri Le Châtelier (1850–1936) who proposed what came to be known as **Le Châtelier's principle**. This states that, *if an outside influence upsets an equilibrium, the system undergoes a change in a direction that counteracts the disturbing influence and, if possible, returns the system to equilibrium*. This is often interpreted as meaning that, if a chemical species is added to one side of an equilibrium, the equilibrium position will shift to use up the added species. Le Châtelier's principle is useful as a predictive tool in

many circumstances. Consider, for example, the following equilibrium for which the forward reaction is exothermic under standard conditions.

According to Le Châtelier's principle, addition of $\text{NO}_2(\text{g})$ to the reaction mixture at equilibrium will result in the production of more $\text{N}_2\text{O}_4(\text{g})$, as the equilibrium position will move to the right to use up the added $\text{NO}_2(\text{g})$. Using similar reasoning, we can see that addition of $\text{N}_2\text{O}_4(\text{g})$ to the reaction mixture at equilibrium will result in the production of more $\text{NO}_2(\text{g})$. If we take the above system at equilibrium and increase the volume of the container in which the reaction is occurring, this will have the effect of decreasing the pressure in the container. To counteract this disturbing influence, we would predict, from Le Châtelier's principle, that the equilibrium position will move to the left to produce more $\text{NO}_2(\text{g})$, as this will minimise the pressure decrease by maximising the amount of gas in the container. Finally, as the forward reaction is exothermic, it gives out heat, which we can therefore consider as being a 'product' of the reaction; in other words, we can write the equation as follows.

If we now take the system at equilibrium and increase its temperature, the equilibrium position will shift to the left to use up the added heat, resulting in the production of more $\text{NO}_2(\text{g})$.

However, predictions made on the basis of Le Châtelier's principle can be incorrect if it is not applied correctly; in fact, adding a reactant or product to a system at equilibrium does not necessarily result in a shift of the equilibrium position. For example, addition of $\text{AgCl}(\text{s})$ to a saturated aqueous solution of AgCl in equilibrium with excess $\text{AgCl}(\text{s})$ does not result in an increase in $[\text{Ag}^+(\text{aq})]$ and $[\text{Cl}^-(\text{aq})]$ in the solution (we will see the reason why below). Most importantly, Le Châtelier's principle does not explain *why* the equilibrium position does or does not change on perturbation of the equilibrium. Therefore, it is better to consider the perturbation of systems at equilibrium by comparison of the values of the equilibrium constant, K , and the reaction quotient, Q , for a particular chemical process. We start with a system at equilibrium for which $Q = K$. We then perturb the system and consider how this alters the value of Q and how the system must alter to make Q again equal to K . We will consider a number of different scenarios using this method.

Adding or removing a product or reactant

The addition or removal of a product or reactant instantaneously alters the concentration of that species in the reaction mixture, provided that the reactant or product in question is not a pure solid or liquid. When this happens, the value of Q changes so that $Q \neq K$ and the system is no longer at equilibrium. We will illustrate this using an equilibrium involving coordination complexes (see the chapter on transition metal chemistry).

$[\text{Cu}(\text{OH}_2)_4]^{2+}$ is blue and $[\text{CuCl}_4]^{2-}$ is yellow; mixtures of the two have an intermediate colour and, therefore, appear blue-green, as illustrated in figure 9.12.

What happens when we increase the chloride ion concentration by adding a small volume of a concentrated aqueous solution of HCl to the solution at equilibrium? To answer this question, we need to write the expression for Q , the reaction quotient. Recalling from the section on heterogeneous systems that H_2O does not appear in the expression for Q because it is a pure liquid, we can write the following.

$$Q = \frac{[\text{CuCl}_4^{2-}]}{[\text{Cu}(\text{OH}_2)_4^{2+}][\text{Cl}^-]^4}$$

Only reactants and products that appear in the expression for Q can influence the position of the equilibrium. We can see that, immediately after adding the HCl solution, the $[\text{Cl}^-]$ in the solution increases. This has the effect of *decreasing* the value of Q , because $[\text{Cl}^-]$ appears on the bottom line of the reaction quotient expression. Thus, we now have the situation where the solution is no longer at equilibrium and $Q < K$. Obviously, to restore equilibrium, we must alter the concentrations of the reactants and products to increase Q so that it again equals K . (Remember that K is a constant at constant temperature, so we must alter the value of Q .) With reference to the expression for Q , there are two ways that we can increase its value; we can make the top line larger, by increasing the amount and, therefore, concentration of $[\text{CuCl}_4]^{2-}$,

or we can make the bottom line smaller, by decreasing the amounts and, therefore, concentrations of $[\text{Cu}(\text{OH}_2)_4]^{2+}$ and Cl^- . These, in fact, equate to the same thing — a shift of the equilibrium position towards *products*. The pronounced green colour of the solution at the right of figure 9.12 shows that this is in fact what happens; there is more yellow $[\text{CuCl}_4]^{2-}$ and less blue $[\text{Cu}(\text{OH}_2)_4]^{2+}$ present in the solution after the system re-establishes equilibrium following addition of concentrated $\text{HCl}(\text{aq})$.

FIGURE 9.12

The effect of concentration changes on the position of equilibrium. The solution in the centre contains a mixture of blue $[\text{Cu}(\text{OH}_2)_4]^{2+}$ and yellow $[\text{CuCl}_4]^{2-}$, so it has a blue-green colour. The tube on the right contains some of the same mixture after the addition of concentrated HCl . It has a more pronounced green colour because the equilibrium is shifted towards $[\text{CuCl}_4]^{2-}$. At the left is some of the original mixture after removal of some Cl^- as insoluble AgCl and subsequent filtering. It is blue because the equilibrium has shifted towards $[\text{Cu}(\text{OH}_2)_4]^{2+}$.

We can use the same reasoning to predict the effect of removing a reactant from the system. If we take the system at equilibrium and add a small volume of a concentrated solution of silver perchlorate, AgClO_4 , the Ag^+ ions react with free Cl^- ions to form insoluble $\text{AgCl}(\text{s})$, thus effectively removing Cl^- ions from the mixture. Again, looking at our expression for Q , we can see that lowering $[\text{Cl}^-]$ makes the bottom line of the reaction quotient expression smaller, which leads to an instantaneous *increase* in the value of Q . The system is no longer at equilibrium, and Q is greater than K . The concentrations of reactants and products must, therefore, change to *decrease* the value of Q so that it again is equal to K . This may be achieved by either decreasing the value of the top line of the reaction quotient expression (lowering the amount and, therefore, concentration of $[\text{CuCl}_4]^{2-}$) or increasing the value of the bottom line (increasing the amounts and, therefore, concentrations of $[\text{Cu}(\text{OH}_2)_4]^{2+}$ and Cl^-). Again, figure 9.12 shows that the colour of the solution becomes more blue following removal of some Cl^- as insoluble AgCl (and subsequent filtering), consistent with the production of more $[\text{Cu}(\text{OH}_2)_4]^{2+}$.

This treatment is purely qualitative but allows us to predict the manner in which an equilibrium shifts *without having to know the actual values of K and Q* . See figure 9.4 for a summary of this treatment.

An important example already alluded to (in our discussion of Le Châtelier's principle) is that of a sparingly soluble ionic salt in equilibrium with its constituent aqueous ions. Consider, for instance, a saturated aqueous solution of silver chloride, AgCl , in the presence of solid AgCl . The relevant equilibrium is as follows.

We write the reaction quotient expression as shown, remembering that pure solids and pure liquids do not appear in the expressions for either K or Q .

$$Q = [\text{Ag}^+][\text{Cl}^-]$$

What would be the effect of adding more solid AgCl to the equilibrium mixture? $\text{AgCl}(\text{s})$ does not appear in the expression for Q so addition of $\text{AgCl}(\text{s})$ has *no effect* on the position of equilibrium.

Le Châtelier's principle can lead to incorrect predictions in problems of this type (in this case, it would predict an increase in $[\text{Ag}^+]$ and $[\text{Cl}^-]$), and it is preferable to use the comparison of Q and K to determine the effect of adding or removing reactants or products.

We will see more of these types of problems in the chapter on solutions and solubility.

Changing the pressure in gaseous reactions

There are two ways of changing the total pressure in a gaseous reaction mixture at equilibrium:

- changing the volume of the system
- adding an inert gas.

We will look at these in turn.

Changing the volume of the system

Changing the volume of a gas mixture at equilibrium changes both the concentrations and partial pressures of the reactant and product gases, and this can alter the value of Q . Increasing the volume will decrease the partial pressures of all gases and therefore decrease the total pressure, whereas decreasing the volume will have the opposite effect. We will consider the effect of increasing the volume of the reaction vessel on the equilibrium position for the formation of ammonia from nitrogen and hydrogen.

For this equilibrium, we would normally write Q_p as follows.

$$Q_p = \frac{\left(\frac{p_{\text{NH}_3}}{p^\ominus}\right)^2}{\left(\frac{p_{\text{N}_2}}{p^\ominus}\right)\left(\frac{p_{\text{H}_2}}{p^\ominus}\right)^3}$$

However, in this case, it is more instructive to use Q_c to determine the effect of changing the volume of the reaction mixture. Hence, we can write:

$$Q_c = \frac{[\text{NH}_3]^2}{[\text{N}_2][\text{H}_2]^3}$$

Remembering that $c = \frac{n}{V}$, we can rewrite this as shown.

$$Q_c = \frac{\left(\frac{n_{\text{NH}_3}}{V}\right)^2}{\frac{n_{\text{N}_2}}{V} \times \left(\frac{n_{\text{H}_2}}{V}\right)^3} = \frac{\frac{(n_{\text{NH}_3})^2}{V^2}}{\frac{n_{\text{N}_2}}{V} \times \frac{(n_{\text{H}_2})^3}{V^3}}$$

As $\frac{n}{V}$ is the same as nV^{-1} , we can simplify this expression as follows. (See the Maths for Chemistry section at the end of this chapter for help with simplifying complex fractions.)

$$\begin{aligned} Q_c &= \frac{\frac{(n_{\text{NH}_3})^2}{V^2}}{\frac{n_{\text{N}_2}}{V} \times \frac{(n_{\text{H}_2})^3}{V^3}} = \frac{(n_{\text{NH}_3})^2 V^{-2}}{(n_{\text{N}_2}) V^{-1} \times (n_{\text{H}_2})^3 V^{-3}} = \frac{(n_{\text{NH}_3})^2}{(n_{\text{N}_2})(n_{\text{H}_2})^3} \times \frac{V^{-2}}{V^{-4}} \\ &= \frac{(n_{\text{NH}_3})^2}{n_{\text{N}_2}(n_{\text{H}_2})^3} \times V^2 \end{aligned}$$

While this may look somewhat daunting, the important point is that we have shown that the value of Q_c is proportional to V^2 — in other words, when we increase V , we increase the value of Q . Increasing the volume of the reaction vessel, V , will increase the value of Q , making $Q > K$. The system will then change in a way that makes the value of Q smaller; that is, making the value of the top line of the reaction quotient expression smaller by reducing n_{NH_3} or making the value of the bottom line larger by increasing n_{N_2} and n_{H_2} . This means that, when the volume of the reaction mixture is increased, the

reaction mixture composition shifts towards reactants, resulting in the production of more N_2 and H_2 . Increasing the volume of the reaction vessel in gas phase reactions which have a larger number of reactant molecules than product molecules will always result in a shift of the reaction mixture composition towards reactants.

Consider the following equilibrium.

A similar treatment to that above shows that:

$$Q_c = \frac{\left(\frac{n_{\text{HI}}}{V}\right)^2}{\frac{n_{\text{H}_2}}{V} \times \frac{n_{\text{I}_2}}{V}} = \frac{\frac{(n_{\text{HI}})^2}{V^2}}{\frac{n_{\text{H}_2}}{V} \times \frac{n_{\text{I}_2}}{V}} = \frac{(n_{\text{HI}})^2 V^{-2}}{n_{\text{H}_2} V^{-1} \times n_{\text{I}_2} V^{-1}} = \frac{(n_{\text{HI}})^2}{n_{\text{H}_2} n_{\text{I}_2}} \times \frac{V^{-2}}{V^{-2}} = \frac{(n_{\text{HI}})^2}{n_{\text{H}_2} n_{\text{I}_2}}$$

In this case, the value of Q_c *does not depend on* V . Thus, increasing or decreasing the volume of this reaction mixture has *no effect* on the position of the equilibrium. This is always the case when there is the same number of moles of gas on each side of the equation in a gas phase reaction.

The final example uses the following familiar equilibrium.

To look at the effect of increasing the volume of the system at equilibrium, we use the same treatment as above to give the following.

$$Q_c = \frac{\left(\frac{n_{\text{NO}_2}}{V}\right)^2}{\frac{n_{\text{N}_2\text{O}_4}}{V}} = \frac{\frac{(n_{\text{NO}_2})^2}{V^2}}{\frac{n_{\text{N}_2\text{O}_4}}{V}} = \frac{(n_{\text{NO}_2})^2 V^{-2}}{n_{\text{N}_2\text{O}_4} V^{-1}} = \frac{(n_{\text{NO}_2})^2}{n_{\text{N}_2\text{O}_4}} \times \frac{V^{-2}}{V^{-1}} = \frac{(n_{\text{NO}_2})^2}{n_{\text{N}_2\text{O}_4}} \times \frac{1}{V}$$

We can see that the value of Q_c is *inversely proportional to* V — in other words, as the volume increases, the value of Q_c decreases so $Q < K$. To re-establish equilibrium, the system will respond to increase the value of Q ; that is, making the value of the top line of the reaction quotient expression larger by increasing n_{NO_2} or making the value of the bottom line smaller by decreasing $n_{\text{N}_2\text{O}_4}$. Both scenarios correspond to an equilibrium shift towards products following an increase in the volume of the reaction mixture. Increasing the volume of the reaction vessel in gas phase reactions which have a larger number of product molecules than reactant molecules will always result in a shift of the equilibrium towards products.

We can summarise the above three examples by stating that:

$$Q_c \propto V^{-\Delta n_{\text{gas}}}$$

where $\propto$ means ‘is proportional to’ and Δn_{gas} = (number of moles of gaseous products) – (number of moles of gaseous reactants).

Table 9.2 outlines the three possibilities for an increase in volume of a reaction vessel containing a system initially at equilibrium.

TABLE 9.2 Effect on equilibrium of a change in the volume of the reaction vessel

Δn_{gas}	$V^{-\Delta n_{\text{gas}}}$	As V increases	Q_c versus K_c	Direction for equilibrium
+ve	<1	Q_c decreases	$Q_c < K_c$	Towards products
0	1	Q_c is constant	$Q_c = K_c$	No change
–ve	>1	Q_c increases	$Q_c > K_c$	Towards reactants

Adding an inert gas at constant volume

Adding an inert gas (which, by definition, is unreactive) to a gaseous reaction mixture at equilibrium increases the total pressure of the system, but *does not alter the position of equilibrium*. To prove this, let’s consider adding the inert gas helium to the $\text{N}_2\text{O}_4/\text{NO}_2$ equilibrium mixture. As helium does not react with either the reactant or product, our expressions for both Q_c and Q_p

for this equilibrium remain unchanged in the presence of helium. Hence, as there is no term for $[\text{He}]$ or p_{He} in the expressions for Q_c or Q_p , respectively, addition of helium *cannot have any effect on the position of equilibrium* as it cannot alter the value of Q . This is true in all cases where the total pressure of the reaction mixture is altered by addition of an inert gas.

Changing the temperature of a reaction mixture

The value of the equilibrium constant, K , for any reaction can be changed only by altering the temperature of the reaction mixture. We can predict the effect of changing the temperature of a reaction mixture at equilibrium from the sign of $\Delta_r H^\circ$ for the forward reaction. Jacobus Henricus van't Hoff (figure 9.13) (1852–1911) was a Dutch chemist who, in 1901, was awarded the first Nobel Prize in chemistry for his significant contributions to chemical thermodynamics. However, possibly his most remarkable achievement was in organic chemistry, with his realisation that carbon atoms bearing four attached atoms adopt a tetrahedral, rather than a square planar, arrangement. What made this so remarkable was that he published this work at the age of 22.

The **van't Hoff equation** states:

$$\frac{d\ln K}{dT} = \frac{\Delta_r H^\circ}{RT^2}$$

The left-hand side of this equation is simply the slope of a plot of $\ln K$ versus T . As both R and T on the right-hand side are always positive, the slope of the plot of $\ln K$ versus T will therefore have the same sign as that of $\Delta_r H^\circ$ (figure 9.14).

FIGURE 9.13

Jacobus Henricus van't Hoff (1852–1911), namesake of the van't Hoff equation

FIGURE 9.14

Plots of $\ln K$ versus T for situations where $\Delta_r H^\circ$ is: (a) positive and (b) negative

For example, the reaction of nitrogen and hydrogen to form ammonia is exothermic so the graph of $\ln K$ versus T will have a negative slope.

This means that, as we increase the temperature, $\ln K$, and hence K , will *decrease*. Thus, the production of ammonia becomes less favourable as we increase the temperature of the reaction mixture.

We can make the following generalisations about the effect of temperature changes on the position of equilibrium.

- For an *endothermic* reaction ($\Delta_r H$ is positive), increasing the temperature *increases* the value of K , the equilibrium constant, so *products* become more favoured (figure 9.13a).
- For an *exothermic* reaction ($\Delta_r H$ is negative), increasing the temperature *decreases* the value of K , the equilibrium constant, so *reactants* become more favoured (figure 9.13b).

Figure 9.15 demonstrates the temperature dependence of the equilibrium involving complexes of Cu^{2+} discussed previously, for which the forward reaction is endothermic. Cooling the reaction mixture *decreases* the equilibrium constant, giving a shift towards the reactants; heating the mixture *increases* the equilibrium constant, so more product is formed.

FIGURE 9.15

The effect of temperature on the equilibrium:

The tube in the centre shows an equilibrium mixture of the two complexes. When the solution is cooled in ice (left), the equilibrium shifts towards the blue $[\text{Cu}(\text{OH}_2)_4]^{2+}$. When heated in boiling water (right), the equilibrium shifts towards the yellow $[\text{CuCl}_4]^{2-}$. This behaviour indicates that the reaction is endothermic in the forward direction.

This illustrates the qualitative use of the van't Hoff equation. We can also use it quantitatively; if we know the value of an equilibrium constant, K , at a particular temperature, T_1 , we can use the following form of the van't Hoff equation to determine the value of the equilibrium constant at another temperature, T_2 .

$$\ln K_{T_2} - \ln K_{T_1} = \frac{-\Delta_r H^\circ}{R} \left(\frac{1}{T_2} - \frac{1}{T_1} \right)$$

This assumes that $\Delta_r H^\circ$ is constant over the temperature range T_1 to T_2 .

Addition of a catalyst

Catalysts are substances that affect the rates of chemical reactions without actually being used up. While addition of a catalyst helps bring a system to chemical equilibrium more rapidly, the position of equilibrium is not affected. This is because catalysts are not included in the overall balanced chemical equation for the reaction, and so do not appear in the expression for the reaction quotient, Q .

WORKED EXAMPLE 9.9

Predicting equilibrium shifts

The chemical reaction $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2\text{NO}_2(\text{g})$ is endothermic, with $\Delta_r H^\circ = +56.9 \text{ kJ mol}^{-1}$. If we start with an equilibrium mixture of $\text{N}_2\text{O}_4(\text{g})$ and $\text{NO}_2(\text{g})$, how is the amount of NO_2 in the mixture affected by: (a) adding N_2O_4 , (b) lowering the pressure by increasing the volume of the container, (c) raising the temperature and (d) adding a catalyst to the system? Which of these changes alters the value of K_c ?

Analysis

We are taking an equilibrium mixture of $\text{N}_2\text{O}_4(\text{g})$ and $\text{NO}_2(\text{g})$ and making various changes to the system. We must

determine, via comparison of the values of Q and K , whether these changes alter the equilibrium position and, therefore, how this affects the amount of $\text{NO}_2(\text{g})$.

Solution

To answer these questions, we first write the expression for Q and then use it to determine the effect of the change made.

$$Q_c = \frac{[\text{NO}_2]^2}{[\text{N}_2\text{O}_4]}$$

- (a) Adding $\text{N}_2\text{O}_4(\text{g})$ instantaneously decreases the value of Q_c so $Q_c < K_c$. To make $Q_c = K_c$, the equilibrium

shifts to the right to increase the value of Q_c , resulting in the production of more $\text{NO}_2(\text{g})$. The amount of $\text{NO}_2(\text{g})$ *increases*.

(b) We have seen that increasing the volume of the container reduces the value of Q_c because the value of Q_c is inversely proportional to V . Hence, to make $Q_c = K_c$, the equilibrium shifts to the right to increase the value of Q_c , resulting in the production of more $\text{NO}_2(\text{g})$. The amount of $\text{NO}_2(\text{g})$ *increases*.

(c) The forward reaction is endothermic, meaning that $\Delta_r H^\circ$ is positive; by applying the van't Hoff equation, a plot of $\ln K_c$ versus T has a positive slope. Thus $\ln K_c$, and therefore K_c , increases with increasing temperature, so

$Q_c < K_c$. To make $Q_c = K_c$, the value of Q_c must increase, resulting in the production of more $\text{NO}_2(\text{g})$ at equilibrium. The amount of $\text{NO}_2(\text{g})$ *increases*.

(d) As stated above, a catalyst can have no effect on the position of equilibrium. The amount of $\text{NO}_2(\text{g})$ remains unchanged.

Finally, the only change that alters the value of K_c is a change in temperature.

Is our answer reasonable?

Compare each of our answers with examples given in this section to confirm that they are logically consistent.

PRACTICE EXERCISE 9.12

Consider the following equilibrium.

For the forward reaction, $\Delta_r H^\circ = -297 \text{ kJ mol}^{-1}$. How is the amount of SO_2 at equilibrium affected by the following?

- (a) adding $\text{O}_2(\text{g})$
- (b) adding $\text{S}(\text{s})$
- (c) raising the temperature
- (d) decreasing the volume of the container

How (if at all) does each of these changes affect the value of K_p for the reaction?

CHEMICAL CONNECTIONS

The Haber–Bosch process: the most important equilibrium on the planet?

Nitrogen is an essential element in all biological systems, being a component of such important biomolecules as amino acids and nucleic acids. As 78% of our atmosphere is gaseous N_2 , nature has an abundant supply of this element for incorporation into biomolecules. However, as we have learned in previous chapters, gaseous nitrogen molecules are held together by a triple bond, with a bond enthalpy of 942 kJ mol^{-1} , and this renders the N_2 molecule extremely unreactive. Nature overcomes this by utilising a remarkable enzyme called nitrogenase, different variants of which occur in bacteria and legumes, to convert N_2 to NH_3 at 25°C and $1.013 \times 10^5 \text{ Pa}$. The resulting NH_3 is then used in the biosynthesis of the amino acids glutamine and glutamic acid.

Nitrogen is also an essential component of fertilisers, which the ever-expanding human population requires to assist in growing food, and NH_3 is the primary feedstock for the fertiliser industry (figure 9.16). However, we humans are currently not as clever as nature when it comes to utilising N_2 , and we must, of necessity, resort to the Haber–Bosch process, the direct combination of N_2 and H_2 at elevated temperature and pressure, to prepare NH_3 . The importance of this reaction can be appreciated from the fact that

the Haber–Bosch process uses an estimated 1–2% of the Earth's entire annual energy production! Let that sink in for a bit before we continue ...

FIGURE 9.16

A fertiliser factory requires NH_3 as feedstock for its products. The Haber–Bosch process is used to produce NH_3 and is responsible for up to 2% of humans' total worldwide use of power.

Now let's investigate the following equilibrium.

As we've seen earlier, $\Delta_r G^\circ = -33.4 \text{ kJ mol}^{-1}$ for the forward reaction at 298 K, implying that the product will be favoured under these conditions, which is certainly what we want. Knowing that $\Delta_r H^\circ = -92.38 \text{ kJ mol}^{-1}$ for the forward reaction at 298 K tells us that the value of the equilibrium constant will decrease as the temperature increases, and therefore $\text{NH}_3(\text{g})$ production will be favoured at low temperatures, while the fact that there are 4 mol of gaseous reactants and 2 mol of gaseous products suggests that high pressures will favour formation of $\text{NH}_3(\text{g})$. In practice, however, things are not so simple. The forward reaction is slow, and requires the presence of an iron-based catalyst in order to proceed at a useful rate. Running the

reaction at a high temperature will increase the rate of the forward reaction, but will move the equilibrium position towards reactants. The compromise involves carrying out the reaction at around 400–450 °C, at a pressure around $200 \times 10^5 \text{ Pa}$. Under these conditions, only about 15% conversion to $\text{NH}_3(\text{g})$ is achieved at equilibrium, but removal of the $\text{NH}_3(\text{g})$ by cooling to give $\text{NH}_3(\text{l})$, which shifts the equilibrium position towards the formation of more product, combined with recycling of unreacted N_2 and H_2 , results in an overall conversion approaching 100%.

As you can see, the Haber–Bosch process is extremely energy-intensive. Because of this, chemists around the world have been trying for many years to mimic nature's low-temperature/low-pressure process. While significant advances have been made, a viable alternative to the Haber–Bosch process remains elusive at present. So, if you would like a Nobel Prize, put your mind to this problem.

9.5 Equilibrium calculations

LEARNING OBJECTIVE 9.5 Carry out calculations involving equilibria.

You have seen that the magnitude of an equilibrium constant gives us some feel for the composition of a reaction mixture at equilibrium. Sometimes, however, it is necessary to have more than merely a qualitative knowledge of equilibrium concentrations. This requires that we be able to use the equilibrium constant expression for quantitative calculations.

Equilibrium calculations for gaseous reactions can be performed using either K_p or K_c , but for reactions in solution we must use K_c . Whether we deal with concentrations or partial pressures, however, the same basic principles apply.

Overall, we can divide equilibrium calculations into two main categories:

1. calculating equilibrium constants from known equilibrium concentrations or partial pressures
2. calculating one or more equilibrium concentrations or partial pressures using a known value of K_c or K_p , given initial concentrations of reactants and products.

Calculating K_c from equilibrium concentrations: the concentration table

One way to determine the value of K_c for an equilibrium is to carry out the reaction, measure the concentrations of reactants and products after equilibrium has been reached, and then substitute these equilibrium values into the equilibrium constant expression to calculate K_c . As an example, let's look again at the decomposition of N_2O_4 .

In section 9.2, we saw that, if 0.0350 mol of N_2O_4 is placed into a 1 L flask at 25 °C, the concentrations of N_2O_4 and NO_2 at equilibrium are as follows.

$$\begin{aligned}[\text{N}_2\text{O}_4] &= 0.0292 \text{ mol L}^{-1} \\ [\text{NO}_2] &= 0.0116 \text{ mol L}^{-1}\end{aligned}$$

To calculate K_c for this reaction, we substitute the equilibrium concentrations into the equilibrium constant expression.

$$K_c = \frac{[\text{NO}_2]^2}{[\text{N}_2\text{O}_4]} = \frac{(0.0116)^2}{0.0292}$$

Therefore:

$$K_c = 4.61 \times 10^{-3}$$

Let's now look at this example in a different way, using a **concentration table** to illustrate the changes in concentration of reactants and products as the reaction proceeds to equilibrium. We set up the concentration table as follows.

	$\text{N}_2\text{O}_4(\text{g})$	$\rightleftharpoons$	$2\text{NO}_2(\text{g})$
Initial concentration (mol L^{-1})			
Change in concentration (mol L^{-1})			
Equilibrium concentration (mol L^{-1})			

The purpose of a concentration table is to determine the equilibrium concentrations of reactants and products in an equilibrium. In this case, we actually know what the equilibrium concentrations are, but this still serves as a good example. There are six cells to populate in the table, and we can fill four of them using the data given in the question, plus the fact that there will be no NO_2 present at the start of the reaction. We do this as follows. (In this text, we will always highlight the given data in concentration tables.)

	$\text{N}_2\text{O}_4(\text{g})$	$\rightleftharpoons$	$2\text{NO}_2(\text{g})$
Initial concentration (mol L^{-1})	0.0350		0
Change in concentration (mol L^{-1})			
Equilibrium concentration (mol L^{-1})	0.0292		0.0116

We now only need to fill the cells in the 'Change in concentration' row. We can calculate these numbers from the initial and equilibrium concentrations. As the reaction has proceeded to the equilibrium, the concentration of $\text{N}_2\text{O}_4(\text{g})$ has dropped from $0.0350 \text{ mol L}^{-1}$ to $0.0292 \text{ mol L}^{-1}$. Remembering that 'a change in' is defined as being 'final value – initial value', we calculate the change in its concentration as follows.

$$0.0292 \text{ mol L}^{-1} - 0.0350 \text{ mol L}^{-1} = -0.0058 \text{ mol L}^{-1}$$

The negative sign shows that the concentration of $\text{N}_2\text{O}_4(\text{g})$ has decreased. The same reasoning gives the change in concentration of $\text{NO}_2(\text{g})$ as follows.

$$0.0116 \text{ mol L}^{-1} - 0 \text{ mol L}^{-1} = 0.0116 \text{ mol L}^{-1}$$

The positive value denotes a concentration increase.

Note that 0.0116 is 2×0.0058 ; in other words, the concentration of $\text{NO}_2(\text{g})$ has increased by twice the amount that the concentration of $\text{N}_2\text{O}_4(\text{g})$ has decreased. This is what we would expect given the stoichiometry of the reaction. Our final concentration table is therefore as follows.

	$\text{N}_2\text{O}_4(\text{g})$	$\rightleftharpoons$	$2\text{NO}_2(\text{g})$
Initial concentration (mol L^{-1})	0.0350		0
Change in concentration (mol L^{-1})	-0.0058		$+(2 \times 0.0058)$
Equilibrium concentration (mol L^{-1})	0.0292		0.0116

You can see that, for both $\text{N}_2\text{O}_4(\text{g})$ and $\text{NO}_2(\text{g})$, the equilibrium concentrations are the sum of the initial concentration and the change in concentration. This is an important point that we will encounter in every concentration table.

We will now consider a situation in which we don't know the concentrations of all reactants and products in an equilibrium. In such cases, we must use a concentration table together with some stoichiometric manipulations to determine the values of equilibrium constants. We will illustrate this by considering the reaction of $\text{H}_2(\text{g})$ with $\text{I}_2(\text{g})$ to give $2\text{HI}(\text{g})$.

Suppose we placed 0.200 mol of H_2 and 0.200 mol of I_2 into a 2.00 L flask at a particular temperature. When the following equilibrium was established, the I_2 concentration had dropped to 0.020 mol L^{-1} .

What is the value of K_c for this equilibrium at this temperature? We begin, as we should always do, by writing the equilibrium constant expression as follows.

$$K_c = \frac{[\text{HI}]^2}{[\text{H}_2][\text{I}_2]}$$

From this, it is obvious that we only know one of the three equilibrium concentrations in this expression. We must therefore set up a concentration table to determine the others. We begin by filling in all of the concentration data we are given.

	$\text{H}_2(\text{g})$	+	$\text{I}_2(\text{g})$	$\rightleftharpoons$	$2\text{HI}(\text{g})$
Initial concentration (mol L^{-1})	0.100		0.100		
Change in concentration (mol L^{-1})					
Equilibrium concentration (mol L^{-1})			0.020		

We assume that, at the very start of the reaction, there is no HI present, so we are then able to fill in one more cell.

	$\text{H}_2(\text{g})$	+	$\text{I}_2(\text{g})$	$\rightleftharpoons$	$2\text{HI}(\text{g})$
Initial concentration (mol L^{-1})	0.100		0.100		0
Change in concentration (mol L^{-1})					
Equilibrium concentration (mol L^{-1})			0.020		

In order to complete the rest of the table, we will use the fact stated above that the equilibrium concentrations are the sum of the top two values in each column. Specifically, we can say that:

$$\begin{aligned} \text{equilibrium concentration of } \text{I}_2 &= \text{initial concentration of } \text{I}_2 + \text{change in concentration of } \text{I}_2 \\ 0.020 \text{ mol L}^{-1} &= 0.100 \text{ mol L}^{-1} + \text{change in concentration of } \text{I}_2 \end{aligned}$$

Thus:

$$\text{change in concentration of } \text{I}_2 = (0.020 - 0.100) \text{ mol L}^{-1} = -0.080 \text{ mol L}^{-1}$$

The negative sign, as above, denotes a decrease in concentration. Having calculated this change in concentration of I_2 , we can now say, from the stoichiometry of the reaction, that the change in concentration of H_2 will be the same; that is, $-0.080 \text{ mol L}^{-1}$. We can also say from the stoichiometry that the change in concentration of HI will be twice the change in concentration of both H_2 and I_2 , and will be of the opposite sign, as it is being formed in the reaction. We add these data to our concentration table.

	$\text{H}_2(\text{g})$	+	$\text{I}_2(\text{g})$	$\rightleftharpoons$	$2\text{HI}(\text{g})$
Initial concentration (mol L^{-1})	0.100		0.100		0
Change in concentration (mol L^{-1})	-0.080		-0.080		$+(2 \times 0.080)$
Equilibrium concentration (mol L^{-1})			0.020		

We now fill the remaining two cells by adding the numbers in the $\text{H}_2(\text{g})$ and $2\text{HI}(\text{g})$ columns.

	H ₂ (g)	+	I ₂ (g)	⇌	2HI(g)
Initial concentration (mol L ⁻¹)	0.100		0.100		0
Change in concentration (mol L ⁻¹)	-0.080		-0.080		+(2 × 0.080)
Equilibrium concentration (mol L ⁻¹)	0.020		0.020		0.160

We now plug the equilibrium concentration values into the equilibrium constant expression to determine the value of K_c .

$$K_c = \frac{[\text{HI}]^2}{[\text{H}_2][\text{I}_2]} = \frac{(0.160)^2}{(0.020)(0.020)} = 64$$

We can summarise the key points concerning concentration tables as follows.

1. The only values that we can substitute into the equilibrium constant expression are equilibrium concentrations — the values that appear in the last row of the table.
2. When we enter initial concentrations into the table, they should be in units of moles per litre (mol L⁻¹). The initial concentrations are those present in the reaction mixture at the instant when all the constituents are mixed; we imagine that no reaction has occurred at this time.
3. The changes in concentrations always occur in the same ratio as the coefficients in the balanced equation. Consider, for example, the following equilibrium.

We find that the N₂(g) concentration decreases by 0.10 mol L⁻¹ during the approach to equilibrium, and the entries in the 'Change in concentration' row would be as follows.

	3H ₂ (g)	+	N ₂ (g)	⇌	2NH ₃ (g)
Change in concentration (mol L ⁻¹)	-3 × (0.10) = -0.30		-1 × (0.10) = -0.10		+2 × (0.10) = +0.20

4. In constructing the 'Change in concentration' row, be sure that the reactant concentrations all change in the same direction and that the product concentrations all change in the opposite direction. If the concentrations of the reactants decrease, all the entries for the reactants in the 'Change in concentration' row should have a negative sign and all the entries for the products should be positive. Keep these points in mind as we construct the concentration tables for other equilibrium problems.

PRACTICE EXERCISE 9.13

NO₂(g) can decompose to give NO(g) and O₂(g) according to the following equilibrium.

When a mixture of the three gases was introduced into an empty vessel and the system was allowed to come to equilibrium, it was found that the NO concentration had decreased by 0.00050 mol L⁻¹. How had the concentrations of O₂ and NO₂ changed?

PRACTICE EXERCISE 9.14

A student placed 0.200 mol of PCl₃(g) and 0.100 mol of Cl₂(g) into a 1.00 L container at 250 °C. After the following reaction came to equilibrium, it was found that the container contained 0.120 mol of PCl₃.

- (a) What were the initial concentrations of the reactants and product?
- (b) By how much had the concentrations of the reactants and product changed when the reaction reached equilibrium?
- (c) What were the equilibrium concentrations of the reactants and product?
- (d) What is the value of K_c for this reaction at this temperature?

Calculating equilibrium concentrations from initial concentrations

A more complex type of calculation involves the use of initial concentrations and K_c to calculate equilibrium concentrations. Although some of these problems can be rather complicated, we can learn the general principles involved by working on simple calculations. Even these, however, require a little applied algebra. This is where the concentration table can be very helpful.

WORKED EXAMPLE 9.10

Using K_c to calculate equilibrium concentrations — 1

The water-gas shift reaction is used to prepare high-purity hydrogen gas for use in ammonia production. The equilibrium equation for this process is as follows.

For this equilibrium:

$$K_c = 4.06 \text{ at } 500^\circ\text{C}$$

If 0.100 mol of CO and 0.100 mol of $\text{H}_2\text{O(g)}$ are placed in a 1.00 L reaction vessel at this temperature, what are the concentrations of the reactants and products when the system reaches equilibrium?

Analysis

The key to solving this kind of problem is recognising that, at equilibrium:

$$K_c = \frac{[\text{CO}_2][\text{H}_2]}{[\text{CO}][\text{H}_2\text{O}]} = 4.06$$

We must find values for the concentrations that satisfy this condition. Because we don't know what these concentrations are, we represent them algebraically in the concentration table as unknowns.

Initial concentration: The initial concentrations of CO and H_2O are both 0.100 mol L^{-1} . Since no CO_2 or H_2 is initially placed into the reaction vessel, their initial concentrations are both exactly 0 at the instant of mixing CO and H_2O .

Change in concentration: Some CO_2 and H_2 must form for the reaction to reach equilibrium. This also means that some CO and H_2O must react. But how much? If we knew the answer, we could calculate the equilibrium concentrations. Therefore, the changes in concentration are our unknown quantities.

Let us allow x to represent the amount of CO per litre that reacts. Notice that we could just as easily have chosen x to be the amount of H_2O per litre that reacts or the amount of CO_2 or H_2 per litre that forms. There is nothing special about having chosen CO to define x . The change in the concentration of CO is then $-x$. (It is negative because the approach of the system to equilibrium decreases the CO concentration.) Because CO and H_2O react in a 1 : 1 mole ratio, the change in the H_2O concentration is also $-x$. Since 1 mol each of CO_2 and H_2 is formed from 1 mol of CO, the CO_2 and H_2O concentrations both increase by x (their changes are $+x$).

Equilibrium concentration: We obtain the equilibrium concentrations as follows.

$$\left(\begin{array}{c} \text{equilibrium} \\ \text{concentration} \end{array} \right) = \left(\begin{array}{c} \text{initial} \\ \text{concentration} \end{array} \right) + \left(\begin{array}{c} \text{change in} \\ \text{concentration} \end{array} \right)$$

Solution

Here is the completed concentration table.

	CO(g)	+	H ₂ O(g)	⇌	CO ₂ (g)	+	H ₂ (g)
Initial concentration (mol L ⁻¹)	0.100		0.100		0		0
Change in concentration (mol L ⁻¹)	-x		-x		+x		+x
Equilibrium concentration (mol L ⁻¹)	0.100 - x		0.100 - x		x		x

Note that the last line in the table tells us that the equilibrium CO and H_2O concentrations are equal to the amount per litre that was present initially minus the amount per litre that has reacted. The equilibrium concentrations of CO_2 and H_2 equal the amount per litre of each that forms, since no CO_2 or H_2 is present initially.

Next, we substitute the quantities from the 'Equilibrium concentration' row into the equilibrium constant expression and solve for x .

$$K_c = \frac{[\text{CO}_2][\text{H}_2]}{[\text{CO}][\text{H}_2\text{O}]} = 4.06$$

$$= \frac{(x)(x)}{(0.100 - x)(0.100 - x)} = 4.06$$

which we can write as:

$$\frac{x^2}{(0.100 - x)^2} = 4.06$$

In this problem, we can solve the equation for x most easily by taking the square root of both sides.

$$\frac{x}{(0.100 - x)} = \sqrt{4.06} = 2.01$$

Rearranging gives:

$$x = 2.01(0.100 - x) = 0.201 - 2.01x$$

Collecting terms in x gives:

$$x + 2.01x = 0.201 \quad 3.01x = 0.201 \quad x = 0.0668$$

Now that we know the value of x , we can calculate the equilibrium concentrations from the last row of the table.

$$\begin{aligned} [\text{CO}] &= 0.100 - x = 0.100 - 0.0668 = 0.033 \text{ mol L}^{-1} \\ [\text{H}_2\text{O}] &= 0.100 - x = 0.100 - 0.0668 = 0.033 \text{ mol L}^{-1} \\ [\text{CO}_2] &= x = 0.0668 \text{ mol L}^{-1} \\ [\text{H}_2] &= x = 0.0668 \text{ mol L}^{-1} \end{aligned}$$

Is our answer reasonable?

First, we should check that all concentrations are positive numbers. They are. One way to check the answers is to substitute the equilibrium concentrations we've found into the equilibrium constant expression and evaluate the reaction quotient. If our answers are correct, Q_c should equal K_c . Let's check.

$$Q_c = \frac{[\text{CO}_2][\text{H}_2]}{[\text{CO}][\text{H}_2\text{O}]} = \frac{(0.0668)^2}{(0.033)^2} = 4.1$$

Rounding K_c to two significant figures gives 4.1, so the calculated concentrations are correct.

WORKED EXAMPLE 9.11

Using K_c to calculate equilibrium concentrations – 2

In worked example 9.10, it was stated that the equilibrium:

has:

$$K_c = 4.06 \text{ at } 500^\circ\text{C}$$

Suppose 0.0600 mol of CO and 0.0600 mol of H_2O are mixed with 0.100 mol of CO_2 and 0.100 mol of H_2 in a 1.00 L reaction vessel. Determine the concentrations of all the reactants and products when the mixture reaches equilibrium at this temperature.

Analysis

We will proceed in much the same way as in worked example 9.10. However, this time, determining the algebraic signs of x will not be quite so simple because none of the initial concentrations is 0. The best way to determine the algebraic signs is to use the initial concentrations to calculate the initial reaction quotient. Then we can compare the values of Q_c and K_c , and then by reasoning we will determine which way the reaction must proceed to make the value of Q_c equal that of K_c .

Solution

The equilibrium constant expression for the reaction is as follows.

$$K_c = \frac{[\text{CO}_2][\text{H}_2]}{[\text{CO}][\text{H}_2\text{O}]}$$

Let's use the initial concentrations, shown in the concentration table below, to determine the value of the reaction quotient immediately after mixing.

$$Q_c = \frac{(0.100)(0.100)}{(0.0600)(0.0600)} = 2.78 < K_c$$

As indicated, the value of Q_c is less than that of K_c , so the system is not at equilibrium. To reach equilibrium, the value of Q_c must become larger, which requires an increase in the concentrations of CO_2 and H_2 and a corresponding decrease in the concentrations of CO and H_2O . This means that, for CO_2 and H_2 , the change must be positive, and, for CO and H_2O , the change must be negative.

Here is the completed concentration table.

	CO(g)	+	$\text{H}_2\text{O(g)}$	$\rightleftharpoons$	$\text{CO}_2\text{(g)}$	+	$\text{H}_2\text{(g)}$
Initial concentration (mol L^{-1})	0.0600		0.0600		0.100		0.100
Change in concentration (mol L^{-1})	$-x$		$-x$		$+x$		$+x$
Equilibrium concentration (mol L^{-1})	$0.0600 - x$		$0.0600 - x$		$0.100 + x$		$0.100 + x$

Substituting equilibrium quantities into the equilibrium constant expression gives us the following.

$$K_c = \frac{[\text{CO}_2][\text{H}_2]}{[\text{CO}][\text{H}_2\text{O}]} = \frac{(0.100 + x)^2}{(0.0600 - x)^2} = 4.06$$

Taking the square root of both sides yields:

$$\frac{0.100 + x}{0.0600 - x} = 2.01$$

To solve for x , we first multiply each side by $(0.0600 - x)$ to obtain:

$$0.100 + x = 2.01(0.0600 - x) = 0.121 - 2.01x$$

Collecting terms in x to one side and the constants to the other gives:

$$\begin{aligned}x + 2.01x &= 0.121 - 0.100 \\3.01x &= 0.021 \\x &= 0.0070\end{aligned}$$

Now we can calculate the equilibrium concentrations as follows.

$$[\text{CO}] = [\text{H}_2\text{O}] = (0.0600 - x) = 0.0600 - 0.0070 = 0.053 \text{ mol L}^{-1}$$

$$[\text{CO}_2] = [\text{H}_2] = (0.100 + x) = 0.100 + 0.0070 = 0.107 \text{ mol L}^{-1}$$

Is our answer reasonable?

As a check, we can evaluate the reaction quotient using the calculated equilibrium concentrations.

$$Q = \frac{(0.107)^2}{(0.0530)^2} = 4.08$$

This is acceptably close to the value of K_c . (It is not *exactly* equal to K_c because of the rounding of answers during the calculations.)

In worked examples 9.10 and 9.11, we were able to simplify the solution by taking the square root of both sides of the algebraic equation obtained by substituting equilibrium concentrations into the equilibrium constant expression. Such simplifications are not always possible, however, as illustrated in worked example 9.12.

Using K_c to calculate equilibrium concentrations – 3

At a certain temperature, $K_c = 4.50$ for the following equation.

If 0.300 mol of N_2O_4 is placed into a 2.00 L container at this temperature, calculate the equilibrium concentrations of both gases.

Analysis

As in worked example 9.11, we first write the equilibrium constant expression.

$$K_c = \frac{[\text{NO}_2]^2}{[\text{N}_2\text{O}_4]} = 4.50$$

We will need to find algebraic expressions for the equilibrium concentrations and substitute them into the equilibrium constant expression. To obtain these, we set up the concentration table for the reaction.

Initial concentration: The initial concentration of N_2O_4 is $0.300 \text{ mol}/2.00 \text{ L} = 0.1500 \text{ mol L}^{-1}$. Since no NO_2 was placed in the reaction vessel, its initial concentration is exactly 0.

Change in concentration: There is initially no NO_2 in the reaction mixture, so we know its concentration must increase. This means the N_2O_4 concentration must decrease as some of the NO_2 is formed. We will represent the amount of N_2O_4 per litre that reacts as x , so the change in the N_2O_4 concentration is $-x$. Because of the stoichiometry of the reaction, the NO_2 concentration must increase by $2x$, so its change in concentration is $+2x$.

Equilibrium concentration: As before, we add the change to the initial concentration in each column to obtain expressions for the equilibrium concentrations.

Solution

Here is the concentration table.

	$\text{N}_2\text{O}_4(\text{g})$	$\rightleftharpoons$	$2\text{NO}_2(\text{g})$
Initial concentration (mol L^{-1})	0.150		0
Change in concentration (mol L^{-1})	$-x$		$+2x$
Equilibrium concentration (mol L^{-1})	$0.150 - x$		$2x$

Now we substitute the equilibrium quantities into the equilibrium constant expression as shown.

$$\begin{aligned} K_c &= \frac{[\text{NO}_2]^2}{[\text{N}_2\text{O}_4]} = 4.50 \\ &= \frac{(2x)^2}{(0.150 - x)} = 4.50 \\ &= \frac{4x^2}{(0.150 - x)} = 4.50 \end{aligned}$$

This time the left side of the equation is not a perfect square, so we cannot just take the square root of both sides as in worked examples 9.10 and 9.11. However, because the equation involves terms in x^2 and x and a constant, we can use the quadratic formula. For a quadratic equation of the form $ax^2 + bx + c = 0$:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

Expanding the above equation, we get:

$$4x^2 = 4.50(0.150 - x) = 0.675 - 4.50x$$

Arranging terms in the standard order gives:

$$4x^2 + 4.50x - 0.675 = 0$$

Therefore, the quantities we will substitute into the quadratic formula are: $a = 4$, $b = 4.50$ and $c = -0.675$. Making these substitutions gives the following.

$$\begin{aligned}x &= \frac{-4.50 \pm \sqrt{(4.50)^2 - 4(4)(-0.675)}}{2(4)} \\&= \frac{-4.50 \pm \sqrt{31.05}}{8} \\&= \frac{-4.50 \pm 5.57}{8}\end{aligned}$$

Because of the $\pm$ term, there are two values of x that satisfy the equation: $x = 0.134$ and $x = -1.26$. However, only the first value, $x = 0.134$, makes any sense chemically (see below). Using this value, the equilibrium concentrations are as follows.

$$\begin{aligned}[\text{N}_2\text{O}_4] &= 0.150 - 0.134 = 0.016 \text{ mol L}^{-1} \\[\text{NO}_2] &= 2(0.134) = 0.268 \text{ mol L}^{-1}\end{aligned}$$

Notice that, if we had used the negative root, -1.26 , the equilibrium concentration of NO_2 would be negative. Negative concentrations are impossible, so $x = -1.26$ is not acceptable for chemical reasons. In general, whenever you use the quadratic equation in a chemical calculation, one root will be satisfactory and the other will lead to an answer that does not make sense chemically.

Is our answer reasonable?

Once again, we can evaluate the reaction quotient using the calculated equilibrium values. When we do this, we obtain $Q = 4.49$, which is acceptably close to 4.50 , the given value of K_c .

PRACTICE EXERCISE 9.15

0.0500 mol of $\text{H}_2(\text{g})$ and 0.0500 mol of $\text{I}_2(\text{g})$ were placed into a 0.500 L vessel and the following equilibrium was established.

If $K_c = 49.5$ for this equilibrium at the temperature of the experiment, determine the equilibrium concentrations of $\text{H}_2(\text{g})$, $\text{I}_2(\text{g})$ and $\text{HI}(\text{g})$.

Equilibrium problems can be much more complex than worked example 9.12. However, when K is either very large or very small, simplifying assumptions can be made that allow an approximate solution to be obtained. This is illustrated in worked example 9.13.

WORKED EXAMPLE 9.13

Simplifying approximations in equilibrium calculations

The thermal decomposition of water to its elements occurs only to a very small extent, even at high temperatures; at 1000°C , $K_c = 7.3 \times 10^{-18}$ for the equilibrium:

If water vapour at an initial concentration of 0.100 mol L^{-1} is allowed to react at 1000°C , what will the H_2 concentration be when the reaction reaches equilibrium?

Analysis

We begin, as always, by writing the equilibrium constant expression, K_c as follows.

$$K_c = \frac{[\text{H}_2]^2[\text{O}_2]}{[\text{H}_2\text{O}]^2} = 7.3 \times 10^{-18}$$

We then set up the concentration table and proceed as we have done before. However, we will find that we can make simplifying assumptions in this problem because of the extremely small value of the equilibrium constant.

Solution

Here is the concentration table.

	$2\text{H}_2\text{O(g)}$	$\rightleftharpoons$	$2\text{H}_2\text{(g)}$	$+$	$\text{O}_2\text{(g)}$
Initial concentration (mol L^{-1})	0.100		0		0
Change in concentration (mol L^{-1})	$-2x$		$+2x$		$+x$
Equilibrium concentration (mol L^{-1})	$0.100 - 2x$		$2x$		x

We now substitute the equilibrium concentrations into the equilibrium constant expression.

$$\begin{aligned}K_c &= \frac{[\text{H}_2]^2[\text{O}_2]}{[\text{H}_2\text{O}]^2} = 7.3 \times 10^{-18} \\&= \frac{(2x)^2(x)}{(0.100 - 2x)^2} = 7.3 \times 10^{-18} \\&= \frac{4x^3}{(0.100 - 2x)^2} = 7.3 \times 10^{-18}\end{aligned}$$

This is a cubic equation and the mathematics required to solve such equations exactly are beyond the scope of this text. However, in this case, the magnitude of K_c allows us to make simplifications to this equation that allow its straightforward solution. Because K_c is so incredibly small, we know that, at equilibrium, not much H_2O will have reacted. This means that, to a very good approximation, the concentration of H_2O at equilibrium equals the initial concentration of H_2O . In other words, the term x in the concentration table is tiny, so $0.100 - 2x \approx 0.100$. Making this assumption simplifies the cubic expression as follows.

$$K_c = \frac{4x^3}{(0.100 - 2x)^2} \approx \frac{4x^3}{(0.100)^2} = 7.3 \times 10^{-18}$$

Hence:

$$\begin{aligned}4x^3 &= (0.100)^2 \times (7.3 \times 10^{-18}) = 7.3 \times 10^{-20} \\x^3 &= 1.8 \times 10^{-20} \\x &= \sqrt[3]{1.8 \times 10^{-20}} = 2.6 \times 10^{-7}\end{aligned}$$

We can now obtain the H_2 concentration, which is equal to $2x$ (from the concentration table).

$$\begin{aligned}[\text{H}_2] &= 2 \times (2.6 \times 10^{-7}) \\&= 5.2 \times 10^{-7} \text{ mol L}^{-1}\end{aligned}$$

Is our answer reasonable?

We must first show that the assumption we made was justified. We do this by showing that $(0.100 - 2x)$ is indeed essentially equal to 0.100.

$$0.100 - 2x = 0.100 - (5.2 \times 10^{-7}) = 0.09999948$$

When we round 0.09999948 to three significant figures, it is 0.100. This shows that our assumption is justified.

We can now show that our answer is reasonable. The tiny value of K_c leads us to expect that the equilibrium concentration of hydrogen is very small, which it is. We can also substitute our equilibrium values into the expression for K_c (remember that $[\text{O}_2] = x$) and confirm that this gives a value acceptably close to 7.3×10^{-18} . It should also be noted that the exact solution of the original cubic equation using a calculator gives $x = 2.6 \times 10^{-7}$, again showing that our assumption leads to a reasonable answer.

PRACTICE EXERCISE 9.16

In air at 25°C and $1.013 \times 10^5 \text{ Pa}$, the N_2 concentration is 0.033 mol L^{-1} and the O_2 concentration is $0.00810 \text{ mol L}^{-1}$. The reaction below has $K_c = 4.8 \times 10^{-31}$ at 25°C .

Taking the N_2 and O_2 concentrations given above as initial values, calculate the equilibrium NO concentration that should exist in our atmosphere from this reaction at 25°C .

The simplifying assumption made in worked example 9.13 is valid because a very small number was subtracted from a much larger one. We could also have neglected x (or $2x$) if it were a very small number that was being added to a much larger one. Remember that you can neglect x only if it is added or subtracted; you can never neglect x if it occurs as a multiplying or dividing factor.

As an arbitrary rule of thumb, you can expect these simplifying assumptions to be valid if the concentration from which x is subtracted, or to which x is added, is at least 400 times greater than K . For instance, in worked example 9.13, $2x$ was subtracted from 0.100. Since 0.100 is much larger than $400 \times (7.3 \times 10^{-18})$, we expect the assumption $0.100 - 2x \approx 0.100$ to be valid. However, even though the simplifying assumption is expected to be valid, always check to see if it really is after finishing the calculation. If the assumption proves invalid, then some other way to solve the algebra must be found.

Given that calculators are now used routinely in examinations (some of the authors remember a time when this wasn't the case) the above approximations have become essentially redundant, as exact solutions of the most complicated equations can be obtained at the touch of a button. However, this is not to say that the principles underlying the assumptions are unimportant. You should appreciate that the concentrations of some equilibrium components are going to be negligibly small when the equilibrium constant is either very large or very small.

CHEMICAL CONNECTIONS

Hyperventilation

Have you ever found yourself getting so excited or scared that you reach the point where you're breathing extremely rapidly? If so, you may have experienced *hyperventilation*, the symptoms of which are dizziness, palpitations and sweating, amongst other things. When you breathe out, you expel significant amounts of $\text{CO}_2(\text{g})$ and when you breathe very fast, you breathe out more $\text{CO}_2(\text{g})$ than normal. In the body, CO_2 dissolves in blood (an aqueous solution) to form 'carbonic acid', $\text{H}_2\text{CO}_3(\text{aq})$, and any alteration of CO_2 levels affects the position of the following equilibrium, which can then affect the pH of your blood by affecting $[\text{H}_3\text{O}^+]$.

We can use the principles of equilibrium we have learned in this chapter to explain why breathing into a paper bag can be used to stop hyperventilation (figure 9.17).

Consider the above equilibrium for which the reaction quotient expression is shown below.

$$Q_c = \frac{[\text{H}_3\text{O}^+][\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]}$$

If we remove $\text{H}_2\text{CO}_3(\text{aq})$ by breathing out lots of $\text{CO}_2(\text{g})$, then the value of Q_c will increase, and the equilibrium will therefore move to the left to decrease the value of Q_c . This then alters the pH by decreasing $[\text{H}_3\text{O}^+]$ and it is this that causes the symptoms of hyperventilation. If you breathe into a paper bag, you are essentially breathing in the $\text{CO}_2(\text{g})$ that you have just breathed out. This means that the amount of $\text{CO}_2(\text{g})$, and hence $[\text{H}_2\text{CO}_3]$, will increase, counteracting the above process and resulting in the position of equilibrium moving back towards the right.

FIGURE 9.17

Breathing into a paper bag results in the inhalation of CO_2 , re-establishing the equilibrium in the blood that was disrupted by hyperventilating.

SUMMARY

9.1 Define chemical equilibrium.

Chemical equilibrium occurs when the chemical composition of a system does not change with time. When the forward and reverse reactions in a chemical system occur at equal rates, a dynamic equilibrium exists and the concentrations of the reactants and products remain constant. For a given overall chemical composition, the amounts of reactants and products that are present at equilibrium are the same regardless of whether the equilibrium is approached from the direction of pure 'reactants', pure 'products' or any mixture of them.

9.2 Use the equilibrium constant, K , and the reaction quotient, Q .

The equilibrium constant expression contains only gases and species in solution. When all components in an equilibrium equation are gases or species in solution, the equilibrium constant expression is a fraction. The concentrations of the products at equilibrium, each divided by c° and raised to a power equal to its stoichiometric coefficient in the balanced chemical equation, are multiplied together in the top line (numerator). The bottom line (denominator) is constructed in the same way from the concentrations of the reactants at equilibrium, each divided by c° and raised to a power equal to its stoichiometric coefficient. The numerical value of the equilibrium constant expression is the equilibrium constant, K_c . If partial pressures of gases, divided by p° and raised to their stoichiometric coefficients, are used in the equilibrium constant expression, K_p is obtained. The thermodynamic equilibrium constant is obtained when activities, rather than pressures or concentrations, are used in the equilibrium constant expression. The equilibrium constant is constant at constant temperature. The magnitude of the equilibrium constant reflects the extent to which the forward reaction has proceeded to completion when equilibrium is reached.

The reaction quotient, Q , has the same form as K , but the concentrations or pressures are nonequilibrium values. Pure solids and pure liquids do not appear in the expressions for K and Q .

When an equation is multiplied by a factor n to obtain a new equation, we raise its value of K to the power of n to obtain K for the new equation. When two equations are added, we multiply their values of K to obtain the new K . When an equation is reversed, we take the reciprocal of its value of K to obtain the new K .

The values of K_p and K_c are equal only if the same number of moles of gas appear on each side of the chemical equation. When the numbers of moles of gas are different, K_p is related to K_c by the following equation where $R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1}$, T = absolute temperature and Δn_{gas} is the difference between the number of moles of gaseous products and the number of moles of gaseous reactants in the balanced equation.

$$K_p = K_c \left(\frac{1000 RT}{p^\circ} \right)^{\Delta n_{\text{gas}}}$$

An equilibrium where all substances are in the same phase is called a homogeneous equilibrium, while one with substances

in more than one phase is a heterogeneous equilibrium. The equilibrium constant expression for a heterogeneous equilibrium omits concentration terms for pure liquids and pure solids.

9.3 Show how equilibrium and Gibbs energy are related.

Gibbs energy diagrams for chemical reactions show the variation in Gibbs energy of a system as a reaction mixture proceeds from pure reactants to pure products. These diagrams show a minimum, due to the Gibbs energy of mixing of reactants and products, and this minimum corresponds to the equilibrium composition of the reaction mixture. The position of the minimum with respect to the proportion of products to reactants is related to the sign and magnitude of $\Delta_r G^\circ$ for the forward reaction: if $\Delta_r G^\circ$ is large and negative, the forward reaction proceeds essentially to completion and the equilibrium mixture consists predominantly of products; if $\Delta_r G^\circ$ is large and positive, the forward reaction proceeds only to a very small extent and negligible amounts of products are present at equilibrium. $\Delta_r G^\circ$ is related to the equilibrium constant for a chemical reaction by the following equation.

$$\Delta_r G^\circ = -RT \ln K$$

The spontaneity of any change in composition of a reaction mixture is given by the sign of $\Delta_r G$ for that change. $\Delta_r G$ is related to $\Delta_r G^\circ$ by the following equation.

$$\Delta_r G = \Delta_r G^\circ + RT \ln Q$$

9.4 Predict how an equilibrium will respond to change.

The response of a system at equilibrium to a chemical or physical change can be predicted by determining the effect of such a change on the value of Q , the reaction quotient. Any change that affects the value of Q instantaneously removes the system from equilibrium because $Q \neq K$; the way in which the value of Q must change (increase or decrease) to again make $Q = K$ determines the direction of spontaneous change in the reaction mixture. Temperature alone can change the value of K for a chemical equilibrium, and the direction in which spontaneous change must occur to re-establish equilibrium in these cases may be determined by the sign of $\Delta_r H^\circ$ for the forward reaction, via the van't Hoff equation.

$$\frac{d \ln K}{dT} = \frac{\Delta_r H^\circ}{RT^2}$$

Pure solids, pure liquids, inert gases and catalysts do not appear in the expression for Q so addition of these can have no effect on the position of equilibrium.

9.5 Carry out calculations involving equilibria.

Given a set of equilibrium concentration or pressure conditions, we can calculate the value of the equilibrium constant for a reaction, and we can also use the given value of an equilibrium constant to calculate equilibrium concentrations or pressures. We can use a concentration table to assist in such calculations.

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation
Equilibrium constant expression	9.2	This expression defines the relationship between the equilibrium concentrations or partial pressures of the reactants and products in a chemical reaction. For the equilibrium: $aA + bB \rightleftharpoons cC + dD$ $K_c = \frac{[C]^c[D]^d}{[A]^a[B]^b} \quad \text{and} \quad K_p = \frac{\left(\frac{p_C}{p^\ominus}\right)^c \left(\frac{p_D}{p^\ominus}\right)^d}{\left(\frac{p_A}{p^\ominus}\right)^a \left(\frac{p_B}{p^\ominus}\right)^b}$
Reaction quotient expression	9.2	This expression has the same form as the equilibrium constant expression, and is used to characterise systems that are not at equilibrium. The concentrations or partial pressures in the expression can have any value. For the equilibrium: $aA + bB \rightleftharpoons cC + dD$ $Q_c = \frac{[C]^c[D]^d}{[A]^a[B]^b} \quad \text{and} \quad Q_p = \frac{\left(\frac{p_C}{p^\ominus}\right)^c \left(\frac{p_D}{p^\ominus}\right)^d}{\left(\frac{p_A}{p^\ominus}\right)^a \left(\frac{p_B}{p^\ominus}\right)^b}$
Comparison of the values of Q and K	9.2	At equilibrium, $Q = K$. If the system is disturbed such that $Q > K$, the reaction must shift towards reactants to restore equilibrium; if $Q < K$, the reaction must shift towards products to restore equilibrium.
$K_p = K_c \left(\frac{1000 RT}{p^\ominus} \right)^{\Delta n_{\text{gas}}}$	9.2	This equation allows interconversion of K_p and K_c values; Δn_{gas} is the change in the number of moles of gas, which is calculated using the coefficients of gaseous products and reactants.
Manipulation of equilibrium equations	9.2	1. When the direction of an equation is reversed, the new equilibrium constant is the reciprocal of the original. 2. When the coefficients are multiplied by a factor, the equilibrium constant is raised to a power equal to that factor. 3. When chemical equilibria are added, their equilibrium constants are multiplied.
Magnitude of the equilibrium constant	9.2	1. When K_c is very large, the equilibrium position lies towards the products. 2. When $K_c \approx 1$, the concentrations of reactants and products are similar at equilibrium. 3. When K_c is very small, the equilibrium position lies towards the reactants.
Value of $\Delta_r G^\ominus$ for a reaction	9.3	The magnitude and sign of $\Delta_r G^\ominus$ indicate qualitatively whether or not a significant amount of products will form. If $\Delta_r G^\ominus$ is reasonably large and negative, the reaction will proceed largely towards products. If $\Delta_r G^\ominus$ is reasonably large and positive, the equilibrium mixture will contain mainly reactants.
$\Delta_r G = \Delta G^\ominus + RT \ln Q$	9.3	This equation relates the reaction quotient, Q , to $\Delta_r G$, which enables us to determine whether a reaction is at equilibrium and, if not, the direction of spontaneous change required to reach equilibrium.
$\Delta_r G^\ominus = -RT \ln K$	9.3	This equation relates $\Delta_r G^\ominus$ to the equilibrium constant, K .
Concentration table	9.5	This may be used in problems involving equilibria to determine the concentrations of reactants and products at equilibrium.

KEY TERMS

activities Effective concentrations that give rise to thermodynamic equilibrium constants when substituted into an equilibrium constant expression.

chemical equilibrium A situation in which the chemical composition of a system does not change with time.

concentration table A table that outlines the changes in concentration that occur as a chemical system comes to equilibrium.

dynamic equilibrium An equilibrium in which the rates of the forward and reverse reactions are equal.

equilibrium constant (K) The value of the equilibrium constant expression when the system is at equilibrium.

equilibrium constant expression A fraction in which the numerator is the product of the equilibrium molar concentrations of the products, each raised to a power equal to its coefficient in the equilibrium equation, and the denominator is the product of the equilibrium molar concentrations of the reactants, each raised to a power equal to its coefficient in the equation. (For gaseous reactions, partial pressures can be used in place of molar concentrations.)

Gibbs energy diagram A plot of the changes in Gibbs energy for a system versus its composition.

heterogeneous equilibrium An equilibrium system involving more than one phase.

heterogeneous reaction A reaction in which not all of the chemical species are in the same phase.

homogeneous equilibrium An equilibrium system in which all components are in the same phase.

homogeneous reaction A chemical reaction in which all participating species are in the same phase.

Le Châtelier's principle If an outside influence upsets an equilibrium, the system undergoes a change in a direction that counteracts the disturbing influence and, if possible, returns the system to equilibrium.

reaction quotient (Q) The numerical value of the equilibrium constant expression under any conditions; see also *equilibrium constant expression*.

reaction quotient expression A fraction in which the numerator is the product of the molar concentrations of the products, each raised to a power equal to its coefficient in the equilibrium equation, and the denominator is the product of the molar concentrations of the reactants, each raised to a power equal to its coefficient in the equation. (For gaseous reactions, partial pressures can be used in place of molar concentrations.)

thermodynamic equilibrium constant An equilibrium constant defined in terms of activities.

van't Hoff equation $\frac{d \ln K}{dT} = \frac{\Delta H^\circ}{RT^2}$ This shows how the value of an equilibrium constant varies with temperature.

REVIEW QUESTIONS

Note: Unless otherwise stated, all questions refer to a temperature of 25.0 °C.

Chemical equilibrium

LO1

9.1 What information do the stoichiometric coefficients in a balanced chemical equation provide in terms of how far the reaction proceeds towards completion?

9.2 What is meant when we say that chemical reactions are reversible?

9.3 What is a dynamic equilibrium?

The equilibrium constant, K , and reaction quotient, Q

LO2

9.4 Although the forms of the equilibrium constant and the reaction quotient appear similar, they differ in one crucial aspect. What is the difference between the two?

9.5 What possible values can Q , the reaction quotient, have?

9.6 Outline the method for writing the equilibrium constant expression K_c for any equilibrium.

9.7 Give the equation which relates K_p to K_c and define all the terms used. Why is the factor of 1000 required? (*Hint:* Consider the concentration units that result from use of the ideal gas equation.)

9.8 Use the equation referred to in question 9.7 to show that if $\Delta n_{\text{gas}} = 0$, then the values of K_c and K_p will be identical. Show why this must be the case, from a consideration of the forms of the expressions for both K_c and K_p .

9.9 What would a K_c value of 5.1×10^7 for a particular equilibrium imply about the relative amounts of reactants and products at equilibrium?

9.10 Arrange the following equilibria in order of increasing tendency to proceed towards completion.

9.11 What is the difference between a heterogeneous equilibrium and a homogeneous equilibrium?

9.12 Pure ethanol at 25.00 °C and 1.013×10^5 Pa has a density of 0.7849 g mL^{-1} . What is the concentration of pure ethanol under these conditions?

Equilibrium and Gibbs energy

LO3

9.13 Sketch a graph to show how Gibbs energy changes during a phase change such as the melting of a solid.

9.14 Sketch the shape of the Gibbs energy curve for a chemical reaction that has a negative $\Delta_r G^\circ$. Indicate the composition of the reaction mixture when it is at equilibrium.

9.15 Why does a reaction that has a positive value of $\Delta_r G^\circ$ proceed in the forward direction at all?

9.16 Suppose a reaction has a positive $\Delta_r S^\circ$. Will more or less product be present at equilibrium as the temperature is raised? Assume that $\Delta_r H^\circ$ and $\Delta_r S^\circ$ are independent of temperature.

9.17 Write the equation that relates the Gibbs energy change to the value of the reaction quotient for a reaction.

9.18 The equation that relates the equilibrium constant to the standard Gibbs energy change for a reaction is $\Delta_r G^\circ = -RT \ln K$. Which equilibrium constant, K_p or K_c , must we use in this equation for a gas phase equilibrium?

9.19 What is an activity, in thermodynamic terms?

9.20 What is the value of K for a reaction for which $\Delta_r G^\circ = 0$?

How systems at equilibrium respond to change**LO4****9.21** Consider the equilibrium below.

How will it be affected by the following?

- (a) addition of $\text{CH}_4(\text{g})$
- (b) addition of $\text{H}_2(\text{g})$
- (c) removal of $\text{CS}_2(\text{g})$
- (d) decreasing the volume of the container
- (e) increasing the temperature (the forward reaction is endothermic)

9.22 The forward reaction in the following equilibrium has $\Delta_r H^\circ = -171.07 \text{ kJ mol}^{-1}$.How will the amount of $\text{N}_2\text{O}_4(\text{g})$ present in an equilibrium mixture of these gases be affected by the following?

- (a) adding $\text{NO}(\text{g})$
- (b) removing $\text{O}_2(\text{g})$
- (c) increasing the volume of the reaction vessel
- (d) adding a catalyst
- (e) decreasing the temperature

9.23 ClF_3 is an extremely reactive compound that can be made from the reaction of fluorine with chlorine. The forward reaction of the following equilibrium has $\Delta_r H^\circ = -163 \text{ kJ mol}^{-1}$.

In which direction will the position of equilibrium be shifted by the following changes?

- (a) addition of $\text{Cl}_2(\text{g})$
- (b) removal of $\text{ClF}_3(\text{g})$
- (c) removal of $\text{F}_2(\text{g})$
- (d) increasing the temperature of the reaction mixture
- (e) addition of helium gas to the reaction mixture while keeping the volume of the reaction vessel constant
- (f) decreasing the volume of the container

9.24 Consider the following equilibrium, which has $\Delta_r H^\circ = -77.07 \text{ kJ mol}^{-1}$ for the forward reaction.How will the amount of NO in an equilibrium mixture of these gases be affected by the following?

- (a) addition of $\text{Cl}_2(\text{g})$
- (b) removal of $\text{NOCl}(\text{g})$
- (c) decreasing the temperature
- (d) increasing the volume of the reaction vessel

9.25 Under what circumstances will changing the volume of the reaction vessel not affect the position of equilibrium of a gas phase equilibrium?**Equilibrium calculations****LO5****9.26** Phosgene, COCl_2 , is a poisonous gas that was used as a chemical weapon in World War I. Today, it is used on a large scale in industry in the manufacture of plastics and foams. It can be prepared from the reaction of CO and Cl_2 according to the following equation.A mixture of $\text{CO}(\text{g})$ and $\text{Cl}_2(\text{g})$ was prepared at a particular temperature, such that the initial concentrations immediately after mixing were $[\text{CO}] = 4.76 \times 10^{-2} \text{ mol L}^{-1}$ and $[\text{Cl}_2] = 6.12 \times 10^{-2} \text{ mol L}^{-1}$. When equilibrium was reached, $[\text{COCl}_2]$ was $5.40 \times 10^{-3} \text{ mol L}^{-1}$. Construct a concentration table for this system using these data.**9.27** When carrying out equilibrium calculations, it is sometimes possible to make simplifying assumptions. Under what conditions can such assumptions be made?**9.28** Cl_2 reacts with Br_2 in CCl_4 solution at a particular temperature to form BrCl according to the following equation.If the initial concentrations were $[\text{Br}_2] = 0.6 \text{ mol L}^{-1}$ and $[\text{Cl}_2] = 0.4 \text{ mol L}^{-1}$ and $[\text{BrCl}] = 0.0 \text{ mol L}^{-1}$, which of the following concentration versus time graphs could represent this reaction? Explain why you rejected each of the other four graphs.

REVIEW PROBLEMS

- 9.29** Write the equilibrium constant expression for each of the following equilibria in terms of concentrations. **LO2**

- 9.30** Reverse the equilibrium equations in problem 9.29 and write the K_p expressions for these. **LO2**

- 9.31** Write the equilibrium constant expression for each of the following equilibria in aqueous solution. **LO2**

- 9.32** At 27°C , $K_p = 1.5 \times 10^{18}$ for the following equilibrium. **LO2**

What is the value of K_p for the following equilibrium at the same temperature?

- 9.33** Use the following equilibria: **LO2**

to calculate K_c for the following equilibrium.

- 9.34** Write the equilibrium constant expression for each of the following equilibria in terms of concentrations. **LO2**

How does the value of K_c for equilibrium (a) compare with that of K_c for equilibrium (b)?

- 9.35** Write the equilibrium constant expression K_c for the following equilibrium. **LO2**

How does the value of K_c for this equilibrium compare with the value of K_c for equilibrium (a) in problem 9.34?

- 9.36** Write the equilibrium constant expression K_p for a system comprising liquid water and water vapour in equilibrium with each other. **LO2**

- 9.37** Why are pure solids and pure liquids not included in equilibrium constant expressions? **LO2**

- 9.38** For which of the following equilibria does the value of K_p equal that of K_c ? **LO2**

- 9.39** The following equilibrium has $K_p = 6.3 \times 10^{-3}$ at 225°C . **LO2**

What is the value of K_c at this temperature?

- 9.40** The following equilibrium has $K_c = 2.38 \times 10^3$ at 500°C . **LO2**

What is the value of K_p at this temperature?

- 9.41** One possible way of removing NO from the exhaust of a petrol engine is to cause it to react with CO in the presence of a suitable catalyst. **LO2**

At 300°C , this equilibrium has $K_c = 2.2 \times 10^{59}$. What is K_p at 300°C ?

- 9.42** The following equilibrium has $K_p = 6.25 \times 10^{-7}$ at 400°C . **LO2**

What is the value of K_c at this temperature?

- 9.43** The following equilibrium has $K_p = 2.17 \times 10^1$ at 395°C . **LO2**

What is the value of K_c at this temperature?

- 9.44** The maximum density of pure water at atmospheric pressure ($1.013 \times 10^5 \text{ Pa}$) is 1.000 g mL^{-1} . This occurs at a temperature of 3.98°C . What is the concentration of pure water in mol L^{-1} under these conditions? **LO2**

- 9.45** Osmium, Os, is believed to be the most dense of the naturally occurring elements, with a density of 22.59 g cm^{-3} . What is the concentration of any sample of pure osmium? **LO2**

- 9.46** Write the equilibrium constant expression, K_c , for the following heterogeneous equilibria. **LO2**

- 9.47** The following heterogeneous equilibrium has $K_c = 6.25 \times 10^{33}$ at 25°C . **LO5**

If 0.125 mol of both $\text{HCl}(\text{g})$ and $\text{I}_2(\text{s})$ are placed in a 1.00 L reaction vessel, what will be the equilibrium concentrations of $\text{HI}(\text{g})$ and $\text{Cl}_2(\text{g})$ in the reaction vessel?

- 9.48** At 25°C , $K_c = 360$ for the following equilibrium. **LO2**

If solid AgCl is added to a solution containing $0.1000 \text{ mol L}^{-1} \text{ Br}^-$, calculate the equilibrium concentrations of Br^- and Cl^- .

- 9.49** Use the $\Delta_r G^\circ$ data supplied in appendix A to calculate the value of K_p for the following equilibria at 25°C . **LO3**

- 9.50** The forward reaction in the following equilibrium has $\Delta_r G^\circ_{1273 \text{ K}} = -9.67 \text{ kJ mol}^{-1}$. **LO3**

A 1.00 L reaction vessel at 1273 K contains 0.0200 mol NO_2 , 0.040 mol NO , $0.015 \text{ mol N}_2\text{O}$ and 0.0350 mol O_2 . Is the reaction mixture at equilibrium? If not, in which direction will spontaneous change occur for the system to reach equilibrium?

- 9.51** The forward reaction in the following equilibrium has $\Delta_r G^\circ_{673 \text{ K}} = -79.8 \text{ kJ mol}^{-1}$. **LO3**

Is a gas mixture containing 0.047 mol HCOOH, 0.061 mol CO and 0.013 mol H₂O in a 1.75 L reaction vessel at 400 °C at equilibrium? If not, in which direction will spontaneous change occur for the system to reach equilibrium?

- 9.52** The forward reaction in the following equilibrium, for which $\Delta_r G^\circ = -50.79 \text{ kJ mol}^{-1}$, can be used to convert coal to methane, the major component of natural gas. **L03**

What is the value of K_p for this reaction at 25 °C? Does this value of K_p suggest that it is worth studying this reaction as a means of methane production?

- 9.53** One of the important reactions in living cells from which the organism draws energy is the reaction of adenosine triphosphate (ATP) with water to give adenosine diphosphate (ADP) and a free phosphate ion. **L03**

The value of $\Delta_r G^\circ$ for the reverse reaction at 37 °C (normal human body temperature) is -33 kJ mol^{-1} . Write the equilibrium constant expression and calculate the value of the equilibrium constant for the equilibrium at this temperature.

- 9.54** What is the value of the reaction quotient, Q , at the very beginning of a chemical reaction before any products have been formed? What happens to the value of Q as the reaction proceeds to give products? **L03**
- 9.55** Methanol, a potential replacement for petrol as a fuel in cars, can be made from H₂ and CO by the forward reaction in the following equilibrium. **L03**

At 500 K, this equilibrium has $K_p = 6.25 \times 10^{-3}$. Calculate $\Delta_r G^\circ_{500\text{K}}$ for the reverse reaction in this equilibrium.

- 9.56** Refer to the table of $\Delta_r G^\circ$ values in appendix A to determine $\Delta_r G^\circ$ for the forward reaction in the following equilibrium. **L03**

What is the value of K_p for this equilibrium at 25 °C?

- 9.57** Use the data in table 9.7 to calculate $\Delta_r G^\circ_{773\text{K}}$ for the forward reaction in the following equilibrium. **L03**

What is the value of K_p for the equilibrium at this temperature?

- 9.58** The following equilibrium has $K_c = 0.18$ at a particular temperature. **L03**

Analysis of a reaction vessel containing these three gases at this temperature showed them to be present in the following concentrations:

$[\text{PCl}_3] = 0.0275 \text{ mol L}^{-1}$, $[\text{Cl}_2] = 0.0317 \text{ mol L}^{-1}$, $[\text{PCl}_5] = 0.00168 \text{ mol L}^{-1}$.

(a) Is the system at equilibrium?

(b) If not, in which direction will a spontaneous change occur to restore equilibrium?

- 9.59** At 460 °C, the following equilibrium has $K_c = 85.0$. **L05**

A reaction flask at 460 °C contains these gases at the following concentrations:

$[\text{SO}_2] = 0.0450 \text{ mol L}^{-1}$, $[\text{NO}_2] = 0.00250 \text{ mol L}^{-1}$, $[\text{NO}] = 0.00750 \text{ mol L}^{-1}$, $[\text{SO}_3] = 0.00850 \text{ mol L}^{-1}$.

(a) Is the system at equilibrium?

(b) If not, in which direction will a spontaneous change occur to restore equilibrium?

- 9.60** At a certain temperature, the following equilibrium has $K_c = 0.521$. **L05**

If a reaction mixture at equilibrium contains CO at a concentration of 0.247 mol L^{-1} and H₂ at a concentration of 0.194 mol L^{-1} , what is the concentration of CH₃OH in the mixture?

- 9.61** For the following equilibrium $K_c = 64$ at a certain temperature. **L05**

Suppose it was found that the concentration of NH₃ and N₂ in an equilibrium mixture of the three gases was 0.130 mol L^{-1} and $0.0920 \text{ mol L}^{-1}$, respectively. What was the equilibrium concentration of H₂ in the mixture?

- 9.62** At 773 °C, a mixture of CO(g), H₂(g) and CH₃OH(g) was allowed to come to equilibrium. At equilibrium, the concentrations of the three gases were: $[\text{CO}] = 0.105 \text{ mol L}^{-1}$, $[\text{H}_2] = 0.250 \text{ mol L}^{-1}$ and $[\text{CH}_3\text{OH}] = 0.00261 \text{ mol L}^{-1}$. Calculate K_c for the following equilibrium. **L05**

- 9.63** Ethene, C₂H₄, and water react under appropriate conditions to give ethanol.

An equilibrium mixture of these gases at a certain temperature had the following concentrations: $[\text{C}_2\text{H}_4] = 0.0148 \text{ mol L}^{-1}$, $[\text{H}_2\text{O}] = 0.0336 \text{ mol L}^{-1}$ and $[\text{C}_2\text{H}_5\text{OH}] = 0.180 \text{ mol L}^{-1}$. What is the value of K_c for the equilibrium? **L05**

- 9.64** A mixture of H₂(g), Br₂(g) and HBr(g) will eventually come to equilibrium. At a high temperature, 2.00 mol of HBr was placed in a 4.00 L container. At equilibrium, the concentration of Br₂ was $0.0955 \text{ mol L}^{-1}$. What is K_c for the following equilibrium at this temperature? **L05**

- 9.65** A 0.050 mol sample of formaldehyde vapour, HCHO, was placed in a heated 500 mL vessel and some of it decomposed to set up the equilibrium: **L05**

At equilibrium, the HCHO(g) concentration was 0.066 mol L^{-1} . Calculate the value of K_c for this equilibrium.

- 9.66** A reaction vessel at high temperature contained the following gases at the given initial concentrations: $[\text{N}_2\text{O}] = 0.184 \text{ mol L}^{-1}$, $[\text{O}_2] = 0.377 \text{ mol L}^{-1}$, $[\text{NO}_2] = 0.0560 \text{ mol L}^{-1}$, $[\text{NO}] = 0.294 \text{ mol L}^{-1}$. As NO₂ is the only coloured gas in the mixture, its concentration was monitored by following the intensity of the colour. At equilibrium, the NO₂ concentration was 0.118 mol L^{-1} . What is the value of K_c for the following equilibrium at this temperature? **L05**

- 9.67** At 25 °C, 0.0560 mol O₂ and 0.020 mol N₂O were placed in a 1.00 L container where the following equilibrium was then established. **L05**

At equilibrium, the NO_2 concentration was 0.020 mol L^{-1} . What is the value of K_c for this equilibrium?

- 9.68** At 25°C , $K_c = 0.145$ for the following equilibrium in the solvent CCl_4 . **LO5**

If the initial concentration of BrCl in the solution is 0.047 mol L^{-1} , calculate the equilibrium concentrations of Br_2 and Cl_2 .

- 9.69** The equilibrium constant, K_c , for the following equilibrium was found to be 0.500 at a specific temperature. **LO5**

If 0.175 mol of SO_3 and 0.175 mol of NO are placed in a 1.00 L container and allowed to react until equilibrium is established, calculate the equilibrium concentration of each gas.

- 9.70** For the equilibrium in problem 9.69, a reaction mixture is prepared in which 0.160 mol of NO_2 and 0.160 mol of SO_2 are placed in a 1.00 L vessel. What are the concentrations of all four gases at equilibrium? How do these equilibrium values compare with those calculated in problem 9.69? Account for your observation. **LO5**

- 9.71** At a particular temperature, the following equilibrium has $K_c = 0.400$. **LO5**

1.00 mol of each of $\text{CO}(\text{g})$, $\text{H}_2\text{O}(\text{g})$, $\text{CO}_2(\text{g})$ and $\text{H}_2(\text{g})$ were introduced into an evacuated 50 L vessel and the mixture was allowed to come to equilibrium at the particular temperature. Calculate the equilibrium concentration of each gas.

- 9.72** The following equilibrium has $K_c = 3.2 \times 10^{-34}$ at 25°C .

If a reaction vessel initially contains $0.0350 \text{ mol L}^{-1}$ of HCl , what will be the concentrations of H_2 and Cl_2 at equilibrium? **LO5**

- 9.73** At 200°C , $K_c = 1.4 \times 10^{-10}$ for the following equilibrium. **LO5**

If 0.225 mol of N_2O and 0.450 mol of NO_2 are placed in a 4.00 L container, what is the NO concentration at equilibrium?

- 9.74** At 2000°C , the decomposition of CO_2 , shown below, has $K_c = 6.4 \times 10^{-7}$. **LO5**

If 2.6×10^{-2} mol of CO_2 is placed in a 2.00 L container that is then heated to 2000°C , what is the concentration of CO when equilibrium has been established?

- 9.75** At 500°C , the decomposition of $\text{H}_2\text{O}(\text{g})$ into $\text{H}_2(\text{g})$ and $\text{O}_2(\text{g})$ proceeds according to the following equilibrium with $K_c = 6.0 \times 10^{-28}$. **LO5**

What amounts of $\text{H}_2(\text{g})$ and $\text{O}_2(\text{g})$ are present at equilibrium in a 2.00 L reaction vessel at this temperature if the container originally held 0.00721 mol of H_2O ?

- 9.76** At a certain temperature, $K_c = 0.18$ for the following equilibrium. **LO5**

If 0.0580 mol of PCl_5 is placed in a 2.00 L vessel at this temperature, what is the concentration of PCl_3 at equilibrium?

- 9.77** At 460°C , the following equilibrium has $K_c = 85.0$. **LO5**

Suppose 0.120 mol of SO_2 , 0.0328 mol of NO_2 , 0.0913 mol of NO and 0.159 mol of SO_3 are placed in a 10.0 L container at this temperature. What are the concentrations of all the gases when the system reaches equilibrium?

- 9.78** At a certain temperature, $K_c = 0.500$ for the equilibrium. **LO5**

If 0.400 mol SO_3 and 0.300 mol NO are placed in a 2.00 L container and allowed to come to equilibrium, what are the NO_2 and SO_2 concentrations?

- 9.79** At 25°C , $K_c = 6.90$ for the following equilibrium in the solvent CCl_4 . **LO5**

A solution was prepared with the initial concentrations: $[\text{BrCl}] = 0.0425 \text{ mol L}^{-1}$, $[\text{Br}_2] = 0.0305 \text{ mol L}^{-1}$, $[\text{Cl}_2] = 0.0243 \text{ mol L}^{-1}$. What are the equilibrium concentrations of all three compounds?

- 9.80** At a certain temperature, $K_c = 4.3 \times 10^5$ for the following equilibrium: **LO5**

If 0.200 mol of HCOOH is placed in a 1.00 L vessel, what are the concentrations of CO and H_2O when the system reaches equilibrium?

- 9.81** The equilibrium below has $K_c = 2.0 \times 10^9$ at 25°C . **LO5**

If 0.112 mol of H_2 and 0.224 mol of Br_2 are placed in a 10.0 L container, what are the equilibrium concentrations of all components at 25°C ?

ADDITIONAL EXERCISES

- 9.82** Show, by writing expressions for K_p and K_c , and making appropriate substitutions, that for the equilibrium: **LO2**

$$K_p = K_c \left(\frac{1000 RT}{p^\circ} \right)^{-1}$$

- 9.83** We have seen that if the value of K for an equilibrium is very large, then products will predominate at equilibrium, while a

very small value of K means that hardly any products will be formed. If $K = 1$, we might expect the concentrations of reactants and products to be equal. To show that this is not necessarily the case, consider the following equilibrium, for which $K = 1$ at a particular temperature. **LO5**

Assume we introduce 1.00 mol of both A(g) and B(g) into a 1.00 L evacuated container, and then let the system come to equilibrium at the particular temperature. Show that, at equilibrium, $[A] = [B] = 0.618 \text{ mol L}^{-1}$ and $[C] = 0.382 \text{ mol L}^{-1}$. Repeat this calculation for the following equilibrium, which has $K = 1$ at a particular temperature.

Use $[A] = [B] = [C] = 1.00 \text{ mol L}^{-1}$ as initial concentrations. Show that, at equilibrium, $[A] = [B] = [C] = 0.682 \text{ mol L}^{-1}$ and $[D] = 0.318 \text{ mol L}^{-1}$.

Comment on whether or not you consider the equilibrium concentrations of reactants and products to be equal in both situations. Under what conditions will the concentrations of reactants and products be identical for an equilibrium having $K = 1$?

- 9.84** Consider the two equilibria below, both of which have $K_c = 2$. **LO2**

Show that, at equilibrium, the ratio of products to reactants, $[Y]/[X]$, in the second equilibrium increases as $[Y]$ increases, while the same ratio remains constant in the first equilibrium. At what $[Y]$ is the ratio $[Y]/[X] = 1$ for the second equilibrium? Discuss how this example is important with respect to determining the position of equilibrium in equilibria having similar values of K .

- 9.85** With reference to figure 9.10, would you expect the change in composition $4 \rightarrow 1$ to occur spontaneously? Outline your reasoning. **LO3**

- 9.86** At a particular temperature, $K_c = 0.914$ for the following equilibrium. **LO5**

A mixture was prepared containing 0.100 mol of NO_2 , 0.100 mol of NO , 0.100 mol of N_2O and 0.100 mol of O_2 in a 4.00 L container. What are the equilibrium concentrations of each gas?

- 9.87** At 27°C , $K_p = 1.5 \times 10^{18}$ for the following equilibrium. **LO5**

If 0.070 mol of NO is placed in a 1.00 L vessel and equilibrium is established, what are the equilibrium concentrations of NO , N_2O and NO_2 ?

- 9.88** The equilibrium

has $K_c = 0.0156$ at a particular temperature. 0.100 mol of HI was introduced into an evacuated 2.00 L glass bulb at this temperature, and the system was allowed to come to equilibrium. Determine the equilibrium concentrations of the three gases. How will these concentrations change if 0.020 mol of H_2 is added to the equilibrium mixture?

- 9.89** A sample of liquid water was injected into an evacuated reaction vessel at 25.0°C and the system was allowed to come to equilibrium at this temperature. If $\Delta_r G^\circ = 8.60 \text{ kJ mol}^{-1}$ for the forward process of the following equilibrium, what is the pressure of $\text{H}_2\text{O}(g)$ in the reaction vessel at equilibrium at 25.0°C ? **LO3**

- 9.90** It is important that you obtain an appreciation for the values of K that correspond to particular values of ΔG° , and vice versa. **LO3**

- (a) Use a spreadsheet to complete the following table for $T = 25.0^\circ\text{C}$.
(b) Plot ΔG° versus $\ln K$ for each of the two sets of data in the table.
(c) What is the slope of each graph?

$\Delta G^\circ/\text{kJ mol}^{-1}$	K	K	$\Delta G^\circ/\text{kJ mol}^{-1}$
-100.00		1.00×10^{-50}	
-50.00		1.00×10^{-20}	
-30.00		1.00×10^{-10}	
-20.00		1.00×10^{-5}	
-10.00		1.00×10^{-2}	
-5.00		1.00×10^0	
0.00		1.00×10^1	
5.00		1.00×10^2	
10.00		1.00×10^3	
20.00		1.00×10^4	
30.00		1.00×10^5	
50.00		1.00×10^{10}	
100.00		1.00×10^{20}	
		1.00×10^{50}	

- 9.91** In worked example 9.13 we showed that we could make a simplifying assumption in an equilibrium calculation. This assumption was that subtraction of the change in concentration of a product from the initial concentration of a reactant gave a value that was essentially equal to the initial concentration of the reactant. In mathematical terms, this becomes: **LO5**

(initial concentration of reactant) - (change in concentration of product) $\approx$ (initial concentration of reactant)

We stated that this assumption was valid when the initial concentration of reactant is at least 400 times greater than the value of K .

- (a) Use the equilibrium:

with initial concentrations $[A] = 1.00 \text{ mol L}^{-1}$ and $[B] = [C] = 0.00 \text{ mol L}^{-1}$ to show that

$$K = \frac{x^2}{(1.00 - x)}$$

- (b) Use the expression given in (a) to calculate x exactly for the following values of K : 0.1, 0.05, 0.01, 0.005, 0.0025, 0.0001, 0.000 01, 0.000 001.
(c) Repeat the calculations in (b) assuming $(1.00 - x) = 1.00$.
(d) Determine the percentage error in the value of x for each calculation.

MATHS FOR CHEMISTRY

The natural logarithm: ln or log_e

You are probably familiar with logarithms. You know, for example, that $10^2 = 100$ and that therefore, the logarithm of 100 is 2. Likewise, $1\,000\,000 = 10^6$, and so the logarithm of 1 000 000 is 6. However, it is important to realise that there is more than one type of logarithm. The logarithms discussed in the above sentences are logarithms to the base 10 — in other words, these are the powers to which 10 must be raised in order to obtain the desired number. We sometimes signify these types of logarithms by the symbol 'log₁₀', although we usually just use the symbol 'log'. In chemistry we use these logarithms extensively in problems involving pH, where $\text{pH} = -\log[\text{H}_3\text{O}^+]$ (see the chapter on acids and bases).

Another type of logarithm which is commonly used is the natural logarithm (ln), sometimes called the logarithm to the base e ($\log_e$). In this case, instead of using 10 as the base as we did above, the number e is used. e is an irrational number, whose first few digits are 2.718 281 828 4. Just as any number can be expressed in the form 10^y , where y is the logarithm (log₁₀) of the number, so any number can be expressed in the form e^x , where x is the natural logarithm of the number. For example, $100 = e^{4.605\,170}$, and therefore the natural logarithm of 100 is 4.605 170. Natural logarithms are important in calculus, for the reason that $\int \frac{1}{x} = \ln x + C$. In chemistry, they are used most notably in the equation $\Delta G^\circ = -RT \ln K$ and in the Nernst equation (see the chapter on oxidation and reduction).

It is vital that you recognise the difference between the two types of logarithm discussed above and use the appropriate logarithm in your calculations. Your calculator will have separate buttons for both types of logarithms — don't get them mixed up!

Simplifying complicated fractions

There have been several instances in this chapter involving equations containing fractions divided by fractions. We will now look at how to simplify these.

Consider the equation below.

$$y = \frac{\frac{a}{b}}{\frac{c}{d}}$$

In other words, we are dividing $\frac{a}{b}$ by $\frac{c}{d}$. This can look a little daunting to begin with, but we can utilise a fact we first met in the discussion of units in the chapter on the language of chemistry — we can essentially condense the two fractions into one. Recall that we can write the unit of velocity, the metre per second, in three equivalent ways:

$$\text{m s}^{-1}$$

$$\frac{m}{s}$$

$$m \times \frac{1}{s}$$

These examples illustrate the point that any fraction can be written as the top line multiplied by the *inverse* of the bottom line. For example:

$$\frac{8}{4} = 8 \times \frac{1}{4}$$

We can use this to simplify the original fraction in one of two equivalent ways.

$$y = \frac{\frac{a}{b}}{\frac{c}{d}}$$

1. We treat the top fraction and the bottom fraction separately such that:

$$\begin{aligned}\frac{a}{b} &= a \times \frac{1}{b} \\ &= ab^{-1}\end{aligned}$$

and

$$\frac{c}{d} = c \times \frac{1}{d} = cd^{-1}$$

We then rewrite the original fraction as:

$$y = \frac{ab^{-1}}{cd^{-1}} = \frac{a}{c} \times \frac{b^{-1}}{d^{-1}} = \frac{a}{c} \times \frac{d}{b} = \frac{ad}{bc}$$

recognising that:

$$b^{-1} = \frac{1}{b} \quad \text{and} \quad \frac{1}{d^{-1}} = d$$

2. We treat the whole fraction as a 'top line', consisting of the fraction $\frac{a}{b}$ and a 'bottom line' consisting of the fraction $\frac{c}{d}$. We then multiply the 'top line' $\frac{a}{b}$ by the inverse of the bottom line $\frac{c}{d}$ which then becomes $\frac{d}{c}$. Thus, we obtain:

$$y = \frac{a}{b} \times \frac{d}{c} = \frac{ad}{bc}$$

As you can see, both routes lead to the same answer.

Solutions and solubility

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 10.1** define important terms related to solutions
- 10.2** describe why gases mix spontaneously
- 10.3** outline the energetics involved in the formation of liquid solutions
- 10.4** carry out calculations involving slightly soluble salts
- 10.5** quantify the effects that arise in solutions as a result of colligative properties.

X-rays were first discovered in 1895, enabling doctors to take images of inside a living body. This process relies on the absorption of X-rays by constituents of the body. While objects such as bone give clear images, soft tissue is more difficult to see. Therefore, to create an X-ray image of areas such as the gastrointestinal tract, it is necessary to use a contrast agent that absorbs X-rays well and can be delivered specifically to the required part of the body. Barium sulfate, BaSO_4 , is one such contrast agent. This is ingested by the patient in the form of a barium meal, thereby coating the gastrointestinal tract, and an X-ray is taken shortly thereafter (figure 10.1).

The Ba^{2+} ion is highly toxic. Swallowing a barium salt would generally end in death. However, barium sulfate is only slightly soluble in aqueous solution, meaning that the concentration of Ba^{2+} never approaches toxic levels.

FIGURE 10.1

BaSO_4 absorbs X-rays and is used as a contrast agent to produce images of the gastrointestinal tract. The low solubility of barium sulfate in aqueous solution means the amount of the Ba^{2+} ion does not reach toxic levels in the patient.

In this chapter, we will examine various aspects of solutions and solubility. In addition to outlining the different possible types of solutions, we will investigate the energetics behind the formation of solutions, quantify the solubility of slightly soluble salts using the solubility product, K_{sp} , and show that physical properties such as the freezing and boiling points of solutions depend on the number of solute particles in the solution.

10.1 Introduction to solutions and solubility

LEARNING OBJECTIVE 10.1 Define important terms related to solutions.

The ability of chemical substances to mix with each other is a very important aspect of chemistry. We are familiar with many examples from everyday life; for example, dissolving instant coffee in a cup of hot water, adding detergent to water and cleaning a used paintbrush with turpentine are all situations where we require two substances to mix completely. However, there are also substances that we cannot get to mix no matter how hard we try, the prime example being oil and water (so we don't use water to clean a paintbrush covered in oil-based paint). Many aspects of chemical synthesis, in particular the purification of products following a chemical reaction, rely on the fact that particular substances *don't* mix. An understanding of the principles involved in the formation of solutions is important in many areas of chemistry. In this chapter, we will focus on the energetics of formation of solutions and the quantification of physical properties of solutions.

A **solution** can be defined as a homogeneous mixture of two or more pure substances ('homogeneous' means that all regions of the solution have exactly the same composition). Despite the fact that we often think of a solution as involving some type of liquid, we can have gaseous solutions comprising two or more gases (e.g. air) and even solid solutions comprising two or more solids (e.g. alloys such as brass and solder) in addition to the 'usual' solutions containing a gas, liquid or solid dissolved in a liquid. In the case of liquid solutions, we call the liquid the **solvent**, while the dissolved substance is called the **solute**; the solute is present in smaller amounts than the solvent. A solute is said to be **soluble** in a particular solvent if it dissolves completely in that solvent at the specified temperature. We define the **solubility** of the solute in a particular solvent as the maximum amount of the solute that dissolves completely in a given mass or volume of the solvent at a particular temperature, T , and a particular pressure, p . A **saturated solution** is one in which no more solute will dissolve.

The most common type of saturated solution we will encounter is that illustrated in figure 10.2, in which excess solid solute is in equilibrium with its dissolved form.

The process of dissolving a solute in a solvent to give a homogeneous solution is called **dissolution**. We therefore talk of the dissolution of a solute in a particular solvent.

FIGURE 10.2

A saturated solution. In a saturated solution, a dynamic equilibrium exists between the undissolved solute and the dissolved solute in the solution.

10.2 Gaseous solutions

LEARNING OBJECTIVE 10.2 Describe why gases mix spontaneously.

We will begin our investigation of solutions by looking at mixing two gases to form a gaseous solution. We start with the situation depicted in figure 10.3, where two different pure gases are separated by a divider. When we remove the divider, we find that the two gases mix spontaneously to give a homogeneous gaseous solution. This is not surprising given that the gas molecules are moving randomly at hundreds of metres per second. Even if we cool the two gases, they will still mix completely, albeit more slowly.

In fact, as we saw in the chapter on chemical equilibrium, all gases mix completely with all other gases in all proportions. The fact that the two gases in figure 10.3 mix spontaneously means that ΔG for the mixing process ($\Delta_{\text{mix}}G$) must be negative. Recall from the chapter on chemical thermodynamics:

$$\Delta G = \Delta H - T\Delta S$$

Given that the enthalpy change when two unreactive gases are mixed is usually small because there is little interaction between the atoms or molecules, it is the large positive $\Delta_{\text{mix}}S$ term that ensures that $\Delta_{\text{mix}}G$ is negative. The completely mixed state is far more statistically likely and, therefore, of higher entropy than the unmixed state; this leads to a large entropy increase on mixing, and a correspondingly large positive $\Delta_{\text{mix}}S$ value. In fact, we say that the mixing process is entropy-driven. When we consider the gases at the molecular level (or indeed the atomic level for monatomic gases such as He, Ne, Ar, Kr, Xe and Rn), we can see that there is no impediment to mixing the gases, as the intermolecular forces between individual gas molecules are tiny, and the gas molecules are far apart. However, when we consider condensed-phase solutions (i.e. solutions involving liquids and/or solids), we will see that the magnitude of interatomic or intermolecular attractions in the condensed phase can determine whether or not two substances can mix. In these cases, the enthalpy of mixing becomes important.

FIGURE 10.3

Mixing gases. When two gases, initially in separate compartments (a) suddenly find themselves in the same container (b), they mix spontaneously.

10.3 Liquid solutions

LEARNING OBJECTIVE 10.3 Outline the energetics involved in the formation of liquid solutions.

As mentioned in section 10.1, there are many possible types of solutions. In this section, we will discuss, in detail, the solutions that result from dissolution of a gas, liquid or solid in a liquid.

Gas–liquid solutions

As can be seen in table 10.1, gases display a wide range of solubilities in water. Molecules such as O_2 and N_2 have very limited solubility at room temperature, while the solubility of the polar molecule ammonia is a quite remarkable 51.8 g per 100 g of water at 20 °C. Let's consider the processes that must occur for a gas to dissolve in a liquid. Firstly, 'pockets' must be opened between the solvent molecules to accommodate the gas molecules. Then, the gas molecules must enter and fill these pockets. The first of these processes differs from that for formation of a gaseous solution in that the intramolecular forces between the solvent molecules are not negligible, and neither therefore is the value of $\Delta_{\text{sol}}H$, the enthalpy of solution.

The enthalpy change when a gas dissolves in a liquid therefore has two contributions, as shown in figure 10.4.

1. *Energy is required to open 'pockets' in the solvent.* The solvent must be expanded slightly to accommodate the molecules of the gas. This is an endothermic process since attractions between solvent molecules must be overcome. Water is a special case — it already contains open holes in its network of loose hydrogen bonds around room temperature. For water, very little energy is required to create pockets that can hold gas molecules.
2. *Energy is released when gas molecules enter these pockets.* Intermolecular attractions between the dissolved gas molecules and the surrounding solvent molecules lower the total energy, and energy is released as heat. The stronger the attractions are, the more heat is released. Water can form hydrogen bonds with some gases, such as NH_3 , whereas many organic solvents cannot. More heat is released when such a gas molecule is placed in a pocket in water than in organic solvents.

Enthalpies of solution for gases in organic solvents are often endothermic because the energy required to open up pockets is greater than the energy released by attractions formed between the gas and solvent molecules. Enthalpies of solution for gases in water are often exothermic because water already contains pockets to hold the gas molecules, and energy is released when water and gas molecules attract each other.

TABLE 10.1 Solubilities of common gases in water

Gas	Temperature		
	0 °C	20 °C	50 °C
nitrogen, N ₂	0.0029	0.0019	0.0012
oxygen, O ₂	0.0069	0.0043	0.0027
carbon dioxide, CO ₂	0.335	0.169	0.076
sulfur dioxide, SO ₂	22.8	10.6	4.3
ammonia, NH ₃	89.9	51.8	28.4

Solubilities are in grams of solute per 100 g of water when the gaseous space over the liquid is saturated with the gas and the total pressure is 10⁵ Pa.

FIGURE 10.4

A molecular model of gas solubility in a liquid solvent. (a) A gas dissolves in a liquid organic solvent. Energy is absorbed to open ‘pockets’ in the solvent that can hold the gas molecules. In the second step, energy is released when the gas molecules enter the pockets, where they are attracted to the solvent molecules. Here, the solution process is shown to be endothermic. (b) A gas dissolves in water. Around room temperature, water’s loose network of hydrogen bonds already contains pockets that can accommodate gas molecules, so little energy is needed to prepare the solvent to accept the gas. In the second step, energy is released as the gas molecules take their place in the pockets where they experience attractions to the water molecules. In this case, the solution process is exothermic.

While we stated earlier that gaseous solutions form mainly because of the large entropy of the completely mixed state, the situation is not so straightforward with solutions of a gas in a liquid. Liquid water has a surprisingly ordered structure, and the addition of gas molecules does not necessarily disrupt this structure — in fact, there is experimental evidence that entropy *decreases* on formation of some gas–water solutions. Thus the solubility of a particular gas in water is a subtle balance of enthalpic and entropic effects, and it is often difficult to determine which factor predominates.

We can also see from table 10.1 that the solubility of gases in water varies significantly with temperature, with all the examples given becoming less soluble as the temperature increases. The decreasing solubility of O₂ with increasing temperature has obvious implications for aquatic life, given the gradual warming of the Earth’s oceans.

If we write the dissolution process as an equilibrium between the undissolved gas and the dissolved gas we can see that the equilibrium constant for this process decreases with increasing temperature for the examples in table 10.1.

Recalling the relationship between ΔH and K from the chapter on chemical equilibrium, we can conclude that the dissolution process for these gases is exothermic. However, not all gases become less soluble as the temperature increases; for example, the solubilities of H₂, N₂, CO, He and Ne in common organic solvents, such as toluene and acetone, actually increase with increasing temperature. You can see from these examples that predicting solubilities even in simple systems is fraught with difficulty.

The solubility of a gas in a liquid is affected not only by temperature but also by pressure. For example, the gases in air, chiefly nitrogen and oxygen, while not very soluble in water under ordinary pressures, become increasingly soluble as their pressures are increased (see figure 10.5).

FIGURE 10.5

Gas solubility in water versus pressure of the undissolved gas for nitrogen and oxygen. The amount of gas that dissolves increases as the pressure of that undissolved gas increases.

We can rationalise this observation by again considering the below equilibrium and looking at the effect of increasing the pressure of the undissolved gas on the position of this equilibrium.

The reaction quotient expression for this equilibrium can be written in a form that involves both the pressure of the undissolved gas and the concentration of the dissolved gas.

$$Q = \frac{[\text{gas}_{\text{dissolved}}]}{\left(\frac{p(\text{gas}_{\text{undissolved}})}{p^\circ} \right)}$$

We can see from this that Q is inversely proportional to $p(\text{gas}_{\text{undissolved}})$. Thus, if we increase the pressure of the undissolved gas at constant temperature, we decrease Q so that $Q < K$. To restore equilibrium and make $Q = K$, the equilibrium position shifts towards the right-hand side to increase Q by increasing $[\text{gas}_{\text{dissolved}}]$. Of course, the converse is also true; if we decrease the pressure above a gas–liquid solution, we increase Q , and some of the dissolved gas leaves the solution in order to decrease Q and restore equilibrium. We see this most often whenever we open a bottle of anything fizzy; when the top is removed, bubbles of CO_2 emerge from the solution in response to the sudden lowering of pressure (figure 10.6).

To see how pressure affects gas solubility on a molecular level, imagine a closed container equipped with a piston, containing both a gas and a liquid. Figure 10.7a shows the system at equilibrium; gas molecules move at equal rates between the dissolved and undissolved states. Gas molecules enter the solution at a rate proportional to the frequency with which they collide with the surface of the solution.

FIGURE 10.6

Bottled carbonated beverages fizz when the bottle is opened because the sudden drop in pressure causes a sudden drop in gas solubility.

This frequency increases when we increase the pressure of the undissolved gas (figure 10.7b) because the gas molecules are squeezed closer together. Because liquids and liquid solutions are incompressible, the increased pressure alone has no effect on the frequency with which gas molecules can leave the solution. That means that increasing the pressure favours dissolution of the gas.

FIGURE 10.7

How pressure increases the solubility of a gas in a liquid. (a) At some specific pressure, equilibrium exists between the vapour phase and the solution. (b) An increase in pressure means the system is no longer at equilibrium as more gas molecules are dissolving than are leaving the solution. (c) More gas has dissolved and equilibrium is restored.

As more gas dissolves, however, the rate of the forward process to give dissolved gas steadily slows and the reverse rate increases. It increases because, at a higher concentration of dissolved gas, there are simply more gas molecules in solution per unit of area of the surface of the liquid. Their frequency of escape is proportional to this concentration. But the dissolution process dominates until enough additional gas has dissolved to equalise the opposing rates. We again have equilibrium (figure 10.7c), but now more gas molecules are dissolved in the solution than initially. The position of equilibrium has therefore shifted to favour the dissolved gas.

Henry's law

For gases *that do not react with the solvent*, Henry's law gives the relationship between gas pressure and gas solubility. **Henry's law** states that the concentration of a gas dissolved in a liquid at any given temperature is directly proportional to the partial pressure of the gas above the solution. This is illustrated by the following equation.

$$c_{\text{gas}} = k_{\text{H}} p_{\text{gas}} \text{ (at constant temperature)}$$

Here, c_{gas} is the concentration of the dissolved gas and p_{gas} is the partial pressure (see the chapter on gases) of the gas above the solution. The proportionality constant, k_{H} , is called the *Henry's law constant*, and is unique to each gas. It has units of $\text{mol L}^{-1} \text{Pa}^{-1}$. The equation is true only at low concentrations and pressures and, as we said, for gases that do not react with the solvent.

An alternative (and commonly used) expression of Henry's law is shown below where c_1 and p_1 refer to initial conditions and c_2 and p_2 to final conditions.

$$\frac{c_1}{p_1} = \frac{c_2}{p_2}$$

WORKED EXAMPLE 10.1

Using Henry's law

At 20°C , the solubility of N_2 in water, expressed in terms of mass of dissolved gas per volume of solution, is 0.0150 g L^{-1} when the partial pressure of nitrogen is $7.63 \times 10^4 \text{ Pa}$. Use these data to calculate the Henry's law constant for N_2 in water at this temperature. What is the solubility of N_2 in water at 20°C when its partial pressure is $1.05 \times 10^5 \text{ Pa}$?

Analysis

We will use the Henry's law equation to solve this problem. Given that the units of k_{H} are $\text{mol L}^{-1} \text{Pa}^{-1}$, we must first convert the solubility of N_2 in g L^{-1} to a solubility in mol L^{-1} to ensure our calculated value of k_{H} has the correct units. We then use the calculated value of k_{H} to determine the solubility at the higher pressure.

Solution

We use stoichiometry to determine the solubility of N_2 in mol L^{-1} . We know that 0.0150 g of N_2 will be dissolved in 1.00 L of water under the stated conditions. Therefore:

$$n_{\text{N}_2} = \frac{m}{M} = \frac{0.0150 \text{ g}}{28.02 \text{ g mol}^{-1}} = 5.35 \times 10^{-4} \text{ mol}$$

This is the amount of N_2 that will dissolve in 1.00 L. Thus, the solubility of N_2 is $5.35 \times 10^{-4} \text{ mol L}^{-1}$.

Gathering data, we now have $c_{\text{gas}} = 5.35 \times 10^{-4} \text{ mol L}^{-1}$ and $p_{\text{gas}} = 7.63 \times 10^4 \text{ Pa}$. We use these to calculate k_{H} by rearranging $c_{\text{gas}} = k_{\text{H}} p_{\text{gas}}$.

$$k_{\text{H}} = \frac{c_{\text{gas}}}{p_{\text{gas}}} = \frac{5.35 \times 10^{-4} \text{ mol L}^{-1}}{7.63 \times 10^4 \text{ Pa}} = 7.01 \times 10^{-9} \text{ mol L}^{-1} \text{ Pa}^{-1}$$

We now use this calculated value of k_{H} to determine the solubility at higher pressure.

$$\begin{aligned} c_{\text{gas}} &= k_{\text{H}} p_{\text{gas}} \\ &= 7.01 \times 10^{-9} \text{ mol L}^{-1} \text{ Pa}^{-1} \times 1.05 \times 10^5 \text{ Pa} \\ &= 7.36 \times 10^{-4} \text{ mol L}^{-1} \end{aligned}$$

Therefore, the solubility of N_2 at $1.05 \times 10^5 \text{ Pa}$ is $7.36 \times 10^{-4} \text{ mol L}^{-1}$.

Is our answer reasonable?

As Henry's law states that gas solubility is proportional to gas pressure, we would expect N_2 to be more soluble at higher pressure. Our answer shows this to be the case.

PRACTICE EXERCISE 10.1

At 20°C , the Henry's law constant, k_{H} , for O_2 in water is $1.34 \times 10^{-8} \text{ mol L}^{-1} \text{ Pa}^{-1}$. Calculate the mass of O_2 that would be dissolved per litre of water at an air pressure

of $1.013 \times 10^5 \text{ Pa}$ at this temperature. Note that the partial pressure of oxygen in air under these conditions is $2.13 \times 10^4 \text{ Pa}$.

Liquid-liquid solutions

The formation of a liquid-liquid solution requires that we overcome the attractive forces present between the molecules of the two pure liquids to get the liquids to mix completely. This is an even more complicated situation than formation of a gas-liquid solution, yet we can predict the ability of any two liquids to mix, with some confidence, simply by considering the polarities of the two liquids. For example, we find that ethanol and water mix completely in all proportions — we say they are **miscible** — while hexane and water are essentially **immiscible** and form two layers on addition of one liquid to the other (figure 10.8).

Both water and ethanol are polar molecules, while hexane is essentially non-polar; these facts are central to explaining the behaviour of these liquids on mixing. The —OH functional group in the ethanol molecule leads to extensive hydrogen bonding interactions between ethanol molecules and between ethanol and water molecules (figure 10.9). Thus, the intermolecular attractive forces in the two pure liquids can be compensated for on mixing by the hydrogen bonding interactions between the ethanol and water molecules; the system, therefore, adopts the entropically favoured mixed state. Conversely, hexane molecules are non-polar, therefore they cannot interact strongly with water molecules; this means that the energy required to disrupt the hydrogen bonding network in water cannot be compensated for by water-hexane interactions on mixing. Even if we could disperse water molecules in hexane, each time two water molecules collided, they would tend to 'stick together' through hydrogen bonding interactions. This would continue to occur until all the water molecules had stuck together and the system would eventually become two phases.

We can use similar arguments to explain why non-polar liquids tend to mix with each other. The intermolecular interactions in the pure liquids are low, so there is no energetic impediment to mixing.

In general, when two liquids are of similar polarity, they tend to be miscible, whereas liquids of widely differing polarities are often found to be immiscible. This **like-dissolves-like rule** works well in predicting solubilities, but, as always, there are exceptions. The presence of a polar —OH functional group does not guarantee all alcohols are water soluble; while methanol, CH_3OH , ethanol, $\text{CH}_3\text{CH}_2\text{OH}$, and propan-1-ol, $\text{CH}_3\text{CH}_2\text{CH}_2\text{OH}$, are miscible with water in all proportions, butan-1-ol, $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$, is only partially miscible and pentan-1-ol, $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$, is immiscible.

The differing miscibilities of these alcohols with water cannot be explained in terms of differing polarities as the molecules all have very similar dipole moments ($\sim 5.6 \times 10^{-30} \text{ C m}$). We must therefore consider the relative energetic magnitudes of the hydrogen bonding interactions between the polar —OH functional groups and water, and the dispersion forces between the non-polar hydrocarbon tails

of neighbouring alcohol molecules. For methanol, ethanol and propan-1-ol, the hydrogen bonding interactions between the —OH groups and water dominate, leading to water miscibility. However, as the hydrocarbon tails on the alcohol molecules increase in length beyond three carbon atoms, the dispersion forces between these become strong enough to outweigh the attractive forces between the —OH groups and the water molecules. This causes the alcohol molecules to cluster together as a single hydrophobic phase, leading to immiscibility with water.

FIGURE 10.8

Like dissolves like. (a) Ethanol is soluble in water because the mixed ethanol–water attractions are not significantly weaker than the water–water or ethanol–ethanol attractions. (b) Hexane is not soluble in water because the mixed hexane–water attraction is much weaker than the water–water and hexane–hexane attractions. The stronger attractions in the pure liquids constitute an energy barrier to mixing.

(a)

(b)

FIGURE 10.9

Hydrogen bonds in aqueous ethanol. Ethanol molecules form hydrogen bonds to water molecules through interactions involving both the O atom (donor) and the H atom (acceptor) of the —OH group. These interactions are outlined using dotted bonds.

We can use similar arguments to explain the solubilities of alcohols in non-polar solvents. For example, even though long-chain alcohols are appreciably polar molecules, they are miscible with hexane because of the dispersion forces between the hydrocarbon chain on the alcohol and the hexane molecules. These dispersion forces diminish as the chain length of the alcohol decreases, and we find that the shortest chain alcohol, methanol, is immiscible with hexane.

The long-chain alcohols discussed above are examples of molecules with both polar and non-polar regions; we might therefore expect the different regions of such molecules to display different affinities

towards both polar and non-polar solvents. Indeed, we make use of this behaviour every day when we use soaps and detergents to make oils and water mix. Both detergents and soaps consist of molecules called surfactants (a contraction of the term ‘surface active agents’), which comprise polar and non-polar parts; the polar parts generally result from a full positive or negative charge. The structure of a common surfactant found in shampoos and toothpastes, sodium lauryl sulfate, is shown in figure 10.10. As the polar group is negatively charged, we call this an anionic surfactant. When added to a mixture of two immiscible liquids, the polar end of a surfactant molecule preferentially orients itself in the polar liquid, while the non-polar end is situated in the non-polar liquid. This helps bring the two immiscible phases together. This process will be discussed in greater detail in the chapter that looks at carboxylic acids and their derivatives.

FIGURE 10.10 The structure of sodium lauryl sulfate

Liquid–solid solutions

In moving to solutions of solids in liquids, the basic principles remain the same. We will look first at what happens when sodium chloride, a crystalline salt, dissolves in water.

Figure 10.11 depicts a section of a crystal of NaCl in contact with water. The dipoles of water molecules orient themselves so that the negative ends of some point towards Na^+ ions and the positive ends of others point at Cl^- ions. In other words, *ion–dipole* attractions occur that tend to dislodge ions from the crystal. At the corners and edges of the crystal, ions are held by fewer neighbours within the solid so they are more readily dislodged than those elsewhere on the crystal’s surface. As water molecules dislodge these ions, new corners and edges are exposed and the crystal continues to dissolve.

As they are freed, the ions become completely surrounded by water molecules (see figure 10.11). This phenomenon is called the **hydration** of ions. The *general* term for the surrounding of a solute particle by solvent molecules is **solvation**, so hydration is just a special case of solvation.

Ionic compounds can dissolve in water when the attractions between water dipoles and ions overcome both the attractions of the ions for each other within the crystal and the attractive forces between water molecules in bulk water. Similar events explain why solids composed of polar molecules, such as those of sugar, can dissolve in water (see figure 10.12). Attractions between the solvent and solute dipoles help to dislodge molecules from the crystal and bring them into solution. Again we see that ‘like dissolves like’; a polar solute dissolves in a polar solvent.

The same reasoning explains why non-polar solids, such as wax, are soluble in non-polar solvents, such as benzene. Wax is a solid mixture of long-chain hydrocarbons held together by dispersion forces. The attractions between the molecules of the solvent (benzene) and the solute (wax) are also due to dispersion forces of comparable strength.

FIGURE 10.11

Hydration of ions involves a complex redirection of forces of attraction and repulsion. Before the solution forms, water molecules are attracted only to each other, and Na^+ and Cl^- ions are attracted only to each other in the crystal. In the solution, the ions have water molecules to take the places of their oppositely charged counterparts; in addition, water molecules are attracted to ions even more than they are to other water molecules. (Refer back to figure 2.16 to remind yourself of the colours we use in this text to represent atoms of the various elements in space-filling and ball-and-stick models.)

FIGURE 10.12

Hydration of a polar molecule. A polar solid dissolves in water because its molecules are attracted to the very polar water molecules, causing the solute molecules to become hydrated. Notice that the water molecules orient themselves so their positive ends are near the negative ends of the solute dipoles and their negative ends are near the positive ends of the solute dipoles.

When intermolecular attractive forces within solute and solvent are sufficiently different, the two do not form a solution. For example, ionic solids such as NaCl and very polar molecular solids such as sugar are **insoluble** in non-polar solvents such as benzene and hexane. The molecules of these hydrocarbon solvents are unable to attract ions or very polar molecules with enough force to overcome the much stronger attractions that the ions or polar molecules experience in the solid state.

We have already seen that, while the enthalpy changes on mixing in simple gaseous solutions are minimal, the same is not necessarily true in liquid–liquid solutions. The enthalpy changes on formation of a solution containing a dissolved ionic solid can be substantial and we will now consider these changes in some detail. Recalling from the chapter on chemical thermodynamics that enthalpy is a state function, and therefore does not depend on the way in which we get from the initial state to the final state, we can model the dissolution of an ionic solute in a solvent as a hypothetical two-step process, as shown in figure 10.13.

FIGURE 10.13

Enthalpy diagram for a solid dissolving in a liquid. We can analyse the overall enthalpy change by imagining two separate steps, because enthalpy changes are state functions and so are independent of the path. The overall enthalpy change is the algebraic sum of those for step 1 and step 2.

As you can see from figure 10.13, the first step is endothermic. The particles in the solid solute attract each other, and so energy must be supplied to separate them. The amount of energy required is the **lattice enthalpy**. Recall from the chapter on chemical thermodynamics that the lattice enthalpy is the enthalpy change when 1 mol of a crystalline compound is converted into gaseous particles. For ionic compounds, the gaseous particles are ions; for molecular compounds, they are molecules. For example, the lattice enthalpy of potassium iodide, KI, is the enthalpy change for the following process.

In the second step, the vaporised solute particles enter the solvent and are solvated. This step is exothermic. The enthalpy change when gaseous solute particles obtained from 1 mol of solute are dissolved in a solvent is called the **solvation enthalpy**. If the solvent is water, the solvation enthalpy can also be called the **hydration enthalpy**. For example, the hydration enthalpy of KI is the enthalpy change for the following process.

We can now use a Hess's law approach to determine the **enthalpy of solution** ($\Delta_{\text{sol}}H$). This is the enthalpy change when 1 mol of a crystalline substance is dissolved in a solvent (generally water) to form the solvated ions. Using the equations for lattice enthalpy and hydration enthalpy above, we can write:

This process is shown in detail in figure 10.14.

FIGURE 10.14

Enthalpy of solution — the formation of aqueous potassium iodide

When the numerical value of the enthalpy change for step 1 (endothermic) exceeds that for step 2 (exothermic), the solution forms endothermically; when the converse is true, the solution forms exothermically.

We can test this analysis by comparing the experimental enthalpies of solution of some salts in water with those calculated by Hess's law from lattice and hydration enthalpies (table 10.2). The latter case is illustrated in figure 10.15 for the formation of aqueous sodium bromide. In this case, a Hess's law approach gives the following.

The agreement between calculated and measured values in table 10.2 is not particularly close. This is partly because precise lattice and hydration enthalpies are not known and partly because the model used in our analysis is evidently too simple. Notice, however, that when 'theory' predicts relatively large enthalpies of solution, the experimental values are also relatively large and both values have the same sign (except for NaCl, where the values are close to 0 and fall either side of it). Notice also that the changes in values show the same trends when we compare the three chloride salts — LiCl, NaCl and KCl — and the three bromide salts — LiBr, NaBr and KBr.

Temperature can have a significant effect on the solubility of a solid solute in a liquid. Figure 10.16 shows a plot of solubility versus temperature for a number of ionic salts; it is obvious that all but one

of these examples become more soluble as the temperature increases, which we might intuitively expect. There are few salts that become less soluble as the temperature increases.

TABLE 10.2 Lattice enthalpies, hydration enthalpies and enthalpies of solution for some group 1 metal halides at 25 °C

Compound	Lattice enthalpy (kJ mol ⁻¹)	Hydration enthalpy (kJ mol ⁻¹)	$\Delta_{\text{sol}}H^{(a)}$	
			Calculated $\Delta_{\text{sol}}H$ (kJ mol ⁻¹) ^(b)	Measured $\Delta_{\text{sol}}H$ (kJ mol ⁻¹)
LiCl	+833	-883	-50	-37.0
NaCl	+766	-770	-4	+3.9
KCl	+690	-686	+4	+17.2
LiBr	+787	-854	-67	-49.0
NaBr	+728	-741	-13	-0.602
KBr	+665	-657	+8	+19.9
KI	+632	-619	+13	+20.33

(a) Enthalpies of solution refer to the formation of extremely dilute solutions.

(b) Calculated $\Delta_{\text{sol}}H$ = lattice enthalpy + hydration enthalpy.

FIGURE 10.15 Enthalpy of solution — the formation of aqueous sodium bromide

However, not everything is as straightforward as we would wish. Many of you will have dissolved solid NaOH in water and noticed that the solution gets quite hot as the solid dissolves, meaning that the process is exothermic. From the van't Hoff equation (described in the chapter on chemical equilibrium) we might therefore predict that the equilibrium constant for the dissolution of NaOH should decrease as the temperature increases; hence, NaOH should become less soluble with increasing temperature. As you can see in figure 10.16, the opposite trend is observed, and this can be explained by the nature of solid NaOH in a saturated solution. NaOH generally exists as an anhydrous solid — in other words, the crystalline solid contains no water molecules — and, as we have stated earlier, this dissolves exothermically. However, when we prepare a saturated solution of NaOH by adding excess NaOH to water, analysis of the solid phase shows it to consist not of anhydrous NaOH, but rather the solid *hydrate*, NaOH·H₂O, in which one water molecule is associated with each NaOH unit. In fact, this species dissolves endothermically, so it is more soluble at higher temperatures. You should also appreciate that the van't Hoff equation uses ΔH° values, so $\Delta_{\text{sol}}H$ data measured under nonstandard conditions are of limited use in predicting the variation of solubilities with temperature.

FIGURE 10.16

Solubility in water versus temperature for several substances. Most substances become more soluble when the temperature of the solution increases, but the amount of this increased solubility varies considerably.

CHEMICAL CONNECTIONS

Solid solutions: alloys

Pure metals occur rarely in nature. The majority exist naturally as oxides through reaction with atmospheric oxygen, and require smelting in order to isolate the pure element. The best known of the so-called 'native' metals are gold and silver, both of which were primarily used by early humans for decoration or adornment. Of the few other metals found in their metallic state, copper is arguably the most important, owing to its use as a component of bronze.

Large deposits of metallic copper were present in various parts of the world in prehistoric times. While useful for making small pieces of jewellery, it was too soft and brittle to make large implements and weapons. However, around 5000 years ago, it was found that when tin was heated with copper, a product was obtained that was both stronger and easier to cast than either of its component metals. That product was bronze, a substance so important in human history that an entire age was named after it (see figure 10.17).

There are many different types of bronze, all of which are solid solutions of copper with metals such as tin, zinc, lead, nickel and bismuth in various proportions. Solid solutions of metals are called alloys, and are the subject of enormous interest because of their desirable properties. For example, stainless steel is an alloy of iron with chromium that resists rusting, nitinol is an alloy of nickel and titanium that 'remembers' its shape when heated, and a family of iron alloys with aluminium, nickel and cobalt, collectively called alnico, are very strong permanent magnets.

FIGURE 10.17

Bronze is a solid solution of copper with a variety of other metals. It has been used for thousands of years, beginning of course with the Bronze Age.

10.4 Quantification of solubility: the solubility product

LEARNING OBJECTIVE 10.4 Carry out calculations involving slightly soluble salts.

One of the first experiments regarding solubility that many of you would have carried out is the addition of a solution of silver nitrate to a solution of sodium chloride. Provided that the concentrations are appropriate, a white precipitate of silver chloride forms instantly (see figure 10.18), according to the following equation.

When you saw this precipitate, you very probably wrote in your laboratory report that silver chloride is insoluble. This is not quite correct. If we took some solid AgCl and stirred it in water for a sufficient time, we would find a small amount of both $\text{Ag}^+(\text{aq})$ and $\text{Cl}^-(\text{aq})$ ions dissolved in the water above the solid. Thus, rather than being insoluble, we would more correctly classify AgCl as being slightly soluble in water (1 litre of a saturated aqueous solution of AgCl will contain about 1.9 milligrams of AgCl at 25.0 °C). The solution above the solid would be classified as a saturated solution — in other words, it is a solution in which no more AgCl is able to dissolve. A dynamic equilibrium between the undissolved solid and the dissolved aqueous ions exists within this, and indeed any, saturated solution, provided that there is some undissolved solid present; the solid is dissolving, and the ions are precipitating, but both of these processes are occurring at the same rate, and so no overall change occurs. For silver chloride, we can represent the dissolution process by the following equilibrium.

We can see that the magnitude of the equilibrium constant for this process will be a measure of the solubility of silver chloride in water.

The equilibrium constant for the dissolution of a slightly soluble salt is called the **solubility product** and is abbreviated K_{sp} . For the above equilibrium, we write K_{sp} as shown.

$$K_{\text{sp}} = [\text{Ag}^+][\text{Cl}^-]$$

Recall from the chapter on chemical equilibrium that pure solids *never* appear in an equilibrium constant. Therefore, as we will see below, the expression for K_{sp} for any ionic solid always consists only of the product of the aqueous ions raised to their stoichiometric powers. We can derive an expression for the solubility product of any salt $\text{M}_a\text{X}_b(\text{s})$ by considering the equilibrium constant for its dissolution in water.

Recall from the chapter on chemical equilibrium that equilibrium constants have no units. It is implicit that all concentration terms in an equilibrium constant expression are divided by $c^\ominus$, the standard concentration, thus making them dimensionless. Therefore, K_{sp} values are dimensionless.

For AgCl, $K_{\text{sp}} = 1.8 \times 10^{-10}$ at 25.0 °C, meaning that the solubility of AgCl in water is indeed small *but not zero*. We generally classify salts having K_{sp} values of the order of 10^{-5} or less as slightly soluble. Table 10.3 gives K_{sp} data for a variety of such salts (a more comprehensive list is given in appendix C). In general, the smaller the value of K_{sp} , the less soluble is the salt. However, you should appreciate that direct comparison of K_{sp} values can be made only for salts with the same ratio of anions to cations. For example, CaF_2 is more soluble on a molar basis than AgCl in water ($2.1 \times 10^{-4} \text{ mol L}^{-1}$ compared to $1.3 \times 10^{-5} \text{ mol L}^{-1}$), even though K_{sp} for CaF_2 (3.9×10^{-11}) is smaller than that for AgCl. This is because the equilibrium constant expressions for the two salts do not have identical forms; the equation for dissolution of CaF_2 is as follows.

FIGURE 10.18

Precipitation of AgCl(s) on mixing aqueous solutions of AgNO₃ and NaCl

This then leads to the equilibrium constant expression shown below, which obviously differs from that for AgCl. We will explore this in more detail later.

$$K_{\text{sp}} = [\text{Ca}^{2+}][\text{F}^{-}]^2$$

TABLE 10.3 Solubility products for selected slightly soluble salts at 25 °C

Salt		Dissolved ions	K_{sp}	Solubility (mol L ⁻¹)	Solubility (g L ⁻¹)

(a) Zn(OH)₂(s) exists in more than one solid form; the data listed are for the alpha form.

(b) Al(OH)₃(s) exists in more than one solid form; the data listed are for the amorphous form.

(c) CaCO₃(s) exists in more than one solid form; the data listed are for the calcite form.

The relationship between K_{sp} and solubility

One way to determine the value of K_{sp} for a slightly soluble salt is to measure its solubility; that is, how much of the salt is required to make a saturated solution of a specified volume. The molar concentration of a salt in its saturated solution is called the **molar solubility (s)**; this equals the amount of salt dissolved in 1 litre of the saturated solution at the specified temperature. The molar solubility can be used to calculate K_{sp} , assuming that all of the salt that dissolves is 100% dissociated into its ions. This assumption works reasonably well for slightly soluble salts made of univalent ions, such as silver bromide. For simplicity, and to illustrate the nature of calculations involving solubility equilibria, we will work on the assumption that all salts behave as though they are 100% dissociated. This is not entirely true, especially for salts of polyvalent ions, so the accuracy of our calculations is limited.

WORKED EXAMPLE 10.2

Calculating K_{sp} from solubility data

The very low solubility of radium sulfate, RaSO₄, proved to be an important factor in facilitating Marie Curie's original isolation of the element radium in 1911. The solubility of RaSO₄ in water at 25 °C is 2.1 × 10⁻³ g L⁻¹. Calculate the value of K_{sp} for RaSO₄ at this temperature.

Analysis

The first step in a problem like this is to write the balanced chemical equation for the salt. We then use this to determine the expression for the solubility product, K_{sp} .

Therefore, we can write:

and:

$$K_{sp} = [\text{Ra}^{2+}][\text{SO}_4^{2-}]$$

To calculate the value of K_{sp} , we require the molar concentrations of Ra²⁺ and SO₄²⁻ in the saturated solution, so we must convert the given value of 2.1 × 10⁻³ g L⁻¹ to mol L⁻¹. We then insert these values into the above expression for K_{sp} .

Solution

We know that 2.1 × 10⁻³ g of RaSO₄ is dissolved in every litre of the saturated solution, so we convert this mass to

amount in moles.

$$n = \frac{m}{M} = \frac{2.1 \times 10^{-3} \text{ g}}{322.06 \text{ g mol}^{-1}} = 6.5 \times 10^{-6} \text{ mol}$$

From the balanced chemical equation for the dissolution reaction given above, we know that when 6.5 × 10⁻⁶ mol of RaSO₄(s) dissolves in water, it produces 6.5 × 10⁻⁶ mol of Ra²⁺(aq) ions and 6.5 × 10⁻⁶ mol of SO₄²⁻(aq) ions. Hence, the molar concentrations of Ra²⁺ and SO₄²⁻ are both 6.5 × 10⁻⁶ mol L⁻¹. We now insert these values into the expression for K_{sp} above, remembering that our calculated value of K_{sp} will be dimensionless.

$$\begin{aligned} K_{sp} &= [\text{Ra}^{2+}][\text{SO}_4^{2-}] \\ &= (6.5 \times 10^{-6})(6.5 \times 10^{-6}) \\ &= 4.2 \times 10^{-11} \text{ at } 25^\circ\text{C} \end{aligned}$$

Is our answer reasonable?

Without checking all our arithmetic, the small values of the molar solubility and K_{sp} we have obtained are consistent with what would be expected for a slightly soluble salt. We can also work backwards, using our value of K_{sp} to determine both the molar solubility and the mass solubility of RaSO₄. Doing this gives 6.5 × 10⁻⁶ mol L⁻¹ and 2.1 × 10⁻³ g L⁻¹, respectively, meaning we can be confident our answer is correct.

PRACTICE EXERCISE 10.2

The solubility of thallium(I) iodide, TlI, in water at 20 °C is $1.8 \times 10^{-5} \text{ mol L}^{-1}$. Calculate the value of K_{sp} for TlI assuming that it is 100% dissociated in the solution.

Obviously, if we can calculate the value of K_{sp} from molar solubility data, we should also be able to calculate the molar solubility from K_{sp} . Worked example 10.3 shows how this is done.

WORKED EXAMPLE 10.3

Calculating molar solubility from K_{sp}

In 1873, Camillo Golgi, an Italian physician, published a method which allowed visualisation of complete nerve cells for the first time. He was awarded the Nobel Prize in physiology or medicine for the discovery in 1906 and it is still used today. Golgi's method relies on the reaction of potassium dichromate, $\text{K}_2\text{Cr}_2\text{O}_7$, with silver nitrate, AgNO_3 , to give the slightly soluble salt silver chromate, Ag_2CrO_4 , which precipitates inside the cells (see photo). Calculate the molar solubility of silver chromate, given that $K_{\text{sp}}(\text{Ag}_2\text{CrO}_4) = 1.2 \times 10^{-12}$ at 25 °C.

Analysis

We start, as usual, by writing the balanced chemical equation for the dissolution of $\text{Ag}_2\text{CrO}_4(\text{s})$, and use this to obtain the expression for K_{sp} .

$$K_{\text{sp}} = [\text{Ag}^+]^2[\text{CrO}_4^{2-}] = 1.2 \times 10^{-12}$$

In this case, we know the value of K_{sp} and must determine $[\text{Ag}^+]$ and $[\text{CrO}_4^{2-}]$. However, we have one equation containing two unknowns. To solve this, we must make use of the stoichiometric relationship between $[\text{Ag}^+]$ and $[\text{CrO}_4^{2-}]$ in the saturated solution.

Solution

As this is an equilibrium problem, we can solve it using a concentration table in a similar manner to the examples in the chapter on chemical equilibrium. We set up the concentration table in the usual fashion, recognising that the initial concentrations of the ions will be 0 mol L^{-1} . As the salt dissolves, $s \text{ mol}$ of Ag_2CrO_4 will dissolve to increase the concentrations of Ag^+ and CrO_4^{2-} by $2s$ and s , respectively.

	$\text{Ag}_2\text{CrO}_4(\text{s})$	$\rightleftharpoons$	$2\text{Ag}^+(\text{aq})$	+	$\text{CrO}_4^{2-}(\text{aq})$
Initial concentration (mol L^{-1})			0		0
Change in concentration (mol L^{-1})			$+2s$		$+s$
Equilibrium concentration (mol L^{-1})			$2s$		s

Note that we use s rather than x in this concentration table, as s is defined as the molar solubility; in other words, the amount of the salt dissolved in 1 litre of solution.

We now substitute the equilibrium concentrations into the equilibrium constant expression, K_{sp} .

$$K_{\text{sp}} = [\text{Ag}^+]^2[\text{CrO}_4^{2-}] = (2s)^2(s) = (2s)(2s)(s) = (4s^2)(s) = 4s^3$$

We have now gone from one equation with two unknowns to one equation with a single unknown, s , which we can solve.

$$\begin{aligned} 4s^3 &= 1.2 \times 10^{-12} \\ s^3 &= \frac{1.2 \times 10^{-12}}{4} \\ &= 3.0 \times 10^{-13} \\ s &= \sqrt[3]{3.0 \times 10^{-13}} = 6.7 \times 10^{-5} \end{aligned}$$

Thus, remembering that molar solubility has units of mol L^{-1} , the molar solubility of $\text{Ag}_2\text{CrO}_4(\text{s})$ in water at 25°C is $6.7 \times 10^{-5} \text{ mol L}^{-1}$.

Is our answer reasonable?

The low molar solubility of $10^{-5} \text{ mol L}^{-1}$ implies that the salt is not very soluble and that our answer is at least reasonable. We can quickly check our answer by carrying out the reverse calculation, cubing s and multiplying the answer by 4. This gives a value of K_{sp} of 1.2×10^{-12} , so we can be confident of our answer.

PRACTICE EXERCISE 10.3

Use the K_{sp} data in table 10.3 to calculate the molar solubility of (a) PbI_2 and (b) $\text{Fe}(\text{OH})_3$ in water at 25°C .

We have seen in worked example 10.3 that solubility, s , can be related to K_{sp} . The exact nature of this relationship depends on the chemical formula of the salt. Above, we showed that, for Ag_2CrO_4 , $K_{\text{sp}} = 4s^3$, and this relationship will be the same for all 2 : 1 electrolytes (i.e. those having the formula MX_2 or M_2X). Table 10.4 shows the possible forms of the relationship between solubility, s , and the solubility product K_{sp} for all common types of electrolytes. You should be able to derive these expressions using the method outlined in worked example 10.3.

The common ion effect

Until now, we have considered the solubility only of slightly soluble ionic salts in pure water. Does the solubility of such salts differ if the solvent is not pure water but a solution that already contains one of the ions in the slightly soluble salt? Likewise, what happens if we take a saturated solution of a slightly soluble salt and add a solution of another salt that has one ion in common with the first salt?

TABLE 10.4 The relationship between solubility, s , and the solubility product, K_{sp} , for common electrolytes

Type of electrolyte	Formula of electrolyte	K_{sp} expression in terms of concentration	Solubility, s , in terms of $[M^{n+}]$ and $[X^{n-}]$	K_{sp} expression in terms of solubility, s
1 : 1	MX	$K_{sp} = [M^{n+}][X^{n-}]$	$[M^{n+}] = [X^{n-}] = s$	$K_{sp} = s^2$
2 : 1	MX ₂	$K_{sp} = [M^{2n+}][X^{n-}]^2$	$[M^{2n+}] = s, [X^{n-}] = 2s$	$K_{sp} = 4s^3$
	M ₂ X	$K_{sp} = [M^{n+}]^2[X^{2n-}]$	$[M^{n+}] = 2s, [X^{2n-}] = s$	
3 : 1	MX ₃	$K_{sp} = [M^{3n+}][X^{n-}]^3$	$[M^{3n+}] = s, [X^{n-}] = 3s$	$K_{sp} = 27s^4$
	M ₃ X	$K_{sp} = [M^{n+}]^3[X^{3n-}]$	$[M^{n+}] = 3s, [X^{3n-}] = s$	
3 : 2	M ₂ X ₃	$K_{sp} = [M^{3n+}]^2[X^{2n-}]^3$	$[M^{3n+}] = 2s, [X^{2n-}] = 3s$	$K_{sp} = 108s^5$
	M ₃ X ₂	$K_{sp} = [M^{2n+}]^3[X^{3n-}]^2$	$[M^{2n+}] = 3s, [X^{3n-}] = 2s$	

n denotes the charge on the cation or anion.

We can answer these questions with reference to a saturated solution of $\text{PbCl}_2(\text{s})$ ($K_{sp} = 1.7 \times 10^{-5}$) at equilibrium. To this saturated solution we add a small volume of a concentrated solution of $\text{Pb}(\text{NO}_3)_2$, a soluble lead salt, and look at the effect on the equilibrium position by comparing the relative magnitudes of Q_{sp} and K_{sp} . We begin by writing the balanced chemical equation for the dissolution of PbCl_2 and derive the expression for K_{sp} from this, recalling that the expressions for K_{sp} and Q_{sp} have the same form. (In the chapter on chemical equilibrium, we called Q the reaction quotient. In the case of Q_{sp} , that name is rather incongruous, given that the expression for Q_{sp} is never a fraction. Q_{sp} is sometimes called the **ionic product**.)

Adding a small volume of concentrated $\text{Pb}(\text{NO}_3)_2(\text{aq})$ to the saturated solution instantaneously increases $[\text{Pb}^{2+}]$ and therefore the value of Q_{sp} . This means that $Q_{sp} > K_{sp}$ and therefore, to restore equilibrium, the value of Q_{sp} must be decreased. The system achieves this by precipitating $\text{PbCl}_2(\text{s})$, which reduces both $[\text{Pb}^{2+}]$ and $[\text{Cl}^{-}]$, thereby decreasing the value of Q_{sp} to the point where the equilibrium condition $Q_{sp} = K_{sp}$ is again satisfied. If we were to analyse the saturated solution at this point, we would find $[\text{Cl}^{-}]$ to be less than it was in the original solution. As all the Cl^{-} in solution comes from dissolution of PbCl_2 , this means that $\text{PbCl}_2(\text{s})$ is *less soluble* in the presence of another source of Pb^{2+} . This is a manifestation of the **common ion effect**, which states that any ionic salt is less soluble in the presence of a **common ion**, an ion that is a component of the salt.

We have shown above that PbCl_2 is less soluble in the presence of Pb^{2+} than it is in pure water, and we can also show by the same reasoning that it is less soluble in the presence of another source of Cl^{-} . The common ion effect is not limited to solutions of slightly soluble salts; for example, even the relatively soluble salt NaCl can be precipitated from a concentrated aqueous solution on addition of concentrated HCl , a source of the common ion Cl^{-} . The addition or presence of a common ion *always* lowers the solubility of a salt providing that no further chemical reaction is possible. An example of a situation where a chemical reaction occurs is provided by the slightly soluble salt $\text{AgCl}(\text{s})$, which can react with excess Cl^{-} to form the complex anion $[\text{AgCl}_2]^{-}$, which, in turn, forms soluble salts with a variety of cations.

WORKED EXAMPLE 10.4

Calculations involving the common ion effect

What is the molar solubility of PbI_2 in a 0.10 mol L^{-1} NaI solution at 25°C ?

Analysis

As usual, we begin with the balanced chemical equation and the expression for K_{sp} derived from it.

We construct a concentration table. The initial concentration of Pb^{2+} is 0; we assume that NaI dissociates completely so the initial concentration of I^{-} is 0.10 mol L^{-1} . As in worked example 10.3, we represent the molar solubility of $\text{PbI}_2(\text{s})$ in the NaI solution as $s \text{ mol L}^{-1}$. Therefore, when the $\text{PbI}_2(\text{s})$ dissolves, $[\text{Pb}^{2+}]$ changes by $+s \text{ mol L}^{-1}$ and $[\text{I}^{-}]$ by $+2s \text{ mol L}^{-1}$. We can then calculate the equilibrium concentrations of Pb^{2+} and I^{-} by adding the initial concentrations and the changes. Here is the concentration table.

	$\text{PbI}_2(\text{s})$	$\rightleftharpoons$	$\text{Pb}^{2+}(\text{aq})$	+	$2\text{I}^{-}(\text{aq})$
Initial concentration (mol L^{-1})			0		0.10
Change in concentration (mol L^{-1})			$+s$		$+2s$
Equilibrium concentration (mol L^{-1})			s		$0.10 + 2s$

Solution

Substituting equilibrium values into the K_{sp} expression gives the following.

$$K_{\text{sp}} = [\text{Pb}^{2+}][\text{I}^{-}]^2 = s(0.10 + 2s)^2 = 7.9 \times 10^{-9}$$

A brief inspection reveals that solving this expression for s will be difficult if we cannot simplify the maths. Fortunately, a simplification of the type we first encountered in the chapter on chemical equilibrium is possible. The small value of K_{sp} for PbI_2 tells us that the salt has a very low solubility. We also know that the presence of the common ion I^{-} makes PbI_2 even less soluble. This means very little of the salt will dissolve, so s (or even $2s$) is quite small. Let's assume that $2s$ is much smaller than 0.10 , the numerical value of the concentration of the NaI solution. If this is so:

$$0.10 + 2s \approx 0.10 \text{ (assuming } 2s \text{ is negligible relative to } 0.10\text{)}$$

Substituting 0.10 mol L^{-1} for the I^{-} concentration gives the following.

$$K_{\text{sp}} = s(0.10)^2 = 7.9 \times 10^{-9}$$

$$s = \frac{7.9 \times 10^{-9}}{(0.10)^2} = 7.9 \times 10^{-7}$$

Thus, remembering that the units of molar solubility are mol L^{-1} , the molar solubility of PbI_2 in 0.10 mol L^{-1} NaI solution is $7.9 \times 10^{-7} \text{ mol L}^{-1}$.

Is our answer reasonable?

Check the entries in the table. The initial concentrations come from the NaI solution, which contains no Pb^{2+} but does contain $0.10 \text{ mol L}^{-1} \text{ I}^{-}$. By letting s equal the molar solubility, the coefficients of s in the 'Change in concentration' row equal the coefficients in the equation for the equilibrium. We should always check to see if our simplifying assumption is valid. Notice that $2s$, which equals 1.6×10^{-6} , is indeed vastly smaller than 0.10 , just as we anticipated. (If we add 1.6×10^{-6} to 0.10 and round correctly, we obtain 0.10 .)

PRACTICE EXERCISE 10.4

The molar solubility of NiCO_3 in pure water at 25.0°C is $3.6 \times 10^{-4} \text{ mol L}^{-1}$. Show that the molar solubility of NiCO_3 in $0.10 \text{ mol L}^{-1} \text{ Na}_2\text{CO}_3$ solution at the same temperature is less than $3.6 \times 10^{-4} \text{ mol L}^{-1}$, as predicted by the common ion effect.

Slightly soluble salts containing an appreciably basic anion such as O^{2-} , S^{2-} or CO_3^{2-} , are often found to be soluble in acidic aqueous solution. For example, K_{sp} for $\text{Mg}(\text{OH})_2$ is 7.1×10^{-12} , which corresponds to a solubility in water of 7.0 mg L^{-1} . However, addition of excess acid to a saturated solution of $\text{Mg}(\text{OH})_2$ in equilibrium with the undissolved solid results in complete dissolution of the solid. This can be explained with reference to the equilibrium equation for dissolution.

If H_3O^+ is added to this system, it will react completely with OH^- according to the following equation.

This will lower $[\text{OH}^-]$ in the solution. As $Q_{\text{sp}} = [\text{Mg}^{2+}][\text{OH}^-]^2$, the value of Q_{sp} will decrease on addition of acid. As $Q_{\text{sp}} < K_{\text{sp}}$, the equilibrium position will shift to the right to make the value of Q_{sp} larger through the production of more $\text{Mg}^{2+}(\text{aq})$ and $\text{OH}^-(\text{aq})$ by dissolution of $\text{Mg}(\text{OH})_2(\text{s})$. The newly produced OH^- will then react with more acid, again decreasing the value of Q_{sp} , and causing further dissolution of $\text{Mg}(\text{OH})_2(\text{s})$. As the system contains excess acid, this process will continue until all of the $\text{Mg}(\text{OH})_2(\text{s})$ has dissolved. Similar processes occur for slightly soluble salts containing other strongly and moderately basic anions. However, anions such as Cl^- , Br^- and NO_3^- that are the conjugate bases of strong acids, are too weakly basic to accept a proton, and the solubility of salts containing these anions will not be increased by addition of acid.

Will a precipitate form?

We can use K_{sp} values to predict whether a precipitate will form when solutions containing ionic salts are mixed. We calculate Q_{sp} by determining the molar concentration of the appropriate ions immediately after mixing and compare this value with that of K_{sp} . If $Q_{\text{sp}} > K_{\text{sp}}$ at the instant the solutions are mixed, the equilibrium position will move to the left to make $Q_{\text{sp}} = K_{\text{sp}}$. This will result in the formation of a precipitate. Conversely, if $Q_{\text{sp}} < K_{\text{sp}}$ on mixing the solutions, the equilibrium position will move to the right, the dissolved ions will be favoured, and no precipitate will form.

WORKED EXAMPLE 10.5

Predicting whether a precipitate will form

Will a precipitate of $\text{AgCl}(\text{s})$ form on mixing 50.0 mL of $1.0 \times 10^{-4} \text{ mol L}^{-1}$ $\text{NaCl}(\text{aq})$ with 50.0 mL of $1.0 \times 10^{-6} \text{ mol L}^{-1}$ $\text{AgNO}_3(\text{aq})$ at 25°C ?

Analysis

We have to calculate Q_{sp} for the solution immediately after mixing and compare its value with K_{sp} for AgCl . Thus, we require the molar concentrations of $\text{Ag}^+(\text{aq})$ and $\text{Cl}^-(\text{aq})$ on mixing, remembering that there is a volume change on mixing the two solutions.

Solution

We begin by writing the balanced chemical equation for the dissolution of $\text{AgCl}(\text{s})$ and deriving the expression for K_{sp} from it.

We then calculate the molar concentrations of Ag^+ and Cl^- immediately after mixing by determining the amount of each and dividing it by the volume of the final solution.

$$\begin{aligned}n_{\text{Ag}^+} &= cV = (1.0 \times 10^{-6} \text{ mol L}^{-1}) \times (50.0 \times 10^{-3} \text{ L}) \\ &= 5.0 \times 10^{-8} \text{ mol}\end{aligned}$$

$$\begin{aligned}n_{\text{Cl}^-} &= cV = (1.0 \times 10^{-4} \text{ mol L}^{-1}) \times (50.0 \times 10^{-3} \text{ L}) \\ &= 5.0 \times 10^{-6} \text{ mol}\end{aligned}$$

$$[\text{Ag}^+]_{\text{final}} = \frac{5.0 \times 10^{-8} \text{ mol}}{100 \times 10^{-3} \text{ L}} = 5.0 \times 10^{-7} \text{ mol L}^{-1}$$

$$[\text{Cl}^-]_{\text{final}} = \frac{5.0 \times 10^{-6} \text{ mol}}{100 \times 10^{-3} \text{ L}} = 5.0 \times 10^{-5} \text{ mol L}^{-1}$$

We now substitute these values into the expression for Q_{sp} .

$$Q_{\text{sp}} = [\text{Ag}^+][\text{Cl}^-] = (5.0 \times 10^{-7}) \times (5.0 \times 10^{-5}) = 2.5 \times 10^{-11}$$

Thus, $Q_{\text{sp}} < K_{\text{sp}}$, so we predict that no precipitate of $\text{AgCl}(\text{s})$ will form when the solutions are mixed. Note that, as we saw earlier for K_{sp} , Q_{sp} is dimensionless.

Is our answer reasonable?

As this is essentially a stoichiometric problem, there is no easy check of your answer. In cases like these, you should check your arithmetic and ensure you have transcribed the correct numbers into your calculations. The most common mistake in this type of problem is to forget to take account of the final volume of the mixed solution. We have used the correct numbers, and we have factored in the volume change, so our answer should be correct. This example clearly shows that $\text{AgCl}(\text{s})$ is not insoluble.

PRACTICE EXERCISE 10.5

Will a precipitate form if 50.0 mL of $5.00 \times 10^{-4} \text{ mol L}^{-1}$ $\text{AgNO}_3(\text{aq})$ solution is mixed with 75.0 mL of $1.25 \times 10^{-3} \text{ mol L}^{-1}$ $\text{Na}_2\text{CO}_3(\text{aq})$ solution at 25°C .

Kidney stones

The formation of kidney stones (figure 10.19) is one of the most obvious applications of solubility in the human body. These solids, which range in size from a grain of sand to a golf ball, can lead to the blockage of the ureter, which carries urine from the kidney to the bladder. The most common symptom of kidney stones is excruciating pain, and their removal can require invasive techniques.

Kidney stones generally contain slightly soluble calcium salts of either oxalate ($\text{C}_2\text{O}_4^{2-}$) or phosphate, with the most common components being calcium oxalate monohydrate ($\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$), hydroxyapatite ($\text{Ca}_5\text{OH}(\text{PO}_4)_3$) and brushite ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$). These compounds are thought to be formed when the concentrations of the Ca^{2+} , $\text{C}_2\text{O}_4^{2-}$ and $\text{PO}_4^{3-}/\text{HPO}_4^{2-}$ ions in the urine are high. We can explain this on the basis of what we have learned about solubility in this chapter. We know that when $Q_{\text{sp}} > K_{\text{sp}}$, a precipitate is expected to form, so a high concentration of ions will favour the formation of the solid.

One of the recommended measures to prevent the formation of kidney stones is the daily consumption of significant volumes of water. This will lower the concentration of the ions in the urine, which will lower Q_{sp} , hopefully to the point where $Q_{\text{sp}} < K_{\text{sp}}$, thereby ensuring no precipitate will form. Another reported method of avoiding kidney stones is

to drink orange juice; this is high in citric acid, which binds strongly to the Ca^{2+} ion, thereby lowering the concentration of free Ca^{2+} and consequently lowering Q_{sp} . Regardless of how you do it, if you want to avoid the pain of a kidney stone, keep your Q_{sp} low!

FIGURE 10.19

These kidney stones have been broken into smaller pieces so that they can be passed in the urine. Shockwaves are directed at the stones, shattering them without having to resort to surgery.

10.5 Colligative properties of solutions

LEARNING OBJECTIVE 10.5 Quantify the effects that arise in solutions as a result of colligative properties.

When we prepare a solution by dissolving a small amount of a **nonvolatile** solute, that is, a solute that does not have an appreciable vapour pressure, in a solvent, we find that particular properties of the resulting solution differ significantly from those of the pure solvent. For example, the boiling point of the solution is higher than that of the pure solvent and the freezing point is lower. Interestingly, the magnitudes of the boiling point elevation and the freezing point depression do not necessarily depend on the identity of the solute; if we prepared separate aqueous solutions of NaCl and NaBr by dissolving 1 mol of each salt in 1 kg of water, we would find that the boiling points (about 101 °C) and freezing points (about −3.4 °C) of both solutions would be the same. Properties such as vapour pressure, boiling point elevation, freezing point depression and osmotic pressure, which depend only on the *number* of solute particles in the solution, are called **colligative properties**.

The word ‘colligative’ is derived from the Latin *colligare* meaning ‘to bind together’ and colligative properties do in fact arise from the attractive interactions between solute particles and solvent molecules.

Colligative properties are important in everyday situations. Adding antifreeze to a car’s radiator lowers the freezing point of the coolant solution to well below 0 °C; this reduces the probability of damage to the engine caused by the expansion that occurs on formation of ice. Antifreeze also raises the boiling point of the radiator coolant. Reverse osmosis, a process that relies on colligative properties, is used extensively in the food industry as a method of concentrating heat-sensitive materials, such as fruit and vegetable juices, as it requires only the application of pressure. It is also used for desalination of sea water and to remove acetic acid from fermenting wine.

To be able to quantify the effects of colligative properties, we must first look at ways in which we can express the composition of solutions.

Molarity

The most common method of expressing the concentration of a solution, and the one we have used throughout the book thus far, is in mol L^{-1} ; that is, the amount of substance in a particular volume of solution. This is more properly called the **molar concentration** or **molarity** of a solution and has the symbol c .

$$\text{molarity } (c) = \frac{\text{amount of solute (mol)}}{\text{volume of solution (L)}}$$

However, because solutions (usually) increase their volume when the temperature is raised, and vice versa, the molarity of a solution changes as the temperature changes. For example, a saline solution of known molarity prepared at 25 °C has a different molarity when it is warmed to body temperature.

Molality

Molality is the preferred method of expressing solution composition in situations that involve colligative properties, as these properties are proportional to molality. We define the **molal concentration** or **molality** of a solution as the amount of solute per kilogram of solvent, and use the symbol b .

$$\text{molality } (b) = \frac{\text{amount of solute (mol)}}{\text{mass of solvent (kg)}}$$

The molality of a solution is independent of temperature as mass does not depend on temperature. The molarity and molality of aqueous solutions are numerically different but, as aqueous solutions become more and more dilute, the numerical value of the molarity approaches that of the molality.

WORKED EXAMPLE 10.6

Preparing a solution of a given molality

What mass of NaCl would have to be dissolved in 500.0 g of water to prepare a solution of molality $0.150 \text{ mol kg}^{-1}$?

Analysis

Rearranging the equation for molality given above, we obtain the following.

$$\text{amount of solute (mol)} = \text{molality (mol kg}^{-1}\text{)} \times \text{mass of solvent (kg)}$$

Knowing the amount of solute, NaCl, we then relate amount to mass through the molar mass of NaCl.

Solution

$$\text{amount of NaCl} = \text{molality} \times \text{mass of solvent} = 0.150 \text{ mol kg}^{-1} \times 0.5000 \text{ kg} = 0.0750 \text{ mol}$$

$$m = nM = 0.0750 \text{ mol} \times 58.44 \text{ g mol}^{-1} = 4.38 \text{ g}$$

Therefore, 4.38 g of NaCl needs to be dissolved in 500.0 g of water to give a solution of molality $0.150 \text{ mol kg}^{-1}$.

Is our answer reasonable?

If we round the molar mass of NaCl to 60, 0.1 mol is 6 g and 0.2 mol is 12 g. We also notice that $0.150 \text{ mol kg}^{-1}$ is halfway between 0.1 and 0.2 mol kg^{-1} . So, for 1 kg of water, we'd need halfway between 6 g (0.1 mol) and 12 g (0.2 mol) of NaCl. For half as much water (500 g), we cut these limits in two, so we need halfway between 3 and 6 g of NaCl. Our answer is in this range.

PRACTICE EXERCISE 10.6

Water freezes at a lower temperature when it contains solutes. To study the effect of methanol on the freezing point of water, we might begin by preparing a series of solu-

tions of known molalities. Calculate the mass of methanol, CH_3OH , needed to prepare a $0.250 \text{ mol kg}^{-1}$ solution using 2000 g of water.

Mole fraction

In the chapter on gases, we introduced the mole fraction as a method of expressing the composition of gas mixtures. We can also use it for liquid solutions. We define the **mole fraction (x)** of a particular component of a solution as the amount of that component divided by the total amount of material in the solution. For example, the mole fraction of A, x_A , in a solution containing substances A, B and C would be defined as follows.

$$x_A = \frac{n_A}{n_A + n_B + n_C}$$

Mole fraction is also temperature independent.

We will now see how these alternative measures of solution composition are used when quantifying colligative properties.

Raoult's law

As mentioned earlier, the boiling point of a solution containing a nonvolatile solute is higher than that of the pure solvent. The boiling point of a solvent is the temperature at which the vapour pressure of the solvent is equal to the pressure above the solution, which is generally the atmospheric pressure; therefore, the observation of a higher boiling point must mean that the solution has a lower vapour pressure than the pure solvent, as it now takes greater energy input to raise the vapour pressure of the solution to equal the atmospheric pressure. Providing that the solution is sufficiently dilute (i.e. x_{solvent} is close to 1), **Raoult's law** describes the relationship between the vapour pressure of the solution (p_{solution}), the mole fraction of solvent in the solution (x_{solvent}) and the vapour pressure of the pure solvent (p_{solvent}^*) in a simple two-component system.

$$p_{\text{solution}} = x_{\text{solvent}} p_{\text{solvent}}^* \\ \text{(at constant temperature for dilute solutions)}$$

This equation describes a straight line and so a plot of p_{solution} versus x_{solvent} is linear (figure 10.20).

FIGURE 10.20

A Raoult's law plot. When the vapour pressure of a dilute solution is plotted against the mole fraction of the solvent, a straight line results. It should be stressed that such behaviour is observed only in dilute solutions, that is, those in which x_{solvent} is close to 1.

Because x_{solvent} and x_{solute} are related in a two-component system:

$$x_{\text{solvent}} = 1 - x_{\text{solute}}$$

we can also write Raoult's law in terms of x_{solute} .

$$p_{\text{solution}} = (1 - x_{\text{solute}}) p_{\text{solvent}}^* \\ = p_{\text{solvent}}^* - x_{\text{solute}} p_{\text{solvent}}^*$$

This expression can be rearranged to give the following relationship for the *pressure difference* (Δp) between the pure solvent and the solution:

$$\Delta p = x_{\text{solute}} p_{\text{solvent}}^*$$

where:

$$\Delta p = p_{\text{solvent}}^* - p_{\text{solution}}$$

WORKED EXAMPLE 10.7

Calculation using Raoult's law

What is the vapour pressure of a solution prepared by dissolving 5.00 g of candle wax in 40.0 g of carbon tetrachloride, CCl_4 , at 23 °C? The molecular formula of candle wax is $\text{C}_{22}\text{H}_{46}$ and the vapour pressure of pure CCl_4 at 23 °C is 1.32×10^4 Pa.

Analysis

We use Raoult's law so we must calculate the mole fraction of solvent, x_{solvent} , from the data given by calculating the amount of both $\text{C}_{22}\text{H}_{46}$ and CCl_4 .

Solution

$$n_{\text{CCl}_4} = \frac{m}{M} = \frac{40.0 \text{ g}}{153.81 \text{ g mol}^{-1}} = 0.260 \text{ mol}$$

$$n_{\text{C}_{22}\text{H}_{46}} = \frac{m}{M} = \frac{5.00 \text{ g}}{310.59 \text{ g mol}^{-1}} = 0.0161 \text{ mol}$$

Therefore:

$$n_{\text{total}} = 0.260 \text{ mol} + 0.0161 \text{ mol} = 0.276 \text{ mol}$$

We can now calculate the mole fraction of solvent.

$$x_{\text{solvent}} = \frac{n_{\text{CCl}_4}}{n_{\text{total}}} = \frac{0.260 \text{ mol}}{0.276 \text{ mol}} = 0.942$$

We use this value in Raoult's law.

$$p_{\text{solution}} = x_{\text{solvent}} p_{\text{solvent}}^* = 0.942 \times (1.32 \times 10^4 \text{ Pa}) = 1.24 \times 10^4 \text{ Pa}$$

Hence, dissolving 5.00 g of candle wax in 40.0 g of CCl_4 lowers the vapour pressure by about 6%.

Is our answer reasonable?

The pressure we obtained is less than the vapour pressure of the pure solvent, which is what we would expect from Raoult's law. Barring arithmetic errors, our answer looks sensible.

PRACTICE EXERCISE 10.7

Di(2-ethylhexyl)phthalate, $\text{C}_{24}\text{H}_{38}\text{O}_4$ (molar mass $390.544 \text{ g mol}^{-1}$), is a viscous liquid used in huge quantities as a plasticiser for PVC. Its vapour pressure is negligible at room temperature. The vapour pressure of pure octane at 20 °C is 1.38×10^3 Pa. What is the vapour pressure at 20 °C of a solution of 10.0 g of di(2-ethylhexyl)phthalate in 60.0 g of octane, C_8H_{18} (molar mass $114.224 \text{ g mol}^{-1}$)?

While Raoult's law shows that a solution has a lower vapour pressure than the pure solvent, it does not explain why this is the case. If we compare a pure solvent with a solution containing a nonvolatile solute, we see that the surface of the solution — the interface between the liquid and gas phases — comprises a mixture of solvent and solute molecules, while the surface of the solvent consists only of solvent molecules (figure 10.21). Therefore, there are fewer molecules of solvent at the surface of a solution than of a pure solvent. This means that, in the solution, there are fewer solvent molecules available to evaporate, so we expect the vapour pressure exerted by the solvent molecules to be lower than in the pure solvent.

FIGURE 10.21

Effect of a nonvolatile solute on the vapour pressure of a solvent. (a) Equilibrium between a pure solvent and its vapour. With a high number of solvent molecules at the surface of the liquid, the rate of evaporation is relatively high. (b) In the solution, some of the solvent molecules at the surface have been replaced by solute molecules so there are fewer solvent molecules available to evaporate from the surface of the solution. This lowers the evaporation rate, so, when equilibrium is established, there are fewer molecules in the vapour. The vapour pressure of the solution is therefore less than that of the pure solvent.

A solution that obeys Raoult's law is called an **ideal solution**. Such solutions are generally dilute and have very small values of enthalpy of mixing, implying that there are only small interactions between their constituent molecules. We can think of an ideal solution as being analogous to an ideal gas.

Solutions containing more than one volatile component

When two (or more) components of a liquid solution can evaporate, the vapour contains molecules of each. Each volatile component contributes its own partial pressure to the total pressure. By Raoult's law, the partial pressure of a particular component is directly proportional to the component's mole fraction in the solution, and the total vapour pressure is the sum of the partial pressures. To calculate these partial pressures, we use Raoult's law for each component *A* and *B*.

$$p_A = x_A p_A^*$$

$$p_B = x_B p_B^*$$

The total pressure above a solution of liquids *A* and *B* is then the sum of p_A and p_B .

$$p_{\text{total}} = x_A p_A^* + x_B p_B^* \quad (\text{at constant temperature})$$

Figure 10.22 shows how the vapour pressure of an ideal, two-component solution of volatile compounds changes with composition.

FIGURE 10.22 The vapour pressure of an ideal, two-component solution of volatile compounds

WORKED EXAMPLE 10.8

Calculating the vapour pressure of a solution of two volatile liquids

At 20 °C, acetone has a vapour pressure of 2.13×10^4 Pa. The vapour pressure of water at 20 °C is 2.30×10^3 Pa. Assuming that the mixture obeys Raoult's law, calculate the vapour pressure of a solution of acetone and water containing 80.0 mol% of water.

Analysis

To find p_{total} , we need to calculate the individual partial pressures and then add them.

Solution

A concentration of 80.0 mol% water corresponds to a mole fraction of 0.800 for water and 0.200 for acetone, so:

$$\begin{aligned} p_{\text{acetone}} &= 0.200 \times 2.13 \times 10^4 \text{ Pa} = 4.26 \times 10^3 \text{ Pa} \\ p_{\text{water}} &= 0.800 \times 2.30 \times 10^3 \text{ Pa} = 1.84 \times 10^3 \text{ Pa} \\ p_{\text{total}} &= 6.10 \times 10^3 \text{ Pa} \end{aligned}$$

Is our answer reasonable?

The vapour pressure of the solution (6.10×10^3 Pa) has to be higher than that of pure water (2.30×10^3 Pa), because of the volatile acetone, but less than that of pure acetone (2.13×10^4 Pa), because of the high mole fraction of water. The answer seems to be reasonable.

PRACTICE EXERCISE 10.8

At 20 °C, the vapour pressure of cyclohexane (a hydrocarbon solvent) is 8.80×10^3 Pa and that of toluene (another solvent) is 2.78×10^3 Pa. What is the vapour pressure of

a solution of the two at 20 °C when toluene is present at a mole fraction of 0.700?

Because solutes influence the vapour pressures of solutions, they also affect their boiling and freezing points. The boiling point of a solution of a nonvolatile solute, for example, is higher than that of the pure solvent, and the freezing point of the solution is lower than that of the solvent. Next, we will explain this for aqueous solutions by considering the phase diagram for water.

Boiling point elevation and freezing point depression

We have seen how the presence of a non-volatile solute in a solution increases the boiling point of the solution relative to that of the pure solvent. Such solutions also have lower freezing points than those of the pure solvents, meaning that the attractive forces between solvent molecules in the solution must be smaller than those in the pure solvent at a given temperature. This is due to the presence of solute molecules and the corresponding solute–solvent interactions, which are not present in the pure solvent.

We can illustrate the changes in boiling and freezing points in solutions using a phase diagram. Figure 10.23 shows a phase diagram for an aqueous solution containing a nonvolatile solute (red lines) superimposed on the phase diagram for pure water (blue lines). We know that, at any temperature, the aqueous solution has a lower vapour pressure than pure water, so the liquid–gas equilibrium line lies below that for pure water. This has the effect of lowering the pressure and temperature at the triple point, so the ice–liquid equilibrium line is also displaced. We can see

from the phase diagram that the boiling point of the solution is increased by ΔT_b , relative to water, and the freezing point is depressed below 0°C by ΔT_f . ΔT_b is called the **boiling point elevation** and ΔT_f is called the **freezing point depression**, and both are a direct consequence of lowering the vapour pressure in the solution. They are colligative properties as their magnitudes are directly proportional to the number of solute particles in the solution. We can calculate ΔT_b and ΔT_f from the following equations.

$$\Delta T_b = K_b b$$

$$\Delta T_f = K_f b$$

K_b and K_f are the **molal boiling point elevation constant** and the **molal freezing point depression constant**, respectively, and b is the molality of the solution in mol kg^{-1} . K_b and K_f are properties of the solvent only and are independent of the identity of the solute; table 10.5 gives values of K_b and K_f for a number of solvents. These values apply exactly to very dilute solutions only, but we can use them to estimate the freezing points and boiling points of fairly concentrated solutions with reasonable precision.

FIGURE 10.23

Phase diagram for an aqueous solution of a nonvolatile solute. The blue lines refer to pure water, while the red lines refer to a dilute aqueous solution.

TABLE 10.5

Molal boiling point elevation and freezing point depression constants

Solvent	K_b ($\text{K mol}^{-1} \text{ kg}$)	K_f ($\text{K mol}^{-1} \text{ kg}$)
water	0.51	1.86
acetic acid	3.07	3.57
benzene	2.53	5.07
chloroform	3.63	–
camphor	–	37.7
cyclohexane	2.69	20.0

WORKED EXAMPLE 10.9

Estimating a freezing point using a colligative property

Estimate the freezing point of a solution made from 10.00 g of urea, $\text{CO}(\text{NH}_2)_2$ (molar mass $60.062 \text{ g mol}^{-1}$), in 100.0 g of water.

Analysis

$\Delta T_f = K_f b$ relates concentration to freezing point depression. To use the equation, we must first calculate the molality of the solution.

Solution

$$n_{\text{CO}(\text{NH}_2)_2} = \frac{10.00 \text{ g}}{60.062 \text{ g mol}^{-1}} = 0.1665 \text{ mol}$$

This is the amount of $\text{CO}(\text{NH}_2)_2$ in 100.0 g or 0.1000 kg of water. Therefore:

$$b = \frac{0.1665 \text{ mol}}{0.1000 \text{ kg}} = 1.665 \text{ mol kg}^{-1}$$

For our estimate, we must next use $\Delta T_f = K_f b$. From table 10.5, K_f for water is $1.86 \text{ K mol}^{-1} \text{ kg}$.

$$\begin{aligned}\Delta T_f &= K_f b \\ &= (1.86 \text{ K mol}^{-1} \text{ kg})(1.665 \text{ mol kg}^{-1}) \\ &= 3.10 \text{ K}\end{aligned}$$

Remembering that a temperature difference of 3.10 K is equal to 3.10°C , the solution should freeze at 3.10°C below 0°C , or at -3.10°C .

Is our answer reasonable?

For a solution of molality 1 mol kg^{-1} , the freezing point depression is as follows.

$$\begin{aligned}\Delta T_f &= K_f b \\ &= (1.86 \text{ K mol}^{-1} \text{ kg})(1 \text{ mol kg}^{-1}) \\ &= 1.86 \text{ K}\end{aligned}$$

Therefore, for every unit of molality, the freezing point must be depressed by about 2°C . The molality of this solution is between 1 mol kg^{-1} and 2 mol kg^{-1} , so we expect the freezing point depression to be between about 2°C and 4°C , which it is.

PRACTICE EXERCISE 10.9

Glycerol, $\text{C}_3\text{H}_8\text{O}_3$, is a nonvolatile compound that has been used as an antifreeze in car engines. However, it is not always realised that an antifreeze also raises the boiling

point of water in the cooling system as well. At what temperature does a 5.00% (by mass) aqueous solution of glycerol boil at $1.013 \times 10^5 \text{ Pa}$?

We have described the properties of freezing point depression and boiling point elevation as *colligative*; that is, they depend on the relative *numbers* of particles, rather than their identities. Because the effects are proportional to molal concentrations, experimental values of ΔT_f or ΔT_b can be useful for calculating the molar masses of unknown solutes. We'll see how this works in worked example 10.10.

WORKED EXAMPLE 10.10

Calculating a molar mass from freezing point depression data

A solution made by dissolving 5.65 g of an unknown molecular compound in 110.0 g of benzene froze at 4.39°C . Given that the normal melting point of benzene is 5.45°C , calculate the molar mass of the solute.

Analysis

We can use $\Delta T_f = K_f b$ to calculate the amount of solute in the given solution. Then we can divide the mass of solute by the amount of solute to find the molar mass.

Solution

From table 10.5, the value of K_f for benzene is $5.07 \text{ K mol}^{-1} \text{ kg}$. The magnitude of the freezing point depression is as follows.

$$\Delta T_f = 5.45^\circ\text{C} - 4.39^\circ\text{C} = 1.06^\circ\text{C} = 1.06 \text{ K}$$

We now use $\Delta T_f = K_f b$ to find the molality of the solution.

$$\Delta T_f = K_f b \quad b = \frac{\Delta T_f}{K_f} = \frac{1.06 \text{ K}}{5.07 \text{ K mol}^{-1} \text{ kg}} = 0.209 \text{ mol kg}^{-1}$$

This means that there is 0.209 mol of solute for every kilogram of benzene in the solution. But we have only 110.0 g or 0.1100 kg of benzene. So the actual amount of solute in the given solution is:

$$0.1100 \text{ kg} \times 0.209 \text{ mol kg}^{-1} = 0.0230 \text{ mol}$$

We can now obtain the molar mass.

$$M = \frac{m}{n} = \frac{5.65 \text{ g}}{0.0230 \text{ mol}} = 246 \text{ g mol}^{-1}$$

The mass of 1 mol of the solute is 246 g.

Is our answer reasonable?

The easiest way to check our answer is to do the reverse calculation, starting with 5.65 g of a compound having a molar mass of 246 g mol^{-1} , and determining the resultant

freezing point depression when dissolved in 110.0 g of benzene. If you do this (it's good practice!), you'll find that the answer is correct.

PRACTICE EXERCISE 10.10

A solution made by dissolving 3.46 g of an unknown compound in 85.0 g of benzene froze at 4.13°C . What is the molar mass of the compound?

Osmosis and osmotic pressure

In living things, membranes of various kinds keep mixtures and solutions organised and separated. Yet some substances have to be able to pass through membranes so that nutrients and products of chemical reactions can be distributed correctly. In other words, these membranes must have a selective *permeability*. They must keep some substances from going through while allowing others to pass. Such membranes are said to be *semipermeable*.

The degree of permeability varies with the kind of membrane. For example, a cellophane membrane is made from cellulose and is permeable to water and small solute particles — ions or molecules — but impermeable to very large molecules such as starch and proteins. Special membranes can even be prepared that are permeable only to water but not to any solutes.

Depending on the kind of membrane separating solutions of different concentration, two similar phenomena, *dialysis* and *osmosis*, can be observed. Both are functions of the relative populations of particles in the dissolved materials on either side of the membrane, so they are colligative properties.

When a membrane is capable of allowing both water and small solute particles to pass through, such as membranes found in living systems, the process is called **dialysis**, and the membrane is called a *dialysing membrane*. It does not permit huge molecules, such as proteins and starch, to pass through. Artificial kidney machines use dialysing membranes based on cellulose to help filter and remove the smaller molecules of wastes from the blood while the larger protein molecules, which cannot pass through the membrane, are retained in the blood.

Osmosis is a net shift of only solvent through a membrane, in a direction from the side less concentrated in *solute* to the side more concentrated. Such a membrane is called an **osmotic membrane**. The *direction* in which osmosis occurs, namely, the net movement of solvent from the more dilute solution (or pure solvent) into the more concentrated solution, may be explained with the help of figure 10.24. Water molecules move freely across the membrane. The concentration of water in the aqueous solution (*B*) is lower than the concentration in pure water (*A*). More water molecules are available to cross the membrane from *A* to *B*, so the flow of water molecules *into* the solution is somewhat greater than the flow *out of* the solution. In figure 10.24b, the net flow of water into the solution has visibly increased the volume of *B*.

If we push on the solution, we can force water back through the membrane (from *B* to *A*). The weight of the rising fluid column in figure 10.24b provides a push or opposing pressure that eventually stops osmosis. If we apply further pressure (figure 10.24c), we can force enough water back through the membrane to restore the system to its original condition. The exact opposing pressure needed to prevent any osmotic flow *when one of the liquids is pure solvent* is called the **osmotic pressure** of the solution.

By *exceeding* the osmotic pressure, osmosis can be reversed and we refer to this situation as reverse osmosis. Reverse osmosis allows pure water to be obtained from an aqueous salt solution simply by forcing it through a membrane under high pressure. It is therefore widely used to obtain drinking water from sea water. Reverse osmosis desalination plants in Australia supply water to Sydney, Melbourne, Adelaide, Perth and other cities.

To further illustrate the principles involved in osmosis, consider the situation in figure 10.25. We have a beaker of water in an enclosed space *already saturated in water vapour*, and we have just added a beaker of an aqueous solution of a nonvolatile solute. Water molecules tend to escape into the vapour phase from both beakers, but their rate of escape from the pure water (larger upward arrow) is greater than their rate of escape from the solution (smaller upward arrow). This must be so because the vapour pressure of pure

water is greater than that of the solution, as predicted by Raoult's law. The rate at which water molecules return to the solution from the saturated vapour state is not diminished by the presence of the solute. At the solution–vapour interface, more water molecules return to the solution than leave it, and this takes water from the vapour phase. To keep the vapour phase saturated, more of the pure water must evaporate. The net effect is that water moves from the beaker of pure water into the vapour phase and then into the solution. In osmosis, an osmotic membrane instead of beakers separates the liquids, but the same principles are at work.

FIGURE 10.24 Osmosis and osmotic pressure

The higher the concentration of the *solution*, the more water is transferred to it (figure 10.25). In other words, the osmotic pressure of a solution is proportional to the relative concentrations of its solute and solvent.

FIGURE 10.25 Principles at work in osmosis. Here, beakers, instead of a semipermeable membrane, separate the pure solvent (water) from an aqueous solution containing a nonvolatile solute. Because the vapour pressure of pure water is greater than the vapour pressure of the aqueous solution, molecules transfer from the beaker of pure water to the aqueous solution.

The symbol used for osmotic pressure is Π the capital Greek letter *pi*. In a dilute aqueous solution, Π (Pa) is proportional both to temperature, T (K), and concentration, c in mol m^{-3} .

$$\Pi \propto cT$$

The proportionality constant turns out to be the gas constant, R , so for a *dilute* aqueous solution we can write the following equation.

$$\Pi = cRT$$

$$\text{As } c = \frac{n}{V}:$$

$$\Pi V = nRT$$

where the volume is in units of m^3 .

This is the *van't Hoff equation for osmotic pressure* and is analogous to the ideal gas law. Note that we work in terms of concentration rather than molality here to emphasise the similarity of this equation to the ideal gas law. Recall that, provided the solution is sufficiently dilute, the molality and concentration are numerically essentially equal.

Osmotic pressure is of tremendous importance in biology and medicine. Cells are surrounded by membranes that restrict the flow of salts but allow water to pass through freely. To maintain a constant amount of water, the osmotic pressure of solutions on either side of a cell membrane must be identical. For example, a solution that is 0.9% NaCl by mass has the same osmotic pressure as the contents of red blood cells, and red blood cells bathed in this solution can maintain their normal water content. The solution is said to be **isotonic** with red blood cells. Blood plasma is an isotonic solution.

If a cell is placed in a solution with a salt concentration higher than the concentration within the cell, osmosis causes water to flow out of the cell. Such a solution is said to be **hypertonic**. The cell shrinks and dehydrates, and eventually dies. This process kills freshwater fish that are washed out to sea.

On the other hand, water flows into a cell if it is placed into a solution with an osmotic pressure that is much lower than the osmotic pressure of the cell's contents. Such a solution is called a **hypotonic** solution. A cell placed in distilled water, for example, swells and bursts. The effects of isotonic, hypertonic and hypotonic solutions on red blood cells are shown in figure 10.26.

FIGURE 10.26

Effects on red blood cells that have been placed in isotonic, hypertonic and hypotonic solutions, all at the same magnification: (a) In an isotonic solution (0.9% NaCl by mass), solutions on either side of the cell membrane have the same osmotic pressure, so there is no net flow of water in one direction across the membrane. (b) In a hypertonic solution (5.0% NaCl by mass), water flows from an area of lower salt concentration (inside the cell) to higher concentration (the hypertonic solution), causing the cell to dehydrate. (c) In a hypotonic solution (0.1% NaCl by mass), water flows from an area of lower salt concentration (the hypotonic solution) to higher concentration (inside the cell). The cell swells and bursts.

Obviously, the measurement of osmotic pressure can be very important in preparing solutions used to culture tissues or to administer medicines intravenously. Osmotic pressures can be measured by an instrument called an *osmometer*, illustrated and explained in figure 10.27. Osmotic pressures can be very high, even in dilute solutions, as worked example 10.11 shows.

FIGURE 10.27

Simple osmometer. When solvent moves into the solution by osmosis, the level of the solution in the capillary rises. The height reached is related to the osmotic pressure of the solution.

**WORKED EXAMPLE 10.11****Calculating osmotic pressure**

A solution of $1.00 \times 10^{-3} \text{ mol L}^{-1}$ sugar in water is separated from pure water by an osmotic membrane. What osmotic pressure (in Pa) develops at 25°C ?

Analysis

We can use $\Pi = cRT$. Recall that $R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1}$. As stated above, when we use this equation, the concentration must be expressed in mol m^{-3} to give an answer in Pa ($1 \text{ Pa} = 1 \text{ J m}^{-3}$).

Solution

We multiply the concentration by 1000 to convert from mol L^{-1} to mol m^{-3} ; thus, $c = 1.00 \text{ mol m}^{-3}$.

$$\begin{aligned}\Pi &= (1.00 \text{ mol m}^{-3})(8.314 \text{ J mol}^{-1} \text{ K}^{-1})(298 \text{ K}) \\ &= 2.48 \times 10^3 \text{ J m}^{-3} = 2.48 \times 10^3 \text{ Pa}\end{aligned}$$

Thus, the osmotic pressure of $1.00 \times 10^{-3} \text{ mol L}^{-1}$ sugar in water is $2.48 \times 10^3 \text{ Pa}$. This is roughly 2.5% the value of atmospheric pressure.

Is our answer reasonable?

The units are the greatest cause of error in calculations like this. Remember to express T in K and c in mol m^{-3} , not mol L^{-1} . This will give an answer in Pa.

PRACTICE EXERCISE 10.11

Determine the osmotic pressure of a $0.0156 \text{ mol L}^{-1}$ glucose solution at body temperature (37°C).

In worked example 10.11, you saw that a $1.00 \times 10^{-3} \text{ mol L}^{-1}$ solution of sugar has an osmotic pressure of $2.48 \times 10^3 \text{ Pa}$. This pressure would support a column of the solution roughly 25 cm high. If the solution had been 100 times as concentrated (0.100 mol L^{-1} sugar — still relatively dilute), the height of the column supported would be roughly 25 m.

An osmotic pressure measurement of a dilute solution can be used to determine the molar concentration and, therefore, the molar mass of a molecular solute. Determination of molar mass by osmotic pressure is much more sensitive than determination by freezing point depression or boiling point elevation. Worked example 10.12 shows how experimental measurements of osmotic pressure can be used to determine molar mass.

WORKED EXAMPLE 10.12**Calculating molar mass from osmotic pressure**

An aqueous solution with a volume of 100 mL and containing 0.122 g of an unknown molecular compound has an osmotic pressure of $2.11 \times 10^3 \text{ Pa}$ at 20.0°C . What is the molar mass of the solute?

Analysis

A molar mass is the ratio of mass to amount. We are given the mass of the solute; to calculate the ratio, we need to find the amount equivalent to this mass.

To find the amount of solute, we must first use $\Pi = cRT$ to find the concentration of the solution in mol m^{-3} . Then we can use the given volume of the solution and the concentration to calculate the amount that corresponds to 0.122 g of solute. Finally, we can calculate the molar mass by dividing the mass of solute by the amount of solute.

Solution

First, calculate the solution's concentration using the osmotic pressure. The temperature, 20.0°C , corresponds to 293 K . Recall that $1\text{ Pa} = 1\text{ J m}^{-3}$.

$$\Pi = cRT$$
$$c = \frac{\Pi}{RT} = \frac{2.11 \times 10^3\text{ Pa}}{8.314\text{ J mol}^{-1}\text{ K}^{-1} \times 293\text{ K}} = 0.866\text{ mol m}^{-3} = 8.66 \times 10^{-4}\text{ mol L}^{-1}$$

Therefore, in 100 mL or 0.100 L of solution, we have the following.

$$n = cV = 8.66 \times 10^{-4}\text{ mol L}^{-1} \times 0.100\text{ L}$$
$$= 8.66 \times 10^{-5}\text{ mol}$$

The molar mass of the solute is then obtained in the usual way.

$$M = \frac{m}{n} = \frac{0.122\text{ g}}{8.66 \times 10^{-5}\text{ mol}} = 1.41 \times 10^3\text{ g mol}^{-1}$$

Is our answer reasonable?

All we can do is double-check the calculation of the amount, which turns out to be a little less than 10^{-4} mol . Dividing the mass, roughly 0.12 g, by 10^{-4} mol gives $0.12 \times 10^4\text{ g mol}^{-1}$, or $1.2 \times 10^3\text{ g mol}^{-1}$, which is close to what we found.

PRACTICE EXERCISE 10.12

A solution of a carbohydrate prepared by dissolving 72.4 mg in 100 mL of solution has an osmotic pressure of $3.29 \times 10^3\text{ Pa}$ at 25.0°C . What is the molar mass of the compound?

Measurement of solute dissociation

The molal freezing point depression constant for water is $1.86\text{ K mol}^{-1}\text{ kg}$, and therefore you might think that a 1.00 mol kg^{-1} solution of NaCl would freeze at -1.86°C . Instead, it freezes at about -3.37°C . This greater depression of the freezing point by the salt, which is almost twice 1.86°C , is not hard to understand if we remember that colligative properties depend on the number of solute particles. NaCl(s) undergoes complete **dissociation** into its constituent ions in water according to the following equation.

Therefore, if we dissolve 1 mol of NaCl(s) (58.5 g) in 1 kg of water, the resulting solution has a total molality of *dissolved solute particles* of 2 mol kg^{-1} : 1 mol kg^{-1} of Na^+ ions and 1 mol kg^{-1} of ions. Theoretically, a 1.00 mol kg^{-1} NaCl solution should freeze at $2 \times (-1.86^\circ\text{C})$ or -3.72°C . (Why it actually freezes a little higher than this, at -3.37°C , will be discussed shortly.)

If we made up a 1.00 mol kg^{-1} solution of $(\text{NH}_4)_2\text{SO}_4$, we would have to consider the following dissociation.

So, 1 mol of $(\text{NH}_4)_2\text{SO}_4$ gives a total of 3 mol of ions (2 mol of NH_4^+ and 1 mol of SO_4^{2-}). We expect the freezing point of this solution of $(\text{NH}_4)_2\text{SO}_4$ to be $3 \times (-1.86^\circ\text{C}) = -5.58^\circ\text{C}$.

You should ensure you understand the distinction between *dissolution* and *dissociation*. A slightly soluble ionic solid such as AgCl dissolves only to a very small extent (i.e. it does not undergo complete dissolution), but the small amount of resulting Ag^+ and Cl^- ions in solution are essentially completely dissociated (i.e. they show little tendency to stick together).

When we want to estimate a colligative property of a solution of an electrolyte, we recalculate the solution's molality assuming that the salt dissociates completely. This is illustrated in worked example 10.13.

WORKED EXAMPLE 10.13
Estimating the freezing point of a salt solution

Estimate the freezing point of an aqueous solution of $0.106 \text{ mol kg}^{-1}$ MgCl_2 , assuming that it dissociates completely.

Analysis

The equation that relates a change in freezing temperature to molality is as follows.

$$\Delta T_f = K_f b$$

From table 10.5, K_f for water is $1.86 \text{ K mol}^{-1} \text{ kg}$. We cannot simply use $0.106 \text{ mol kg}^{-1}$ for the molality because MgCl_2 is an ionic compound that dissociates in water; we must use the total molality of ions in the equation.

Solution

When MgCl_2 dissolves in water, it dissociates as follows.

Because 1 mol of MgCl_2 gives 3 mol of ions, the effective (assumed) molality of what we have called $0.106 \text{ mol kg}^{-1}$ MgCl_2 is three times as great.

$$\text{effective molality} = 3 \times 0.106 \text{ mol kg}^{-1} = 0.318 \text{ mol kg}^{-1}$$

Now we can use $\Delta T_f = K_f b$.

$$\begin{aligned} \Delta T_f &= (1.86 \text{ K mol}^{-1} \text{ kg})(0.318 \text{ mol kg}^{-1}) \\ &= 0.591 \text{ K} = 0.591 ^\circ\text{C} \end{aligned}$$

The freezing point is depressed below $0.000 ^\circ\text{C}$ by $0.591 ^\circ\text{C}$, so we calculate that this solution freezes at $-0.591 ^\circ\text{C}$.

Is our answer reasonable?

The molality, as recalculated, is roughly 0.3, so 0.3 of 1.86 (call it 2) is 0.6, which, after we add the unit $^\circ\text{C}$ and subtract from $0 ^\circ\text{C}$, gives $-0.6 ^\circ\text{C}$, which is close to the answer.

PRACTICE EXERCISE 10.13

Calculate the freezing point of an aqueous solution of $0.172 \text{ mol kg}^{-1}$ $\text{Al}_2(\text{SO}_4)_3$ on the assumption that it is 100%

dissociated. Calculate the freezing point of the solution assuming 0% dissociation.

Experiments show that neither the 1.00 mol kg^{-1} $(\text{NH}_4)_2\text{SO}_4$ nor the 1.00 mol kg^{-1} NaCl solution described above freezes at as low a temperature as calculated. Our assumption that an electrolyte separates *completely* into its ions is incorrect. Some oppositely charged ions exist as very closely associated pairs, called **ion pairs**, which behave as single ‘molecules’. Clusters larger than two ions probably exist also. The formation of ion pairs and clusters makes the actual *particle* concentration in a 1.00 mol kg^{-1} NaCl solution somewhat less than 2.00 mol kg^{-1} . As a result, the freezing point depression of 1.00 mol kg^{-1} NaCl is not quite as large as that calculated on the basis of 100% dissociation.

As solutions of electrolytes are made more *dilute*, the observed and calculated freezing points come closer together. At ever greater dilutions, the association of ions is less of a complication because the ions are further apart, so the solutes behave more and more as if they were 100% separated into their ions.

Chemists compare the degrees of dissociation of electrolytes at different dilutions by a quantity called the **van’t Hoff factor** (i). This is the ratio of the observed freezing point depression to the value calculated on the assumption that the solute dissolves as a nonelectrolyte.

$$i = \frac{(\Delta T_f)_{\text{measured}}}{(\Delta T_f)_{\text{calculated as a nonelectrolyte}}}$$

The theoretical van’t Hoff factor is 2 for NaCl , KCl and MgSO_4 , which break up into two ions on 100% dissociation. The theoretical value for K_2SO_4 is 3 because each K_2SO_4 unit gives three ions. The actual van’t Hoff factors for several electrolytes at different dilutions are given in table 10.6. Notice that with decreasing concentration (i.e. at higher dilutions) the experimental van’t Hoff factors agree better with their corresponding theoretical van’t Hoff factors.

The increase in the percentage of complete dissociation that comes with greater dilution is not the same for all salts. In going from molalities of 0.1 to $0.001 \text{ mol kg}^{-1}$, the increase in % dissociation of KCl , as measured by the change in i , is only about 7%. For K_2SO_4 , the increase for the same dilution is about 22%, a difference caused by the anion SO_4^{2-} . This anion has twice the charge of the anion in KCl , so the SO_4^{2-} ion attracts K^+ more strongly than can Cl^- . Hence, letting an ion of $2-$ charge and an ion of $1+$ charge get farther apart by dilution has a greater effect on their acting independently than giving ions of $1-$ and $1+$ charge more room. When *both* cation and anion are doubly charged, the improvement in % dissociation

with dilution is even greater. We can see from table 10.6 that there is an almost 50% increase in the value of i for MgSO_4 as we go from a 0.1 to a $0.001 \text{ mol kg}^{-1}$ solution.

TABLE 10.6 The effect of concentration on the van't Hoff factor

Salt	van't Hoff factor (i)			
	Molal concentration (mol salt/kg water)			If 100% dissociation occurred
	0.1	0.01	0.001	
NaCl	1.87	1.94	1.97	2.00
KCl	1.85	1.94	1.98	2.00
K_2SO_4	2.32	2.70	2.84	3.00
MgSO_4	1.21	1.53	1.82	2.00

There are many substances in which dissociation is far from complete. For example, in 1.00 mol kg^{-1} aqueous acetic acid (a weak acid), the following equilibrium exists.

The solution freezes at -1.90°C . This is only a little lower than that expected (-1.86°C) if no ionisation occurred, which is evidence for only a small amount of ionisation. We can estimate % ionisation by the following calculation.

We first use the data to calculate the *apparent molality* of the solution; that is, the molality of all dissolved species, CH_3COOH , CH_3COO^- and H_3O^+ . We again use $\Delta T_f = K_f b$, but now letting b stand for the apparent molality. K_f is $1.86 \text{ K mol}^{-1} \text{ kg}$, so:

$$b = \frac{\Delta T_f}{K_f} = \frac{1.90 \text{ K}}{1.86 \text{ K mol}^{-1} \text{ kg}} = 1.02 \text{ mol kg}^{-1}$$

If there is 1.02 mol of all solute species in 1 kg of solvent, we have 0.02 mol of solute species more than we started with, because we began with 1.00 mol of acetic acid. Since we get just one *extra* particle for each acetic acid molecule that ionises, the extra 0.02 mol of particles must have come from the ionisation of 0.02 mol of acetic acid. So:

$$\% \text{ ionisation} = \frac{\text{mol of acid ionised}}{\text{mol of acid available}} \times 100\% = \frac{0.02}{1.00} \times 100\% = 2\%$$

In other words, this procedure estimates the % ionisation in 1.00 mol kg^{-1} acetic acid to be 2%. (Other kinds of measurements offer better precision, and the % ionisation of acetic acid at this concentration is actually less than 1%.) We will discuss the ionisation of acids in more detail in the chapter on acids and bases.

Some molecular solutes produce smaller colligative effects than their molal concentrations would lead us to predict. This is often evidence that solute molecules are clustering or undergoing **association** in solution, in the same way as discussed for ions above. For example, when dissolved in benzene, benzoic acid molecules associate as **dimers** held together by hydrogen bonds.

Because of association, the depression of the freezing point of a 1.00 mol kg^{-1} solution of benzoic acid in benzene is only about half of the calculated value. By forming a dimer, benzoic acid has an effective molecular mass twice that normally calculated. The larger effective molar mass reduces the molal concentration of particles by a factor of two, and the effect on the freezing point depression is halved.

SUMMARY

10.1 Define important terms related to solutions.

A solution is a homogeneous mixture of two or more pure substances that can be gases, liquids or solids. The liquid in a liquid solution is called the solvent, and the dissolved substance is the solute. A saturated solution contains the maximum possible amount of dissolved solute at the given temperature and pressure.

10.2 Describe why gases mix spontaneously.

All gases mix spontaneously in all proportions. As the enthalpy change for mixing is usually small, owing to the very low interatomic or intermolecular forces between the gas atoms or molecules, the mixing process is essentially entropy driven.

10.3 Outline the energetics involved in the formation of liquid solutions.

In contrast to gaseous solutions, liquid solutions have significant intermolecular interactions involving solvent molecules so they generally have significant enthalpies of solution, $\Delta_{\text{sol}}H$. The two contributions to $\Delta_{\text{sol}}H$ when a gas dissolves in a liquid are the energy required to open 'pockets' in the solvent and the energy released when gas molecules occupy these pockets. $\Delta_{\text{sol}}H$ values are usually positive for gases in organic solvents and negative for gases in water. The solubilities of gases in water usually decrease with increasing temperature. Henry's law, $c_{\text{gas}} = k_{\text{H}}p_{\text{gas}}$, states that the concentration of a gas in a liquid at constant temperature is directly proportional to the partial pressure of the gas above the solution.

Two liquids that mix completely in all proportions are said to be miscible, while those that do not mix are immiscible. Liquids of similar polarities are often miscible; in other words, 'like dissolves like'. Dissolution of an ionic compound in water gives the hydrated free ions, a specific form of solvation. Polar molecules are generally soluble in polar solvents, and vice versa.

The molar enthalpy of solution of a solid is the enthalpy change when 1 mol of a crystalline substance is dissolved in a solvent. The solubility of a solid in a liquid is temperature dependent and generally increases with increasing temperature.

10.4 Carry out calculations involving slightly soluble salts.

The solubility product, K_{sp} , is the equilibrium constant for the dissolution of a slightly soluble salt in a solvent (usually water). For the general equilibrium shown below, it is written as $K_{\text{sp}} = [\text{M}^{b+}]^a [\text{X}^{a-}]^b$.

The molar solubility (s) of a salt at a specified temperature is the amount of the salt dissolved in 1 litre of a saturated solution at that temperature. The relationship between s and K_{sp} depends on the nature of the salt. For a 1 : 1 salt, $K_{\text{sp}} = s^2$,

for a 1 : 2 salt, $K_{\text{sp}} = 4s^3$, for a 1 : 3 salt, $K_{\text{sp}} = 27s^4$ and, for a 2 : 3 salt, $K_{\text{sp}} = 108s^5$.

The effect of adding a common ion to a saturated solution of a slightly soluble salt can be calculated by comparing Q_{sp} (sometimes called the ionic product) with K_{sp} . We can use the same method to predict if a precipitate will form when two solutions are mixed. The common ion effect shows that salts are always less soluble in the presence of a common ion, providing no further chemical reaction is possible.

10.5 Quantify the effects that arise in solutions as a result of colligative properties.

A solution containing a nonvolatile solute boils at a higher temperature and freezes at a lower temperature than the pure solvent. This can be explained in terms of the colligative properties of the solvent. In so doing, instead of expressing solution composition in terms of molar concentration or molarity, it is necessary to use molal concentration or molality (b).

We use mole fractions, x , when explaining the effect of a solute on boiling and freezing points. Raoult's law, $p_{\text{solution}} = x_{\text{solvent}}p_{\text{solvent}}^*$, shows that the pressure above a solution is proportional to the mole fraction of the solvent in a dilute solution. This is due to a reduction in the number of molecules of solvent at the surface of the solution, which leads to a lower vapour pressure for the solution than for the pure solvent. An ideal solution obeys Raoult's law. Each component of an ideal solution consisting of two volatile liquids A and B obeys Raoult's law, such that $p_{\text{total}} = x_A p_A^* + x_B p_B^*$. The boiling point elevation and freezing point depression of a solution containing a nonvolatile solute is due to the reduced vapour pressure of the solution relative to that of the pure solvent. The magnitudes of these effects can be determined using the equations $\Delta T_b = K_b b$ and $\Delta T_f = K_f b$, where K_b and K_f are the molal boiling point elevation constant and the molal freezing point depression constant of the solvent, respectively, and b is the molality of the solution (mol kg^{-1}).

Dialysis is the passage of water and small solute particles through a semipermeable membrane, while osmosis is the passage of solvent only. Osmosis occurs through an osmotic membrane and results in a net shift of solvent from the side less concentrated in solute to the side more concentrated. The osmotic pressure (Π) is that required to stop this net flow of solvent when one of the liquids is pure water. The van't Hoff equation for osmotic pressure is $\Pi V = nRT$ and is analogous to the ideal gas equation.

Freezing point depression can be used to estimate the degree of dissociation of ionic salts in solution. These results often show that such salts do not dissociate completely but exist to a certain extent as ion pairs in solution. The van't Hoff factor (i) measures the degree of dissociation of an electrolyte in solution. As a solution becomes more dilute, the degree of dissociation increases. Freezing point depression also gives evidence for the association of molecular solutes in solution.

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation
Henry's law	10.3	This law: $c_{\text{gas}} = k_{\text{H}} p_{\text{gas}}$ allows calculation of the solubility of a gas in a solvent at a given pressure from its solubility at another pressure.
Like-dissolves-like rule	10.3	This rule uses chemical composition and structure to predict whether two substances can form a solution.
Solubility product constant, K_{sp}	10.4	We use K_{sp} to calculate the molar solubility of a salt, either in pure water or in a solution that contains a common ion. Comparison of K_{sp} with Q_{sp} allows us to decide whether a precipitate will form on mixing ionic solutions.
Molar solubility	10.4	We can use molar solubility to calculate the value of K_{sp} for a slightly soluble salt.
Common ion effect	10.4	The presence of a common ion in a solution lowers the solubility of a salt containing that common ion in the solution.
Molal concentration (molality)	10.5	The equation: $\text{molality} = \frac{\text{amount of solute (mol)}}{\text{mass of solvent (kg)}}$ provides a temperature-independent concentration expression for use with colligative properties.
Raoult's law	10.5	This expression: $p_{\text{solution}} = x_{\text{solvent}} p_{\text{solvent}}^*$ is used to calculate the effect of a solute on the vapour pressure of a solution.
Freezing point depression (ΔT_f) and boiling point elevation (ΔT_b)	10.5	The expressions: $\Delta T_f = K_f b$ and: $\Delta T_b = K_b b$ enable us to estimate freezing and boiling points, molar masses and % dissociation of a weak electrolyte.
Equation for osmotic pressure	10.5	We use this equation: $\Pi = nRT$ to estimate the osmotic pressure of a solution or to calculate molar masses from osmotic pressure and concentration data.

KEY TERMS

association The clustering of molecular species in solution.

boiling point elevation (ΔT_b) A colligative property of a solution by which the solution's boiling point is higher than that of the pure solvent.

colligative property A property, such as vapour pressure lowering, boiling point elevation, freezing point depression and osmotic pressure, that depends only on the ratio of the numbers of moles of solute and solvent particles and not on their chemical identities.

common ion An ion in a mixture of ionic substances that is common to the formulae of at least two of those substances.

common ion effect The effect by which the solubility of one salt is reduced by the presence of another having a common ion.

dialysis The passage of solvent and small molecules and ions through a semipermeable membrane.

dimer A close association of two similar molecules.

dissociation The breaking apart of a molecule or ionic solid into ions when dissolved in a solvent (usually water).

dissolution The process of dissolving a solute in a solvent.

- enthalpy of solution ($\Delta_{\text{sol}}H$)** The enthalpy change that accompanies the formation of a solution from a solute and a solvent.
- freezing point depression (ΔT_f)** A colligative property of a liquid solution by which the freezing point of the solution is lower than that of the pure solvent.
- Henry's law** The concentration of a gas dissolved in a liquid at any given temperature is directly proportional to the partial pressure of the gas above the solution.
- hydration** The addition of water; the development in an aqueous solution of a 'cage' of water molecules around ions or polar molecules of the solute.
- hydration enthalpy** The enthalpy change when gaseous solute particles (obtained from the vaporisation of 1 mol of solute) are dissolved in water.
- hypertonic** Describes a solution that has a higher osmotic pressure than cellular fluids.
- hypotonic** Describes a solution that has a lower osmotic pressure than cellular fluids.
- ideal solution** A hypothetical solution that obeys Raoult's law exactly.
- immiscible** Describes liquids that do not mix; see also *insoluble*.
- insoluble** Describes a solute that does not dissolve in a solvent.
- ion pair** A more or less loosely associated pair of ions in a solution.
- ionic product** An alternative name for the reaction quotient (Q_{sp}).
- isotonic** Describes a solution that has the same osmotic pressure as cellular fluids.
- lattice enthalpy** The enthalpy change when 1 mol of a crystalline compound is converted into its gaseous constituent particles.
- like-dissolves-like rule** Strongly polar and ionic solutes tend to dissolve in polar solvents, and non-polar solutes tend to dissolve in non-polar solvents.
- miscible** Describes liquids that mix completely; see also *soluble*.
- molal boiling point elevation constant (K_b)** The number of degrees ($^{\circ}\text{C}$) per unit of the molal concentration boiling point elevation of a solution relative to the pure solvent.
- molal concentration (b)** The number of moles of solute in 1000 g of solvent; also called molality.
- molal freezing point depression constant (K_f)** The number of degrees ($^{\circ}\text{C}$) per unit of the molal concentration freezing point depression of a solution relative to the pure solvent.
- molality (b)** Molal concentration.
- molar concentration (c)** The concentration of a solution in units of mol L^{-1} ; also called molarity.
- molar solubility (s)** The number of moles of solute required to prepare 1 L of a saturated solution of the solute.
- molarity (c)** Molar concentration.
- mole fraction (x)** The number of moles of a component in a solution divided by the total number of moles of material in the solution.
- nonvolatile** Describes a substance with a high boiling point and a low vapour pressure that, consequently, does not evaporate.
- osmosis** The passage of solvent molecules, but not those of solutes, through a semipermeable membrane (more limiting than dialysis).
- osmotic membrane** A membrane that allows passage of solvent, but not solute particles.
- osmotic pressure (Π)** The back pressure that has to be applied to prevent osmosis; one of the colligative properties.
- Raoult's law** The vapour pressure of one component above a mixture of molecular compounds equals the product of its mole fraction and its vapour pressure when pure.
- saturated solution** A solution in which no more solute will dissolve at a specified temperature.
- solubility** The maximum amount of a solute that dissolves completely in a given mass or volume of solvent at a particular temperature.
- solubility product (K_{sp})** The equilibrium constant for the dissolution of an ionic salt.
- soluble** Describes a solid or a gas that dissolves in a solvent.
- solute** The dissolved substance contained in a solution.
- solution** A homogeneous mixture in which all particles are of the size of atoms, small molecules or small ions.
- solvation** The development of a cage-like network of a solution's solvent molecules around a molecule or ion of the solute.
- solvation enthalpy** The enthalpy change due to the interaction of gaseous molecules or ions of solute with solvent molecules during the formation of a solution.
- solvent** The liquid component of a solution.
- van't Hoff factor (i)** The ratio of the observed freezing point depression to the value calculated assuming that the solute dissolves as un-ionised molecules.

REVIEW QUESTIONS

Introduction to solutions and solubility

10.1 Define the following terms.

- solution
- solvent
- solute
- solubility
- saturated solution
- dissolution

Gaseous solutions

10.2 Why do two gases mix spontaneously when they are brought into contact?

Liquid solutions

10.3 Outline the two physical processes that occur when a gas dissolves in a liquid. What is the sign of the enthalpy change for each of these processes?

10.4 Methanol, CH_3OH , and water are miscible in all proportions. What does this mean? Explain how the $-\text{OH}$ unit in methanol contributes to this.

LO1

10.5 Petrol (which is composed of hydrocarbon molecules) and water are immiscible. What does this mean? Explain why they are immiscible in terms of structural features of their molecules and forces of attraction between them.

10.6 The halogen molecules $\text{Cl}_2(\text{g})$, $\text{Br}_2(\text{l})$ and $\text{I}_2(\text{s})$ are poorly soluble in water, but all dissolve completely in hexane, C_6H_{14} . Explain this observation.

10.7 The solubility of iodine in water (0.34 g kg^{-1}) is much less than that in ethanol (271.7 g kg^{-1}). Why is this the case, given that both water and ethanol molecules are polar?

10.8 The value of $\Delta_{\text{sol}}H$ for LiBr is -67 kJ mol^{-1} . If an aqueous solution of LiBr is prepared in an insulated container, will the system's temperature increase or decrease as the LiBr dissolves?

10.9 The hydration enthalpies of KCl , NaCl and LiCl are -86 kJ mol^{-1} , -770 kJ mol^{-1} and -883 kJ mol^{-1} , respectively. Given that the anion is the same in each of the salts, how do you account for this trend?

- 10.10** The value of $\Delta_{\text{sol}}H$ for the formation of an acetone–water solution is negative. Explain this in terms of intermolecular forces of attraction.
- 10.11** The value of $\Delta_{\text{sol}}H$ for the formation of an ethanol–hexane solution is positive. Explain this in terms of intermolecular forces of attraction.
- 10.12** If the value of $\Delta_{\text{sol}}H$ for the formation of a mixture of two liquids *A* and *B* is 0, what does this imply about the relative strengths of *A*–*A*, *B*–*B* and *A*–*B* intermolecular attractions?
- 10.13** Use the data in figure 10.16 to determine the approximate mass of solute that will precipitate if a saturated solution of NH_4NO_3 containing 100 g of solvent at 60 °C is cooled to 20 °C.
- 10.14** Use the data in figure 10.16, to determine which salt would precipitate first if a hot concentrated solution in which equal masses of NaBr and NaCl are dissolved is slowly cooled from 50 °C.
- 10.15** On hot summer days the largest fish are found in deep sinks in lake bottoms, where the water is coolest. Use the temperature dependence of oxygen solubility in water to explain why.
- 10.16** State Henry's law and give the equation which defines it.
- 10.17** Mountain streams often contain fewer living things than equivalent streams at sea level. In terms of oxygen solubility at different pressures, give one reason why this might be true.
- 10.18** Explain, in terms of Henry's law, why a bottle of 'fizzy drink' fizzes when the top is removed.
- Quantification of solubility: the solubility product** **LO4**
- 10.19** What is the difference between Q_{sp} and K_{sp} ?
- 10.20** Illustrate the common ion effect by showing what happens to the value of Q_{sp} when a small volume of concentrated NaCl solution is added to a saturated solution of AgCl.
- 10.21** With respect to K_{sp} , what conditions must be met before a precipitate forms in a solution?
- Colligative properties of solutions** **LO5**
- 10.22** How does the molality of a solution vary with increasing temperature? How does the molarity of a solution vary with increasing temperature?
- 10.23** Suppose a 1.0 mol kg⁻¹ solution of a solute is made using a solvent with a density of 1.15 g mL⁻¹. Is the molarity of this solution numerically greater than or less than 1.0? Explain.
- 10.24** What is meant by the term 'colligative property'?
- 10.25** Viewed at a molecular level, what causes a solution containing a nonvolatile solute to have a lower vapour pressure than the solvent at the same temperature?
- 10.26** Methanol and water are completely miscible in all proportions. When they mix, do they form an ideal solution? Why/why not?
- 10.27** When an aqueous solution of sodium chloride is frozen slowly, why don't the ice crystals contain ions of the salt?
- 10.28** Explain why a nonvolatile solute dissolved in water gives the system:
- a higher boiling point than water
 - a lower freezing point than water.
- 10.29** Why do we call dialysing and osmotic membranes 'semipermeable'? What is the opposite of 'permeable'?
- 10.30** What is the key difference between dialysing and osmotic membranes?
- 10.31** What is meant by 'dialysis'?
- 10.32** At a molecular level, explain why in osmosis there is a net migration of solvent from the side of the membrane less concentrated in solute to the side more concentrated in solute.
- 10.33** Two glucose solutions of unequal molarity are separated by an osmotic membrane. Which solution *loses* water, the one with the higher or the lower molarity?
- 10.34** What is the difference between a hypertonic solution and a hypotonic solution?
- 10.35** Why are colligative properties of solutions of ionic compounds usually more pronounced than those of solutions of molecular compounds of the same molalities?
- 10.36** What is the van't Hoff factor? What is its expected value for all nondissociating molecular solutes? If its measured value is slightly larger than 1.0, what does this suggest about the solute? What is suggested by a van't Hoff factor of approximately 0.5?
- 10.37** Which aqueous solution, if either, is likely to have the higher boiling point, 0.50 mol kg⁻¹ NaI or 0.50 mol kg⁻¹ Na₂CO₃?

REVIEW PROBLEMS

- 10.38** Consider the formation of a solution of aqueous lithium chloride. Write the thermochemical equations for the: **LO3**
- conversion of solid LiCl into its gaseous ions
 - subsequent formation of the solution by hydration of the ions.
- The lattice enthalpy of LiCl is 833 kJ mol⁻¹, and the hydration enthalpy of the ions is -883 kJ mol⁻¹.
- (c) Calculate the enthalpy of solution of LiCl in kJ mol⁻¹.
- 10.39** The lattice enthalpy of CsI(s) is 606 kJ mol⁻¹ and its enthalpy of solution in water is 31 kJ mol⁻¹. Use these data to calculate the hydration enthalpy of the ions in the compound. **LO3**
- 10.40** If the enthalpy of solution of an ionic compound in water is -50 kJ mol⁻¹, and the hydration enthalpy is -890 kJ mol⁻¹, estimate the lattice enthalpy of the ionic compound. **LO3**
- 10.41** The Henry's law constant for ethane, C₂H₆, at 25.0 °C is 1.9 × 10⁻⁸ mol L⁻¹ Pa. What is the solubility of ethane in water at this temperature when the pressure of ethane above the solution is 1.013 × 10⁵ Pa? **LO2**
- 10.42** At 9.74 × 10⁴ Pa and 20 °C, nitrogen has a solubility in water of 0.018 g L⁻¹. At 8.16 × 10⁴ Pa and 20 °C, its solubility is 0.015 g L⁻¹. Show that nitrogen obeys Henry's law. **LO4**
- 10.43** The Henry's law constant for argon in water is 1.40 × 10⁻⁸ mol L⁻¹ Pa⁻¹ at 25.0 °C. Use this value to calculate the solubility of Ar in water, in units of g L⁻¹, when the partial pressure of the gas over the solution is 3.60 × 10⁴ Pa and 7.20 × 10⁴ Pa. **LO2**
- 10.44** Write the K_{sp} expressions for each of the following compounds. **LO4**
- CuBr
 - HgI₂
 - Ag₂SO₃
 - PbSO₄
 - Ag₃PO₄
 - Zn(CN)₂
 - Fe(OH)₃
 - Cu₃(AsO₄)₂
 - TiCl
- 10.45** As we saw at the start of this chapter, barium sulfate, BaSO₄, can be safely ingested despite the fact that the Ba²⁺ ion is toxic. This is due to the very low solubility of BaSO₄, with only 0.002 45 g of BaSO₄ dissolving per litre of water at 25 °C. Calculate K_{sp} for BaSO₄. **LO4**
- 10.46** Potassium perchlorate, KClO₄, is a rare example of a poorly water-soluble potassium salt, with a mass solubility of 1.50 g per 100 mL of water at 25.0 °C. Calculate the molar solubility and K_{sp} for KClO₄ at this temperature. **LO4**

- 10.47** When 269 mL of a saturated solution of CuCl was evaporated to dryness, 0.0116 g of solid CuCl was obtained. What is the value of K_{sp} for this salt? **L04**
- 10.48** At 25 °C, the molar solubility of BaCrO₄ is $2.1 \times 10^{-10} \text{ mol L}^{-1}$. Calculate K_{sp} for this salt. **L04**
- 10.49** The molar solubility of Mg₃(PO₄)₂ in water at 25 °C is $3.6 \times 10^{-6} \text{ mol L}^{-1}$. What is the value of K_{sp} for this salt? **L04**
- 10.50** Use the K_{sp} values in table 10.3 to show that the molar solubilities of PbF₂(s) and MgCO₃(s) differ by a factor of approximately 11, despite them having essentially the same value of K_{sp} . **L04**
- 10.51** At 25 °C, K_{sp} for AgCl = 1.8×10^{-10} while that for Ag₂CO₃, 8.1×10^{-12} , is smaller. Which salt, AgCl or Ag₂CO₃, has the larger molar solubility in water? **L04**
- 10.52** At 25 °C, the value of K_{sp} for AgCN is 2.2×10^{-16} and that for Zn(CN)₂ is 3×10^{-16} . In terms of grams per 100 mL of solution, which salt is the more soluble in water? **L04**
- 10.53** A salt with a formula MX has $K_{sp} = 2.7 \times 10^{-7}$. What value of K_{sp} must another slightly soluble salt, MX₃, have if the molar solubilities of the two salts are to be identical? **L04**
- 10.54** Lead sulfate is found in car batteries. At 25 °C, the value of K_{sp} for PbSO₄ is 6.3×10^{-7} . What is the calculated molar solubility of PbSO₄ in water at this temperature? **L04**
- 10.55** Silver chloride, AgCl, has $K_{sp} = 1.8 \times 10^{-10}$ at 25 °C. Calculate the molar solubility of AgCl in the following at 25 °C, assuming that AgCl(s) does not react with excess Cl⁻ to form [AgCl₂]⁻. **L04**
- pure water
 - $0.0100 \text{ mol L}^{-1}$ HCl(aq) solution
 - 0.100 mol L^{-1} HCl(aq) solution
 - 0.100 mol L^{-1} MgCl₂(aq) solution
- 10.56** Gold(III) chloride, AuCl₃, has $K_{sp} = 3.2 \times 10^{-25}$ at 25 °C. Calculate the molar solubility of AuCl₃ in each of the following at 25 °C, assuming that AuCl₃ does not react with any of the compounds listed in (b), (c) or (d). **L04**
- pure water
 - 0.010 mol L^{-1} HCl solution
 - 0.010 mol L^{-1} MgCl₂ solution
 - 0.010 mol L^{-1} Au(NO₃)₃ solution
- 10.57** PbI₂ has $K_{sp} = 7.9 \times 10^{-9}$ at 25 °C. Calculate the molar solubility of PbI₂ at 25 °C in each of the following. **L04**
- 0.200 mol L^{-1} Pb(NO₃)₂(aq) solution
 - 0.200 mol L^{-1} MgI₂(aq) solution
- 10.58** For Mg(OH)₂, $K_{sp} = 7.1 \times 10^{-12}$ at 25 °C. What is the molar solubility of Mg(OH)₂ in 0.20 mol L^{-1} NaOH at 25 °C? **L04**
- 10.59** Calculate the molar solubility of CaCO₃ in a 0.012 mol L^{-1} CaBr₂(aq) solution at 25 °C. **L04**
- 10.60** Calculate the molar solubility of SrSO₄ in a 0.025 mol L^{-1} Na₂SO₄ solution at 25 °C. **L04**
- 10.61** What mass of Fe(OH)₂ would be formed if 2.75 g of NaOH(s) was added to 200 mL of 0.10 mol L^{-1} FeCl₂(aq) solution at 25 °C? What is the molar concentration of Fe²⁺ in the final solution? **L04**
- 10.62** Calculate the mass, in grams, of Zn(OH)₂(s) that would be formed if 1.75 g of NaOH(s) was added to 250 mL of a solution of 0.10 mol L^{-1} ZnCl₂ at 25 °C. **L04**
- 10.63** Does a precipitate of PbCl₂ form when 0.0150 mol of Pb(NO₃)₂ and 0.0120 mol of NaCl are dissolved in 1.00 L of solution at 25 °C? **L05**
- 10.64** Silver acetate, AgOOCCH₃, has $K_{sp} = 2.3 \times 10^{-3}$ at 25 °C. Determine if a precipitate will form when 0.028 mol of AgNO₃ and 0.31 mol of Ca(OOCCH₃)₂ are dissolved in a total volume of 1.00 L of solution at 25 °C. **L05**
- 10.65** Does a precipitate of PbBr₂ form if 50.0 mL of $0.0100 \text{ mol L}^{-1}$ Pb(NO₃)₂ is mixed with the following? **L04**
- 50.0 mL of $0.0100 \text{ mol L}^{-1}$ KBr at 25 °C
 - 50.0 mL of 0.100 mol L^{-1} NaBr at 25 °C
- 10.66** Does a precipitate of barium sulfate, BaSO₄, form if 17.5 mL of 0.100 mol L^{-1} Ba(NO₃)₂(aq) is added to 42.7 mL of $0.0310 \text{ mol L}^{-1}$ Na₂SO₄(aq) at 25 °C? (BaSO₄ has $K_{sp} = 1.1 \times 10^{-10}$ at 25 °C.) **L04**
- 10.67** Determine the molality of a 3.000 mol L^{-1} aqueous solution of NaCl that has a density of 1.07 g mL^{-1} . **L05**
- 10.68** What is the molality of a 0.104 mol L^{-1} solution of acetic acid, CH₃COOH, that has a density of 1.00 g mL^{-1} ? **L05**
- 10.69** Calculate the molal concentration of sucrose, C₁₂H₂₂O₁₁, in a solution made by dissolving 50.0 g of sucrose in 1.00 kg of water. What is the mole fraction of sucrose in the solution? **L05**
- 10.70** An aqueous solution of propan-2-ol, CH₃CH(OH)CH₃ has a mole fraction of alcohol equal to 0.194. What is the molality of the alcohol? **L05**
- 10.71** An aqueous solution of NaNO₃ has a molality of $0.363 \text{ mol kg}^{-1}$ and a density of 1.0185 g mL^{-1} . Calculate the molar concentration of NaNO₃ and mole fraction of NaNO₃ in the solution. **L05**
- 10.72** The vapour pressure of water is $3.13 \times 10^3 \text{ Pa}$ at 25 °C. What is the vapour pressure of a solution prepared by dissolving 33.0 g of the nonvolatile solute C₆H₁₂O₆ in 225 g of water? Assume the solution is ideal. **L05**
- 10.73** A solution is prepared by mixing 45.0 g of benzene and 35.0 g of toluene at 25 °C. Assuming this solution obeys Raoult's law, calculate the pressure at which this solution will boil. The vapour pressures of benzene (C₆H₆), and toluene (C₇H₈), are 1.23×10^4 and $3.54 \times 10^3 \text{ Pa}$ respectively, at 25 °C. **L05**
- 10.74** Pentane, C₅H₁₂, (density = 0.626 g mL^{-1}) and heptane, C₇H₁₆, (density = 0.684 g mL^{-1}) are two liquid hydrocarbons present in petrol. At 20 °C, the vapour pressure of pentane is $5.53 \times 10^4 \text{ Pa}$ and the vapour pressure of heptane is $4.74 \times 10^3 \text{ Pa}$. If equal volumes of the two liquids are mixed, what is the total vapour pressure of the resulting solution? **L05**
- 10.75** The vapour pressure of pure methanol, CH₃OH, is $2.11 \times 10^4 \text{ Pa}$ at 30 °C. What mass of the nonvolatile solute glucose, C₆H₁₂O₆, must be added to 100 g of methanol to obtain a solution with a vapour pressure of $1.95 \times 10^4 \text{ Pa}$ at this temperature? **L05**
- 10.76** A solution containing 6.8 g of a nonvolatile, nondissociating substance dissolved in 1 mol of chloroform, CHCl₃, has a vapour pressure of $6.78 \times 10^4 \text{ Pa}$. The vapour pressure of pure CHCl₃ at the same temperature is $6.92 \times 10^4 \text{ Pa}$. Calculate the following. **L05**
- the mole fraction of the solute
 - the amount of solute in the solution
 - the molar mass of the solute
- 10.77** At 21.0 °C, a solution of 18.26 g of a nonvolatile, non-polar compound dissolved in 33.25 g of bromoethane, CH₃CH₂Br, has a vapour pressure of $4.42 \times 10^4 \text{ Pa}$. The vapour pressure of pure bromoethane at this temperature is $5.26 \times 10^4 \text{ Pa}$. What is the molar mass of the compound? **L05**
- 10.78** The sugar in ice-cream lowers the freezing point of the mixture and can make it difficult to keep ice-cream frozen hard. Estimate the boiling and freezing points of a 2.50 mol kg^{-1} solution of sugar in water. **L05**
- 10.79** A solution contains 52.7 g of the nonvolatile liquid glycerol, HOCH₂CH(OH)CH₂OH, dissolved in 250 g of water. Calculate the approximate freezing point of the solution and the boiling point of the solution. **L05**
- 10.80** What mass of urea, NH₂CONH₂, is required to lower the freezing point of 100 g of water by 2.50 °C? **L05**

- 10.81** What is the boiling point of the solution described in problem 10.80? **L05**
- 10.82** A solution containing 15.00 g of an unknown nondissociating compound dissolved in 235.0 g of benzene freezes at 2.93 °C. Calculate the molar mass of the unknown compound, given that the normal freezing point of benzene is 5.45 °C. **L05**
- 10.83** A solution of 75.0 g of a nonvolatile, nondissociating compound in 1.00 kg of benzene boils at 81.7 °C. Calculate the molar mass of the unknown compound, given that the normal boiling point of benzene is 80.1 °C. **L05**
- 10.84** When 7.76 g of a nondissociating molecular compound was dissolved in 1000 g of benzene, the resulting solution displayed a freezing point depression of 0.307 °C. If the empirical formula of the compound is C_4H_2N , what are its molar mass and molecular formula? **L05**
- 10.85** The osmotic pressure of an aqueous solution of a compound having a concentration of 1.80 g L^{-1} at 25 °C was 2.94 Pa. Calculate the molar mass of the compound. **L05**
- 10.86** In order to characterise a particular polymer, a saturated solution of 0.500 g of the polymer in 1.00 L of water was prepared. This solution was found to have an osmotic pressure of 3.58×10^2 Pa at 25 °C. What is the approximate molar mass of the polymer? **L05**
- 10.87** The vapour pressure of water at 20 °C is 2.30×10^3 Pa. Calculate the vapour pressure at 20 °C of a solution made by dissolving 5.00 g of NaCl in 75.0 g of water. Assume that the solute dissociates completely to give an ideal solution. **L05**
- 10.88** Calculate the mass of $MgCl_2$ that would have to be dissolved in 200 mL of water to give a solution that has a vapour pressure of 5.24×10^3 Pa at 35 °C. Assume that $MgCl_2$ dissociates completely in water and that the resulting solution exhibits ideal behaviour. At 35 °C, the vapour pressure of pure water is 5.55×10^3 Pa. **L05**
- 10.89** Below are the concentrations of the most abundant ions in sea water. **L05**

Ion	Molality (mol kg^{-1})
chloride	0.566
sodium	0.486
magnesium	0.055
sulfate	0.029
calcium	0.011
potassium	0.011
hydrogen carbonate	0.002

Use these data to estimate the osmotic pressure of sea water at 25 °C. What is the minimum pressure needed to desalinate sea water by reverse osmosis?

- 10.90** What is the expected freezing point of a 0.20 mol kg^{-1} solution of $CaCl_2$? (Assume complete dissociation.) **L05**
- 10.91** A 0.050 mol kg^{-1} aqueous solution of mercury(I) nitrate has a freezing point of approximately -0.27 °C. Show how this suggests that the formula of the mercury(I) ion is Hg_2^{2+} . **L05**
- 10.92** A 1.00 mol kg^{-1} aqueous solution of HF freezes at -1.91 °C. What is the percentage ionisation of HF in the solution? **L05**
- 10.93** Calculate the percentage ionisation of a weak electrolyte HX if an aqueous solution of HX of molality 0.106 mol kg^{-1} has a freezing point of -0.212 °C. **L05**
- 10.94** The van't Hoff factor for the solute in 0.100 mol kg^{-1} $NiSO_4(aq)$ is 1.19. What would this factor be if the solution behaved as if it were 100% dissociated? **L05**
- 10.95** What is the expected van't Hoff factor for $Al_2(SO_4)_3$ in an aqueous solution, assuming 100% dissociation? **L05**
- 10.96** A 0.118 mol kg^{-1} solution of LiCl has a freezing point of -0.415 °C. What is the van't Hoff factor for this solute at this concentration? **L05**
- 10.97** Use the data in problem 10.96 to calculate the approximate osmotic pressure of a 0.118 mol kg^{-1} solution of LiCl at 20 °C. **L05**

ADDITIONAL EXERCISES

- 10.98** The 'bends' is a medical emergency caused when a scuba diver rises too quickly to the surface from a deep dive. The origin of the problem can be illustrated by the results of the calculations in this question. At 37 °C (normal body temperature), the solubility of N_2 in water is 0.015 g L^{-1} when its pressure over the solution is 1.0×10^5 Pa. Air is approximately 78 mol% N_2 . **L04**
- (a) What amount of N_2 is dissolved per litre of blood (essentially an aqueous solution) when a diver inhales air at a pressure of 1.0×10^5 Pa?
- (b) What amount of N_2 dissolves per litre of blood when the diver is submerged to a depth of approximately 30 m, where the total pressure of the air being breathed is 4.0×10^5 Pa?

- (c) If the diver surfaces quickly, what volume of N_2 gas (in mL), in the form of tiny bubbles, is released into the bloodstream from each litre of blood (at 37 °C and 1.0×10^5 Pa)?

- 10.99** Deep-sea divers sometimes substitute helium for nitrogen in the air that they carry in their tanks to prevent the 'bends', because helium is much less soluble in blood than nitrogen. Use the simple molecular model of gas solubility discussed in figure 10.4 to explain why helium is relatively insoluble in blood, which is mainly water. **L02**
- 10.100** In this chapter, we stated that in a sample of any gas, the gas atoms or molecules are far apart. Given that a helium atom has a radius of 31 pm, if we introduced 1.00 mol of $He(g)$ into an evacuated vessel having a volume of 24.5 L (the molar volume of a gas at 298 K and 1.013×10^5 Pa),

- what proportion of the volume of the container would be empty space? **L02**
- 10.101** The vapour pressure of a mixture of 250 g of carbon tetrachloromethane, CCl_4 , and 28.9 g of an unknown compound is $1.82 \times 10^4 \text{ Pa}$ at 30°C . The vapour pressure of pure tetrachloromethane at 30°C is $1.88 \times 10^4 \text{ Pa}$, while that of the pure unknown is $1.39 \times 10^4 \text{ Pa}$. What is the approximate molar mass of the unknown? **L05**
- 10.102** Benzene reacts with hot concentrated nitric acid dissolved in sulfuric acid to give chiefly nitrobenzene, $\text{C}_6\text{H}_5\text{NO}_2$. A by-product is often obtained, which comprises 42.86% C, 2.40% H and 16.67% N (by mass). The boiling point of a solution of 5.5 g of the by-product in 45 g of benzene was 1.84°C higher than that of benzene. **L05**
- (a) Calculate the empirical formula of the by-product.
(b) Calculate the molar mass of the by-product and determine its molecular formula.
- 10.103** Excess solid $\text{Mn}(\text{OH})_2$ is added to a solution of $0.100 \text{ mol L}^{-1} \text{ FeCl}_2$. After reaction, what are the molar concentrations of Mn^{2+} and Fe^{2+} in the solution? (For $\text{Mn}(\text{OH})_2$, $K_{\text{sp}} = 1.6 \times 10^{-13}$.) **L04**
- 10.104** Suppose that 50.0 mL of $0.12 \text{ mol L}^{-1} \text{ AgNO}_3$ is added to 50.0 mL of $0.048 \text{ mol L}^{-1} \text{ NaCl}$ solution. **L04**
- (a) What mass of AgCl forms?
(b) Calculate the final concentrations of all of the ions in the solution that is in contact with the precipitate.
(c) What percentage of the Ag^+ ions precipitate?
- 10.105** The high concentration of Ca^{2+} ions in hard water makes it difficult for soap and shampoos to lather properly. A sample of hard water was found to have 244 ppm (parts per million on a weight per volume ratio) Ca^{2+} ions. A 1.25 g sample of K_2CO_3 was dissolved in 1.00 L of this water. What is the new concentration of Ca^{2+} in ppm? (Assume that the addition of K_2CO_3 does not change the volume, and assume that the densities of the aqueous solutions involved are all 1.00 g mL^{-1} .) **L05**
- 10.106** In problem 10.38, we calculated the enthalpy of solution, $\Delta_{\text{sol}}H$, of $\text{LiCl}(\text{s})$. Suppose the lattice enthalpy of LiCl was just 2% greater than the value given in table 10.2. What then would be the calculated $\Delta_{\text{sol}}H$ of $\text{LiCl}(\text{s})$? How would this new value of $\Delta_{\text{sol}}H$ compare with that given in the table? By what percentage is the new value different from the value in the table? (The aim of this calculation is to show that small percentage errors in two large numbers, such as lattice enthalpy and hydration enthalpy, can cause large percentage changes in the absolute difference between them.) **L03**
- 10.107** The osmotic pressure of a dilute solution of a slightly soluble polymer in water was measured using the osmometer in figure 10.27. The difference in height of the liquid levels was 1.17 cm at 25°C . Assume the solution has a density of 1.00 g mL^{-1} . **L05**
- (a) What is the osmotic pressure of the solution?
(b) What is the molarity of the solution?
(c) At what temperature would the solution freeze?
(d) Use your answers to (a)–(c) to explain why freezing point depression cannot be used to determine the molar masses of compounds composed of very large molecules.
- 10.108** Consider an aqueous 1.00 mol kg^{-1} solution of Na_3PO_4 , a compound with useful detergent properties. Calculate the boiling point of the solution assuming the following. **L05**
- (a) It does not ionise at all in solution.
(b) The van't Hoff factor for Na_3PO_4 reflects 100% dissociation into its ions.
The 1.00 mol kg^{-1} solution boils at 100.83°C at $1.0 \times 10^5 \text{ Pa}$.
(c) Calculate the van't Hoff factor for the solute in this solution.
- 10.109** In an aqueous solution of KNO_3 , the concentration is 0.9159 mol% of the salt. The solution's density is 1.0489 g mL^{-1} . Calculate the following. **L05**
- (a) molal concentration of KNO_3
(b) percentage (w/w) of KNO_3
(c) molarity of the KNO_3 in the solution
- 10.110** It was found that the molar solubility of BaSO_3 in $0.10 \text{ mol L}^{-1} \text{ BaCl}_2$ is $8.0 \times 10^{-6} \text{ mol L}^{-1}$. What is the value of K_{sp} for BaSO_3 ? **L04**
- 10.111** Both AgCl and AgI are very slightly soluble salts, but the solubility of AgI is much less than that of AgCl , as can be seen by their K_{sp} values. Suppose that a solution contains both Cl^- and I^- with $[\text{Cl}^-] = 0.050 \text{ mol L}^{-1}$ and $[\text{I}^-] = 0.050 \text{ mol L}^{-1}$ at 25°C . If solid AgNO_3 is added to 1.00 L of this mixture (so that no appreciable change in volume occurs), what is the value of $[\text{I}^-]$ when AgCl first begins to precipitate? **L05**
- 10.112** Some tables of K_{sp} values on the internet list extremely small values; for example, K_{sp} for the red form of HgS is given as 2.0×10^{-54} , while that for yellow HgS is 2.0×10^{-53} . Why are these values unlikely to be correct? (Hint: Calculate the concentrations of Hg^{2+} and S^{2-} in the saturated solutions of each of these compounds.)

Acids and bases

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- 11.1 define acids and bases
- 11.2 identify acid–base reactions in water
- 11.3 perform calculations involving strong acids and bases
- 11.4 perform calculations involving weak acids and bases
- 11.5 explain the relationship between structure and acidity
- 11.6 perform calculations involving buffer solutions
- 11.7 analyse acid–base titrations
- 11.8 identify Lewis acids and bases.

Of all the planets and moons in our solar system, the Earth is the only one that has been found to support life as we know it. This is due to a combination of factors, including the distance from the sun, an atmosphere containing oxygen, and the presence of plentiful amounts of water that is neither too acidic nor too basic. For many years, it was wondered if life existed on Venus, our closest planetary neighbour, as it is about the same size as Earth and has an atmosphere. However, a number of probes have shown that, in addition to the enormous surface pressure (about 100 times that on Earth) and high surface temperature ($\sim 460^\circ\text{C}$), the upper atmosphere contains significant amounts of sulfuric acid, a strong, corrosive acid, inhalation of which would be fatal to any pioneering astronauts. Attention has therefore turned to Mars as a target for human exploration.

However, there are some forms of life on Earth, called acidophiles, which can exist, and indeed thrive, in highly acidic environments with pH values approaching 0. These are often found in geothermal areas in which the concentration of sulfur-containing compounds is high. One such acidophile is the alga *Cyanidium caldarium*, whose green colour is often seen around New Zealand's thermal areas. The presence of this alga is responsible for the green colour of the Waimangu Cauldron (figure 11.1), the world's largest hot spring, located in the central North Island of New Zealand. *Cyanidium caldarium* has managed to adapt to the highly acidic conditions by being able to pump acid out of its cells and using acid-resistant polysaccharide molecules to protect the cells from the acidic environment.

FIGURE 11.1

The colour of the water in the Waimangu Cauldron arises partly from the presence of the acidiphilic alga *Cyanidium caldarium*.

In this chapter, we will discuss a number of aspects of acids and bases. We will investigate the various definitions of acids and bases, show that there is an enormous range of acid and base strengths and that these can be rationalised on the basis of molecular structure, quantify Brønsted–Lowry acid and base behaviour using the concepts of pH, K_a and K_b , and study titrations of acids and bases.

11.1 The Brønsted–Lowry definition of acids and bases

LEARNING OBJECTIVE 11.1 Define acids and bases.

In the chapter on solutions and solubility, we looked at the nature of solutes and showed how freezing point depression measurements give us information about the degree of dissociation of a particular solute. Similar information can also be obtained by measurement of the conductivity of a solution, and this technique is both simpler to carry out and more sensitive than freezing point depression. It is effective because only solutions that contain ions will conduct an electric current. The magnitude of the electric current depends on the concentration and nature of the ions in the solution.

A high concentration of ions allows the passage of a larger current, and therefore gives a larger conductivity than a low concentration, while a pure solvent that contains no ions will have a conductivity of zero.

We tend to think of water as consisting solely of H_2O molecules. Each molecule comprises a central oxygen atom that is covalently bonded to two hydrogen atoms, and we might therefore expect that liquid water would have no ionic character. However, measurements show that pure water does exhibit a small conductivity, consistent with the presence of ions. (This is the reason you should be careful when using electrical appliances near water.) These ions arise from the reaction of water with itself, according to the following equation.

The net result of this reaction is the transfer of a proton (H^+ , a hydrogen atom minus an electron) from one molecule of water to another, and formation of the ionic species H_3O^+ (the **hydronium ion**) and OH^- (the **hydroxide ion**). Reactions such as this, which involve the transfer of a single proton from one species to another are called **acid–base reactions**. The reaction of water with itself represents arguably the simplest example of such a reaction. In this case, water acts as both an acid and a base.

The concept of acids and bases has been known for hundreds of years, but it is only relatively recently that definitions of the words ‘acid’ and ‘base’ have been agreed upon. The word acid derives from the Latin *acidus*, meaning sour; acids do indeed taste sour, but it is not a good idea to taste them in the laboratory. The word alkali, which is synonymous with base, comes from the Arabic *al-qaliy*, literally ‘the ashes’, referring to the ashes of the salt-wort plant that grows in alkaline soils. The first comprehensive theory concerning acids and bases appeared in 1884 in the PhD thesis of the Swedish chemist, Svante Arrhenius (1859–1927; Nobel Prize in chemistry, 1903; figure 11.2), who was nearly failed for proposing that ions could exist in solution. He defined an acid as a substance that released H^+ ions when dissolved in water, and a base as a substance that gave rise to OH^- ions on dissolution in water. This definition is similar to the more general **Brønsted–Lowry** definition of acids and bases, which we will use from this point. This was proposed by Johannes Brønsted, a Danish chemist, and Thomas Lowry, an English chemist, independently of each other in 1923. They considered that acid–base reactions involved proton (H^+) transfer between an acid and a base, which they defined as follows.

- An **acid** is a proton donor.
- A **base** is a proton acceptor.

FIGURE 11.2

Svante Arrhenius proposed the first comprehensive theory of acids and bases.

In other words, a Brønsted–Lowry acid will donate a proton to a Brønsted–Lowry base, which will accept it. From now on, we will refer to Brønsted–Lowry acids and bases simply as acids and bases. To illustrate the Brønsted–Lowry concept, let's return to the example involving water that we introduced previously. We stated that water acted as both an acid and a base, and we can now explain this with reference to the Brønsted–Lowry definition.

One water molecule acts as a proton donor, and is therefore an acid. This water molecule becomes OH^- on the right-hand side of the equation. The other water molecule accepts the donated proton, and therefore acts as a base. This water molecule is converted to H_3O^+ on the right-hand side of the equation. It is instructive to consider this reaction in terms of the structures shown in figure 11.3.

FIGURE 11.3 A mechanistic view of the acid–base reaction of one water molecule with another

In order for H_2O to act as an acid, it must, according to the Brønsted–Lowry definition, have a proton to donate. However, the mere presence of hydrogen atoms, which are potential protons, is not sufficient for a chemical species to act as an acid. For example, methane, CH_4 , contains four hydrogen atoms but shows essentially no acidic properties. For a hydrogen atom to be measurably acidic, it must be bound to another atom via an appreciably polar bond, and therefore acids tend to contain hydrogen atoms bound to group 16 or 17 elements. Figure 11.3 also shows that, for H_2O to act as a base and accept the donated proton, it must have a lone pair of electrons to which the donated proton can covalently bond. The presence of one or more lone pairs is a prerequisite for a species to act as a base, but not all species containing lone pairs act as bases; for example, the chloride ion, Cl^- , contains four lone pairs, but displays negligible basic properties. Bases usually contain group 15 or 16 elements, the atoms of which (especially group 16) are often deprotonated and hence negatively charged. Table 11.1 lists a number of common acids and bases that would be found in any chemistry laboratory. You can see that the acids contain a very polar $\text{H}—\text{X}$ bond, while the bases contain N and deprotonated O atoms with one and three lone pairs, respectively.

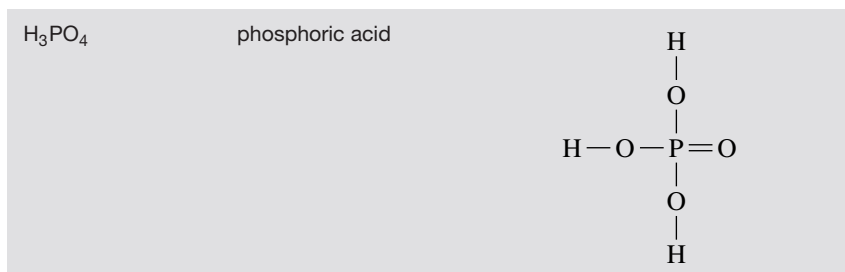

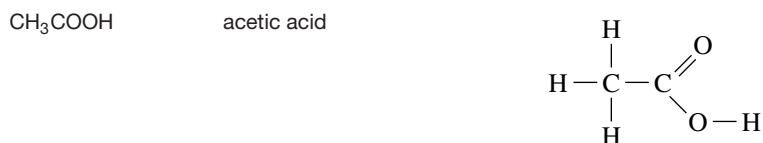

It can be seen from the structures of the acids in table 11.1 that, in some cases, there is more than one very polar $\text{H}—\text{X}$ bond, and these acids can donate more than one proton. Such acids are collectively called **polyprotic acids**. Hydrochloric acid, nitric acid and acetic acid, each of which can donate only one proton, are examples of **monoprotic acids**. Sulfuric acid can donate two protons and is called a **diprotic acid** whereas phosphoric acid, which can donate three protons, is a **triprotic acid**.

Similarly, some bases can accept more than one proton and are collectively called **polyprotic bases**. Hydroxide ion, ammonia and pyridine are examples of **monoprotic bases**, whereas carbonate ion is a **diprotic base**.

Note that the commonly used chemical formulae for some acids can be deceiving in terms of their actual structures. For example, the chemical formula of nitric acid is generally written as HNO_3 , which might imply that the H atom is bonded to the N atom, but, as you can see in table 11.1, this is not the case, and a more descriptive representation, which shows the H atom bonded to an O atom, would be HONO_2 . Similar alternative structures can be drawn for sulfuric acid, $(\text{HO})_2\text{SO}_2$, and phosphoric acid, $(\text{HO})_3\text{PO}$.

TABLE 11.1 Some common acids and bases

Formula	Name	Structure
Acids		
HCl	hydrochloric acid ^(a)	$\text{H}—\text{Cl}:$
HNO_3	nitric acid	

Bases

(a) Pure HCl is a gas at room temperature, and is called hydrogen chloride. Hydrochloric acid refers to a solution of HCl in water.

(b) Pure NH_3 is a gas at room temperature. In the laboratory, it is often used as an aqueous solution.

We now consider the reactions that occur when we place an acid or a base in water. We begin by using a chemical equation and a mechanistic diagram to see what happens when we dissolve gaseous hydrogen chloride in water.

Here, HCl is the acid and H_2O is the base. HCl donates a proton to H_2O , thereby becoming Cl^- , while H_2O , on accepting the proton, becomes H_3O^+ , the hydronium ion. This reaction goes essentially to completion and we say that HCl dissociates completely in aqueous solution.

Similarly, if we dissolve gaseous ammonia, NH_3 , in water, the following reaction occurs.

In this reaction, H_2O acts as an acid, donating a proton to NH_3 and thus becoming OH^- , while NH_3 acts as a base by accepting the proton from H_2O to give NH_4^+ . However, this reaction differs from that for HCl in that it proceeds almost negligibly in the forward direction, and the reaction of ammonia with water is therefore far from complete. Note that water, the solvent in both reactions, acts as a base in the former reaction and an acid in the latter; compounds such as this that can act as either an acid or a base are called **amphiprotic**.

Conjugate acid–base pairs

It is informative to write the reverse equations for the reactions of HCl and NH_3 with water.

We can see that the reverse reactions also involve transfer of a proton, and are therefore themselves acid–base reactions. In the reaction:

H_3O^+ acts as an acid, donating a proton to Cl^- , which acts as a base by accepting it. However, this reaction proceeds almost imperceptibly in the forward direction; we will see why later in this chapter. Similarly, in the reaction:

NH_4^+ acts as an acid, donating a proton to the base OH^- . This illustrates a general feature of all Brønsted–Lowry acid–base reactions: *both the forward and reverse reactions are acid–base reactions*. Furthermore, there are always two sets of species on either side of the equation that differ only by a proton, and we call these **conjugate acid–base pairs**. In the following reaction, both HCl and Cl^- , and H_2O and H_3O^+ differ only by a proton.

We showed that HCl acts as an acid in the forward reaction and Cl^- acts as a base in the reverse reaction. Therefore, Cl^- is the **conjugate base** of HCl , and HCl is the conjugate acid of Cl^- . Using the same reasoning, we can see that H_2O is the conjugate base of H_3O^+ , and H_3O^+ is the conjugate acid of H_2O .

As both the forward and reverse reactions are acid–base reactions, and occur to some extent, it is usual to write acid–base reactions as equilibria. We will look at how we quantify these equilibria later in this chapter.

WORKED EXAMPLE 11.1**Determining the conjugate bases of Brønsted–Lowry acids**

What are the conjugate bases of nitric acid, HNO_3 , and the hydrogen sulfate ion, HSO_4^- ?

Analysis

The members of a conjugate acid–base pair differ by one proton, with the acid having the greater number of protons. To find the formula of the base, we remove one proton from the acid.

Solution

Removing one proton from HNO_3 leaves NO_3^- . The nitrate ion, NO_3^- , is thus the conjugate base of HNO_3 . Removing a proton from HSO_4^- leaves its conjugate base, SO_4^{2-} .

Is our answer reasonable?

As a check, we can compare the two formulae in each pair.

In each case, the formula on the right has one fewer proton than the formula on the left, so it is the conjugate base. We have answered the question correctly.

PRACTICE EXERCISE 11.1

- Write the formula of the conjugate base of each of the following Brønsted–Lowry acids.
 (a) H_2SO_4 (b) HOCl (c) H_3O^+
 (d) CH_3COOH (e) H_2PO_4^- (f) HI
- Write the formula of the conjugate acid of each of the following Brønsted–Lowry bases.
 (a) NO_3^- (b) Br^- (c) OH^-
 (d) ClO_4^- (e) CN^- (f) SO_3^{2-}

WORKED EXAMPLE 11.2**Identifying conjugate acid–base pairs in a Brønsted–Lowry acid–base reaction**

The sodium hydrogen sulfate ion, HSO_4^- , reacts with the phosphate ion, PO_4^{3-} as shown in the equation below. Identify the two conjugate acid–base pairs.

**Analysis**

There are two things that help us to identify the conjugate acid–base pairs in an equation. One is that the members of a conjugate pair differ by a proton. The second is that the members of each pair must be on opposite sides of the reaction arrow. In each pair, the acid has the larger number of protons.

Solution

Two of the formulae in the equation contain PO_4 , so they must belong to the same conjugate pair. The one with the

most protons, HPO_4^{2-} , is the acid, and the other, PO_4^{3-} , is the base. Therefore, one conjugate acid–base pair is HPO_4^{2-} and PO_4^{3-} . The other two ions, HSO_4^- and SO_4^{2-} , belong to the second conjugate acid–base pair; HSO_4^- is the conjugate acid and SO_4^{2-} is the conjugate base.

**Is our answer reasonable?**

A check satisfies us that we have fulfilled the requirements that each conjugate pair has one member on each side of the arrow and that the members of each pair differ from each other by one (and only one) proton.

PRACTICE EXERCISE 11.2

One type of baking powder contains sodium bicarbonate and calcium dihydrogen phosphate. When water is added, the following reaction occurs.

Identify the two acids and the two bases in this reaction. (The H_2CO_3 decomposes to release CO_2 , which causes the cake to rise.)

11.2 Acid–base reactions in water

LEARNING OBJECTIVE 11.2 Identify acid–base reactions in water.

In many of the examples we have considered so far, water has acted as both the solvent, and either the acid or the base. However, acid–base reactions can occur in any solvent, and can even occur in the absence of solvent, as shown in figure 11.4.

As each gas escapes from its concentrated aqueous solution and mingles with the other, a cloud of tiny crystals of $\text{NH}_4\text{Cl}(\text{s})$ forms above the bottles. The product of this reaction, $\text{NH}_4\text{Cl}(\text{s})$, comprises NH_4^+ , the conjugate acid of NH_3 , and Cl^- , the conjugate base of HCl .

This is also a proton transfer reaction, in which gaseous HCl donates a proton to gaseous NH_3 , as shown in the mechanistic diagram.

Given that most acid–base reactions of interest occur in aqueous solution, we will concentrate on water as the solvent for the majority of our discussions.

The autoprotolysis of water

We have shown that water can react with itself to generate hydronium and hydroxide ions according to the following equation.

This reaction, in which a proton is transferred between identical molecules, is called **autoprotolysis** (sometimes called autoionisation). The extent of the autoprotolysis of water can be determined using the equilibrium constant for this process. Using the methods developed in the chapter on chemical equilibrium, and remembering that pure liquids do not appear in an equilibrium constant expression, we write the equilibrium constant for the equilibrium as shown below.

$$K_w = [\text{H}_3\text{O}^+][\text{OH}^-] = 1.0 \times 10^{-14} \quad (T = 25.0^\circ\text{C})$$

Recall from the chapter on chemical equilibrium that the concentration terms in equilibrium constant expressions are implicitly divided by $c^\ominus$ and therefore equilibrium constants are dimensionless.

The extraordinary importance of this equilibrium means that the equilibrium constant is given the special symbol K_w and is called the **autoprotolysis constant of water**. Its very small value shows that the autoprotolysis of water proceeds only to a very small extent and that the equilibrium concentrations of H_3O^+ and OH^- in pure water are small. We can calculate just how small by using the value of K_w and realising from the stoichiometry of the reaction that the equilibrium concentrations of H_3O^+ and OH^- in pure water must be the same.

$$K_w = 1.0 \times 10^{-14} = [\text{H}_3\text{O}^+][\text{OH}^-]$$

As $[\text{H}_3\text{O}^+] = [\text{OH}^-]$ in pure water, we can write the following.

$$[\text{H}_3\text{O}^+] = [\text{OH}^-] = \sqrt{1.0 \times 10^{-14}} = 1.0 \times 10^{-7} \text{ mol L}^{-1}$$

Therefore, $[\text{H}_3\text{O}^+]$ and $[\text{OH}^-]$ in pure water at 25.0°C are both $1.0 \times 10^{-7} \text{ mol L}^{-1}$.

FIGURE 11.4 The reaction of gaseous HCl with gaseous NH_3 .

Like most equilibrium constants, the value of K_w is temperature dependent and increases as the temperature increases. For example, at 40.0 °C, $K_w = 3.0 \times 10^{-14}$ and pure water at this temperature has $[\text{H}_3\text{O}^+] = [\text{OH}^-] = 1.7 \times 10^{-7} \text{ mol L}^{-1}$. Table 11.2 lists values of K_w at a number of temperatures.

TABLE 11.2 K_w at various temperatures

Temperature (°C)	K_w
0	1.5×10^{-15}
10	3.0×10^{-15}
20	6.8×10^{-15}
25	1.0×10^{-14}
30	1.5×10^{-14}
40	3.0×10^{-14}
50	5.5×10^{-14}
60	9.5×10^{-14}

We say that pure water is **neutral**, because it contains equal concentrations of H_3O^+ and OH^- . Aqueous solutions in which $[\text{H}_3\text{O}^+] > [\text{OH}^-]$ are termed **acidic**, whereas aqueous solutions in which $[\text{H}_3\text{O}^+] < [\text{OH}^-]$ are termed **basic** (or **alkaline**). There is an inverse relationship between $[\text{H}_3\text{O}^+]$ and $[\text{OH}^-]$ in aqueous solution at constant temperature; as one increases, the other must decrease in order to keep K_w constant. If we know the value of only one of $[\text{H}_3\text{O}^+]$ or $[\text{OH}^-]$ in a solution, we can use K_w to calculate the other, as illustrated in worked example 11.3.

WORKED EXAMPLE 11.3

Finding $[\text{H}_3\text{O}^+]$ from $[\text{OH}^-]$ or $[\text{OH}^-]$ from $[\text{H}_3\text{O}^+]$

In a sample of blood at 25 °C, $[\text{H}_3\text{O}^+] = 4.6 \times 10^{-8} \text{ mol L}^{-1}$. Find $[\text{OH}^-]$ and decide if the sample is acidic, basic or neutral.

Analysis

We know that the values of $[\text{H}_3\text{O}^+]$ and $[\text{OH}^-]$ are related to each other through K_w at 25 °C as follows.

$$[\text{H}_3\text{O}^+][\text{OH}^-] = 1.0 \times 10^{-14}$$

If we know one concentration, we can always find the other.

Solution

We substitute the given value of $[\text{H}_3\text{O}^+]$ into this equation and solve for $[\text{OH}^-]$.

$$1.0 \times 10^{-14} = (4.6 \times 10^{-8})[\text{OH}^-]$$

Solve for $[\text{OH}^-]$. Remember to include its units — mol L^{-1} or M.

$$[\text{OH}^-] = \frac{1.0 \times 10^{-14}}{4.6 \times 10^{-8}} \text{ mol L}^{-1} = 2.2 \times 10^{-7} \text{ mol L}^{-1}$$

When we compare a $[\text{H}_3\text{O}^+]$ of $4.6 \times 10^{-8} \text{ mol L}^{-1}$ with a $[\text{OH}^-]$ of $2.2 \times 10^{-7} \text{ mol L}^{-1}$, we see that $[\text{OH}^-] > [\text{H}_3\text{O}^+]$. Our answer, then, is that the blood is slightly basic.

Is our answer reasonable?

We know $K_w = 1.0 \times 10^{-14} = [\text{H}_3\text{O}^+][\text{OH}^-]$. So one check is to note that, if $[\text{H}_3\text{O}^+]$ is slightly *less* than $1 \times 10^{-7} \text{ mol L}^{-1}$, $[\text{OH}^-]$ will be slightly *greater* than $1 \times 10^{-7} \text{ mol L}^{-1}$, as it is.

PRACTICE EXERCISE 11.3

A sample of rainwater was found to have $[\text{OH}^-] = 2.6 \times 10^{-9} \text{ mol L}^{-1}$. What is $[\text{H}_3\text{O}^+]$? Is the solution acidic, basic or neutral?

The concept of pH

As we have seen previously, the concentrations of H_3O^+ and OH^- in pure water are very small, and the same is often true of $[\text{H}_3\text{O}^+]$ and $[\text{OH}^-]$ in aqueous solutions of acids and bases. To avoid working with such inconveniently small numbers, we commonly express $[\text{H}_3\text{O}^+]$ in terms of the **pH** of the solution. This approach was developed by the Danish chemist Søren Sørensen (1868–1939) in 1909. pH is defined as the negative logarithm of the concentration of H_3O^+ in a solution, or, in equation form as shown.

$$\text{pH} = -\log[\text{H}_3\text{O}^+]$$

We can also define the **pOH** of a solution as follows.

$$\text{pOH} = -\log[\text{OH}^-]$$

In both cases, p is simply an abbreviation for ‘ $-\log$ ’ (p is derived from the German word *Potenz* meaning ‘power’). Here, log means $\log_{10}$, rather than natural logarithm ($\ln$ or $\log_e$). It is vital that you appreciate the difference between the two types of logarithms; for example, $\log(1 \times 10^2) = 2$, whereas $\ln(1 \times 10^2) \approx 4.605$. You should also ensure that you know under which circumstances the different types of logarithms are used; you generally use log only in calculations involving pH or (as we will see) $\text{p}K_{\text{a}}$.

Having shown that $[\text{H}_3\text{O}^+] = 1.0 \times 10^{-7} \text{ mol L}^{-1}$ in pure water at 25.0°C , we can now calculate the pH of pure water under these conditions.

$$\text{pH} = -\log[\text{H}_3\text{O}^+] = -\log(1.0 \times 10^{-7}) = 7.00$$

There are two things to note here. Firstly, you cannot take the logarithm of a quantity that has units, and therefore we must either implicitly drop the concentration units of $[\text{H}_3\text{O}^+]$ before taking the logarithm or treat the term $[\text{H}_3\text{O}^+]$ as being the dimensionless quantity $\frac{[\text{H}_3\text{O}^+]}{c^\ominus}$, as we did in similar situations in the chapter on chemical equilibrium. Secondly, the number of decimal places in a logarithm of any number is equal to the number of significant figures in that number. Thus, our pH is given to two decimal places, 7.00.

The fact that pure water has a pH of 7 at 25.0°C is probably a familiar result to many of you. Not so familiar perhaps is the pOH of pure water at 25.0°C . Again, we have shown that $[\text{OH}^-] = 1.0 \times 10^{-7} \text{ mol L}^{-1}$ under these conditions and therefore:

$$\text{pOH} = -\log[\text{OH}^-] = -\log(1.0 \times 10^{-7}) = 7.00$$

In both cases, you can see that it is much more convenient to write 7.00 than 1.0×10^{-7} (or indeed 0.000 000 10).

We have shown previously that solutions with $[\text{H}_3\text{O}^+] > [\text{OH}^-]$ are acidic, while those with $[\text{H}_3\text{O}^+] < [\text{OH}^-]$ are basic. This means that (at 25.0°C) solutions with $\text{pH} < 7$ are acidic, and those with $\text{pH} > 7$ are basic (or alkaline).

It is important that you are proficient in dealing with logarithms on your calculator and are able to convert from $[\text{H}_3\text{O}^+]$ to pH and from pH to $[\text{H}_3\text{O}^+]$. The latter involves taking the antilogarithm of the *negative* of the pH, that is, $[\text{H}_3\text{O}^+] = 10^{-\text{pH}}$.

A simple relationship between pH and pOH can be derived, starting from the K_{w} expression. To do this, we make use of the property of logarithms which says that the logarithm of the product of two numbers is equal to the sum of the logarithms of those numbers, that is, $\log(ab) = \log(a) + \log(b)$.

We know that $[\text{H}_3\text{O}^+][\text{OH}^-] = K_{\text{w}}$. If we now take the negative logarithm of both sides, we obtain:

$$-\log[\text{H}_3\text{O}^+] + -\log[\text{OH}^-] = -\log K_{\text{w}}$$

but:

$$-\log[\text{H}_3\text{O}^+] = \text{pH}, \quad -\log[\text{OH}^-] = \text{pOH} \quad \text{and} \quad -\log K_{\text{w}} = \text{p}K_{\text{w}}$$

Therefore:

$$\text{pH} + \text{pOH} = \text{p}K_{\text{w}}$$

where $\text{p}K_{\text{w}}$ is the negative logarithm of K_{w} . At 25.0°C , $K_{\text{w}} = 1.0 \times 10^{-14}$ and therefore this becomes:

$$\text{pH} + \text{pOH} = 14 \text{ (at } 25.0^\circ\text{C)}$$

Note that this equation applies only at 25.0°C and we will assume this temperature in calculations throughout this chapter. Because pH and pOH are related by such a simple expression, it is usual to talk almost exclusively in terms of the pH of a solution, and pOH is rarely used.

It should be noted that our definition of pH below is an approximation.

$$\text{pH} = -\log[\text{H}_3\text{O}^+]$$

The exact definition involves the use of activity (a) rather than concentration, and is written as shown.

$$\text{pH} = -\log a_{\text{H}_3\text{O}^+}$$

However, provided that we work under dilute conditions, concentration is an acceptable approximation to activity, and we will use the equation $\text{pH} = -\log[\text{H}_3\text{O}^+]$ throughout the rest of the text.

Worked examples 11.4, 11.5 and 11.6 illustrate the types of problems you may encounter concerning the manipulations of pH, pOH, $[\text{H}_3\text{O}^+]$ and $[\text{OH}^-]$.

WORKED EXAMPLE 11.4

Calculating pH and pOH from $[\text{H}_3\text{O}^+]$

The dune lakes on K'gari (Fraser Island), off the Queensland coast of Australia, are appreciably acidic due to the presence of natural organic acids from plant material. The water in Boorangoora (Lake McKenzie; figure 11.5), the island's most acidic lake, was found to have an H_3O^+ concentration of $7.1 \times 10^{-5} \text{ mol L}^{-1}$ at 25°C . What are the pH and pOH values of the lake's water?

Analysis

If we know the value of $[\text{H}_3\text{O}^+]$, then we can use $\text{pH} = -\log[\text{H}_3\text{O}^+]$ to find the pH.

Solution

$$\text{pH} = -\log[\text{H}_3\text{O}^+]$$

We substitute $[\text{H}_3\text{O}^+] = 7.1 \times 10^{-5} \text{ mol L}^{-1}$, remembering to omit the units, into this expression to give the following.

$$\text{pH} = -\log(7.1 \times 10^{-5})$$

We first take the logarithm of this number and then take the negative of the logarithm. Using a calculator to find the logarithm of 7.1×10^{-5} gives the value -4.15 (note the negative sign). To find the pH, we change its algebraic sign.

$$\text{pH} = -(-4.15) = 4.15$$

Once we know the pH, the pOH is easily found by using the equation $\text{pH} + \text{pOH} = 14.00$ at 25°C . Therefore, the pOH of the lake water is as follows.

$$\text{pOH} = 14.00 - 4.15 = 9.85$$

Is our answer reasonable?

The value of $[\text{H}_3\text{O}^+]$ is between 1×10^{-5} and $1 \times 10^{-4} \text{ mol L}^{-1}$ so the pH has to be between 5 and 4 (the antilogarithms of 1×10^{-5} and 1×10^{-4} , respectively), which it is. Therefore, the pOH must be between 9 and 10, as it is.

FIGURE 11.5

Boorangoora, the most acidic lake on K'gari (Fraser Island), Queensland, Australia

PRACTICE EXERCISE 11.4

A sample of household bleach was found to have an H_3O^+ concentration of $3.98 \times 10^{-11} \text{ mol L}^{-1}$ at 25°C . What are the pH and pOH values of the sample? Is it acidic, basic or neutral?

WORKED EXAMPLE 11.5

Calculating pH from $[\text{OH}^-]$

The $[\text{OH}^-]$ in a sample of sea water at 25°C was found to be $1.4 \times 10^{-6} \text{ mol L}^{-1}$. What is the pH of the sea water?

Analysis

There are two ways to solve this problem, both of which are equally valid.

The two methods are:

- We could substitute the given value of $[\text{OH}^-]$ into the K_w expression $K_w = [\text{H}_3\text{O}^+][\text{OH}^-] = 1.0 \times 10^{-14}$ to find $[\text{H}_3\text{O}^+]$ and we would then calculate the pH using $\text{pH} = -\log [\text{H}_3\text{O}^+]$.
- We could use the given $[\text{OH}^-]$ to calculate the pOH using $\text{pOH} = -\log[\text{OH}^-]$ and then subtract the pOH from 14.00 to find the pH.

Both methods give the same answer, but the second path is probably easier, so let's proceed that way.

Solution

We use the equation:

$$\text{pOH} = -\log[\text{OH}^-]$$

Substituting $[\text{OH}^-] = 1.4 \times 10^{-6} \text{ mol L}^{-1}$ into this expression gives:

$$\text{pOH} = -\log(1.4 \times 10^{-6})$$

Taking the logarithm gives -5.85 . Therefore:

$$\text{pOH} = -(-5.85) = 5.85$$

Then we subtract this pOH value from 14.00 to find the pH.

$$\text{pH} = 14.00 - 5.85 = 8.15$$

As the pH is only just greater than 7, the sea water will be very slightly basic.

Is our answer reasonable?

The molar concentration of the hydroxide ion is between 1×10^{-6} and 1×10^{-5} , so the pOH must be between 6 and 5 (the antilogarithms of 1×10^{-6} and 1×10^{-5} , respectively) which it is. Thus, the pH should be between 8 ($=14 - 6$) and 9 ($=14 - 5$).

PRACTICE EXERCISE 11.5

The ammonia often found in household cleaning products leads to these being basic. A sample of one brand was found to have $[\text{OH}^-] = 2.14 \times 10^{-3} \text{ mol L}^{-1}$. What is the pH of the solution?

WORKED EXAMPLE 11.6

Calculating $[\text{H}_3\text{O}^+]$ from pH

'Calcareous soil' is soil rich in calcium carbonate and is particularly abundant along the south coast of Australia. The pH of the moisture in such soil generally ranges from just over 7 to as high as 8.3. After one particular soil sample was soaked in water, the pH of the water was measured to be 7.60. What value of $[\text{H}_3\text{O}^+]$ corresponds to a pH of 7.60? Is the soil acidic or basic?

Analysis

The equation we use to calculate $[\text{H}_3\text{O}^+]$ from pH is $[\text{H}_3\text{O}^+] = 10^{-\text{pH}}$.

Solution

We substitute the pH value, 7.60, into the equation above, which gives:

$$[\text{H}_3\text{O}^+] = 10^{-7.60}$$

We therefore need to calculate 10 to the power of -7.60 . The easiest way to do this on a calculator is to press the ' 10^x ' or ' $10^\square$ ' key and then enter -7.60 . (Note that, on some calculators, you may have to do these in the opposite order.) Because the pH has two digits following the decimal point, we obtain two significant figures in the H_3O^+ concentration. Therefore, the answer, correctly rounded, is as follows.

$$[\text{H}_3\text{O}^+] = 2.5 \times 10^{-8} \text{ mol L}^{-1}$$

Because $\text{pH} > 7$ and $[\text{H}_3\text{O}^+] < 1 \times 10^{-7} \text{ mol L}^{-1}$, the soil is basic.

Is our answer reasonable?

The given pH value of 7.60 is between 7 and 8, so the H_3O^+ concentration must lie between 10^{-7} and $10^{-8} \text{ mol L}^{-1}$, as we found.

PRACTICE EXERCISE 11.6

Find the values of $[\text{H}_3\text{O}^+]$ and $[\text{OH}^-]$ that correspond to each of the following pH values. State whether each solution is acidic or basic.

- 2.30 (the approximate pH of lemon juice)
- 6.30 (the approximate pH of milk)
- 10.81 (the pH of milk of magnesia, a laxative and an antacid)
- 3.50 (the pH of orange juice, on average)
- 11.61 (the pH of dilute, household ammonia)

The pH scale ranges from 0 to 14 for most practical applications, although negative values of pH can be obtained in very acidic solutions and pH values greater than 14 occur in concentrated aqueous bases. A 0.10 mol L^{-1} solution of HCl(aq) has a pH of 1.00, while a 0.10 mol L^{-1} solution of NaOH(aq) has a pH of 13.00. Figure 11.6 shows the pH values of some common aqueous solutions. Accurate pH values (± 0.01 pH units) can be easily determined with a pH meter, which uses a glass electrode that is sensitive to H_3O^+ ions (see figure 11.7). Less accurate values can be obtained using pH paper (figure 11.8), while blue and red litmus paper is used only in a qualitative manner to determine whether a solution is acidic or basic.

FIGURE 11.6 The pH scale

FIGURE 11.7

A pH meter has a special combination electrode that is sensitive to hydrogen ion concentration. After the instrument has been calibrated using solutions of known pH, the electrode is dipped into the solution to be tested and the pH is read from the meter. The pH meter detects the difference between the H_3O^+ concentrations in the tested solution and the solution inside the electrode as a voltage, which is then converted to a pH value.

FIGURE 11.8

A pH test paper. The colour of this Hydrión® test strip changed to green when a drop of orange juice was placed on it. According to the colour code, the pH of the juice is approximately 3.5.

The strength of acids and bases

We stated previously that the pH of a 0.10 mol L^{-1} solution of HCl(aq) is 1.00. This means that $[\text{H}_3\text{O}^+]$ in this solution is 0.10 mol L^{-1} and therefore implies that the forward reaction in the equilibrium proceeds to completion.

In other words, HCl is completely dissociated in water. However, if we measure the pH of a 0.10 mol L^{-1} aqueous solution of the seemingly similar acid HF , we find that it is not 1.00 but 2.10. This means that $[\text{H}_3\text{O}^+]$ in the HF solution is not 0.10 mol L^{-1} , but $7.9 \times 10^{-3} \text{ mol L}^{-1}$, and this means that the reaction below does not proceed to completion.

In fact, at any particular time, only about 1 in 13 molecules of HF have reacted with water to form H_3O^+ and F^- , with the majority remaining undissociated. We find a similar situation with a 0.10 mol L^{-1} aqueous solution of acetic acid, CH_3COOH . The measured pH of this solution is again not 1.00 but 2.88, which corresponds to $[\text{H}_3\text{O}^+] = 1.3 \times 10^{-3} \text{ mol L}^{-1}$ and again means that the equilibrium shown lies very much towards the reactants.

These observations indicate that there is a fundamental difference between HCl and both HF and CH_3COOH . HCl is able to transfer its proton completely to water, while HF and CH_3COOH are very poor proton donors towards water. This means they exist predominantly as molecules in aqueous solution, with the result being a low concentration of ions in solution. This can be illustrated using conductivity, the concept we use at the start of section 11.1. Figure 11.9 shows the different conductivities of aqueous solutions containing HCl and CH_3COOH . This behaviour shows the different strengths of the acids. We say that HCl is a **strong acid**, whereas both HF and CH_3COOH are **weak acids**. A general definition of these terms is as follows.

- A strong acid reacts completely with water to give quantitative formation of H_3O^+ .
- A weak acid reacts incompletely with water to form less than stoichiometric amounts of H_3O^+ .

There are analogous definitions for bases.

- A **strong base** reacts completely with water to give quantitative formation of OH^- .
- A **weak base** reacts incompletely with water to form less than stoichiometric amounts of OH^- .

Note that these definitions strictly apply only to Brønsted–Lowry acids in aqueous solution.

The use of the words ‘strong’ and ‘weak’ is somewhat unfortunate, as it implies that there is a distinct cut-off point between strong and weak acids. This is not the case. Our definition of strong acids and bases implies that they are completely dissociated in water and should therefore have comparable strengths — this is true only if we restrict ourselves to relatively dilute aqueous solutions. However, weak acids and bases show an enormous range of strengths in aqueous solution; rather than relying on the qualitative concept ‘weak’ to describe their behaviour, it is more informative to quantify their ability to either donate or accept a proton by looking at the value of the equilibrium constant for their reaction with water, and we will do this in section 11.4. We will first look at the nature of strong acids and bases in aqueous solution.

FIGURE 11.9

Electrical conductivity of solutions of strong and weak acids at equal concentrations. The wires lead to a battery (not shown), which provides electrical power to light the bulb. (a) HCl reacts completely with water to give H_3O^+ and Cl^- , resulting in high conductivity, thus enabling the light to glow brightly. (b) CH_3COOH reacts with water to give only very small amounts of H_3O^+ and CH_3COO^- , so the light is dimmer. (Refer back to figure 2.16 to remind yourself of the colours we use in this text to represent atoms of the various elements in space-filling and ball-and-stick models.)

CHEMICAL CONNECTIONS

Swimming pools and soil

Swimming pools and soil are just two examples of many situations where pH is important.

The water in swimming pools is more than just water; it is a dilute solution of compounds that prevent the growth of bacteria and stabilise the pool lining while allowing us to swim safely in the pool. The pH of a swimming pool should be between 7.2 and 7.6.

The pH can also affect the availability of substances that plants need for growth (figure 11.10). A pH of 6 to 7 is best for most plants; most nutrients are more soluble when the soil is slightly acidic than when it is neutral or slightly basic. If the soil pH is too high, metal ions that plants need, such as iron and manganese, will precipitate and not be available

in the ground water. A very low pH is not good either; if the pH drops to 4–5, metal ions such as aluminium, that are toxic to many plants, are released as their compounds become more soluble. A low pH also inhibits the growth of beneficial bacteria that decompose organic matter in the soil to release nutrients, especially nitrogen.

It is important to be able to measure the pH of these systems. Commercial pH test kits use acid–base indicators. Kits for testing the pH of pool water use phenol red indicator, which changes colour over the pH range of 6.4–8.2, while soil test kits use a ‘universal indicator’, which is a mixture of indicators that enable estimation of pH over a wide range.

FIGURE 11.10

Hydrangeas grown in acidic soil have blue flowers (left), while those grown in alkaline soils have pink/red flowers (right).

11.3 Strong acids and bases

LEARNING OBJECTIVE 11.3 Perform calculations involving strong acids and bases.

We have defined a strong acid as an acid that donates a proton completely to water. Using this definition, for any strong acid HA, the forward reaction of the following equilibrium proceeds to completion.

Similarly, our definition of a strong base says that OH^- is formed quantitatively on reaction with water, and therefore, for any strong base in water, the forward reaction of the following equilibrium shown should proceed to completion.

A list of some strong acids and bases is given in table 11.3.

TABLE 11.3 Examples of strong acids and bases

Strong acids ^(a)	Strong bases
HClO_4 (HOClO_3), perchloric acid	LiOH , lithium hydroxide
HCl , hydrochloric acid	NaOH , sodium hydroxide
HBr , hydrobromic acid	KOH , potassium hydroxide
HI , hydroiodic acid	Ca(OH)_2 , calcium hydroxide
HNO_3 (HONO_2), nitric acid	RbOH , rubidium hydroxide
H_2SO_4 ($(\text{HO})_2\text{SO}_2$), sulfuric acid	NaOCH_3 , sodium methoxide
HCF_3SO_3 (HOSO_2CF_3), trifluoromethanesulfonic acid	CsOH , caesium hydroxide

^(a)The molecular formulae of the acids in parentheses emphasise the actual structure of each acid; note that the acidic proton is attached to an O atom in each of the oxoacids.

The fact that strong acids undergo complete dissociation tells us something about the basicity of their conjugate bases. For example, the equilibrium below lies almost completely to the right-hand side, and therefore the reverse reaction occurs to only a negligible extent.

This means that Cl^- , the conjugate base of HCl , does not readily accept a proton from H_3O^+ , and consequently Cl^- must be a *very* weak base. Such behaviour is common to all strong acids and we can make the generalisation that *the conjugate base of a strong acid is very weak*. We will investigate this

concept further when we discuss weak acids and bases (section 11.4). When writing equations for the dissociation of strong acids and bases in water it is therefore usual to replace the equilibrium arrow with a single forward arrow. We should also note that H_3O^+ is the strongest acid and OH^- is the strongest base that can exist in aqueous solution. We have already seen that the strong acid HCl donates its proton almost completely to water to form H_3O^+ , and the same is true of all acids stronger than H_3O^+ ; they react completely when dissolved in water to form H_3O^+ and none of the undissociated acid is present. Likewise, any base stronger than OH^- will, when dissolved in water, quantitatively deprotonate water to give OH^- . Hence, there are limits to the range of acidities and basicities that can be accessed in water and, if we want to go beyond these limits, we must use a different solvent.

pH calculations in solutions of strong acids and bases

As strong acids and bases react with water almost completely, the calculation of pH in solutions containing strong acids or bases is a relatively straightforward exercise in stoichiometry.

When the solute in an aqueous solution is a strong monoprotic acid, such as HCl or HNO_3 , we expect to obtain 1 mol of H_3O^+ for every mole of the acid in the solution. Thus, a $1.0 \times 10^{-2} \text{ mol L}^{-1}$ solution of HCl contains $1.0 \times 10^{-2} \text{ mol L}^{-1}$ of H_3O^+ , and a $2.0 \times 10^{-3} \text{ mol L}^{-1}$ solution of HNO_3 contains $2.0 \times 10^{-3} \text{ mol L}^{-1}$ of H_3O^+ .

To calculate the pH of a solution of a strong monoprotic acid, we use $[\text{H}_3\text{O}^+]$ obtained from the stated molar concentration of the acid. Thus, a $1.0 \times 10^{-2} \text{ mol L}^{-1}$ HCl solution has $[\text{H}_3\text{O}^+] = 1.0 \times 10^{-2} \text{ mol L}^{-1}$, and therefore the $\text{pH} = -\log[\text{H}_3\text{O}^+] = -\log(1.0 \times 10^{-2}) = 2.00$.

For strong bases, calculating the pH from $[\text{OH}^-]$ is similarly straightforward. A $5.0 \times 10^{-2} \text{ mol L}^{-1}$ solution of NaOH contains $5.0 \times 10^{-2} \text{ mol L}^{-1}$ of OH^- because the base is fully dissociated and each mole of NaOH releases 1 mol of OH^- when it dissociates. Therefore, $\text{pOH} = -\log(5.0 \times 10^{-2}) = 1.30$, and $\text{pH} = 14.00 - 1.30 = 12.70$ at 25°C .

For bases such as $\text{Ba}(\text{OH})_2$, we have to recognise that 2 mol of OH^- are released by each mole of the base.

Therefore, if a solution contained $1.0 \times 10^{-2} \text{ mol Ba}(\text{OH})_2$ per litre, the concentration of OH^- would be $2.0 \times 10^{-2} \text{ mol L}^{-1}$. Of course, once we know the OH^- concentration we can calculate pOH, from which we can calculate the pH. Worked example 11.7 illustrates the kinds of calculations we have just described.

WORKED EXAMPLE 11.7

Calculating pH, pOH, $[\text{H}_3\text{O}^+]$ and $[\text{OH}^-]$ for aqueous solutions of strong acids or bases

HBr is a strong acid and $\text{Ca}(\text{OH})_2$ is a strong base. Calculate the pH, pOH, $[\text{H}_3\text{O}^+]$ and $[\text{OH}^-]$ of the following.

- a $5.5 \times 10^{-2} \text{ mol L}^{-1}$ aqueous solution of HBr at 25°C
- a $3.8 \times 10^{-3} \text{ mol L}^{-1}$ aqueous solution of $\text{Ca}(\text{OH})_2$ at 25°C

Analysis

Because HBr is a strong acid and $\text{Ca}(\text{OH})_2$ is a strong base, they will both dissociate completely to give quantitative formation of H_3O^+ and OH^- , respectively. We therefore use the stoichiometry of the balanced equilibrium equations to calculate $[\text{H}_3\text{O}^+]$ and $[\text{OH}^-]$, assuming these reactions proceed to completion.

Each mole of HBr produces 1 mol of H_3O^+ , so the given concentration of HBr will be equal to the concentration of H_3O^+ . We then use this to calculate the pH, pOH and $[\text{OH}^-]$.

$\text{Ca}(\text{OH})_2$ is a dibasic base; each mole of $\text{Ca}(\text{OH})_2$ will produce 2 mol of OH^- . Hence, the concentration of OH^- will be twice the given concentration of $\text{Ca}(\text{OH})_2$. We then use $[\text{OH}^-]$ to calculate $[\text{H}_3\text{O}^+]$, pOH and pH.

Solution

- HBr is completely dissociated, so in $5.5 \times 10^{-2} \text{ mol L}^{-1}$ HBr , $[\text{H}_3\text{O}^+] = 5.5 \times 10^{-2} \text{ mol L}^{-1}$. Therefore:

$$\text{pH} = -\log[\text{H}_3\text{O}^+] = -\log(5.5 \times 10^{-2}) = 1.26$$

Thus, in $5.5 \times 10^{-2} \text{ mol L}^{-1}$ HBr , the pH is 1.26. The pOH is $(14.00 - 1.26) = 12.74$. To find $[\text{OH}^-]$, we can use this value of pOH.

$$[\text{OH}^-] = 10^{-\text{pOH}} = 10^{-12.74} = 1.8 \times 10^{-13} \text{ mol L}^{-1}$$

Note how much smaller $[\text{OH}^-]$ is in this acidic solution than it is in pure water. This makes sense because the solution is quite acidic.

(b) As stated above, $\text{Ca}(\text{OH})_2$ is a strong base, and $[\text{OH}^-]$ will be twice the concentration of $\text{Ca}(\text{OH})_2$. Therefore:

$$[\text{OH}^-] = 2 \times (3.8 \times 10^{-3}) \text{ mol L}^{-1} = 7.6 \times 10^{-3} \text{ mol L}^{-1}$$
$$\text{pOH} = -\log[\text{OH}^-] = -\log(7.6 \times 10^{-3}) = 2.12$$

Thus, the pOH of this solution is 2.12, and the pH = $(14.00 - 2.12) = 11.88$. We can then obtain $[\text{H}_3\text{O}^+]$ from the following equation.

$$[\text{H}_3\text{O}^+] = 10^{-\text{pH}} = 10^{-11.88} = 1.3 \times 10^{-12} \text{ mol L}^{-1}$$

We would expect the concentration of H_3O^+ to be very low because the solution is quite basic.

Is our answer reasonable?

In (a), the concentration of H_3O^+ is between $10^{-2} \text{ mol L}^{-1}$ and $10^{-1} \text{ mol L}^{-1}$ and so the pH must be between 1 and 2, as we found. In (b), the concentration of OH^- is between $10^{-3} \text{ mol L}^{-1}$ and $10^{-2} \text{ mol L}^{-1}$. Hence, the pOH must be between 2 and 3, which it is.

PRACTICE EXERCISE 11.7

Calculate $[\text{H}_3\text{O}^+]$ and the pH of an aqueous $7.4 \times 10^{-2} \text{ mol L}^{-1}$ NaOH solution.

Suppression of the autoprotolysis of water

In the preceding calculations, we have assumed that all of the H_3O^+ or OH^- in the solutions of strong acid or base comes from the acid or the base, respectively. However, there is another potential source of both H_3O^+ and OH^- in an aqueous solution, namely water. We have seen that the autoprotolysis of water gives rise to low concentrations of H_3O^+ and OH^- , and we will now show the conditions under which we are justified in neglecting these contributions. We will consider only a solution of strong acid, but realise that analogous arguments apply for a solution of a strong base.

In an aqueous solution of any acid, there are two sources of H_3O^+ ; the acid itself, and water. Thus:

$$[\text{H}_3\text{O}^+]_{\text{total}} = [\text{H}_3\text{O}^+]_{\text{from acid}} + [\text{H}_3\text{O}^+]_{\text{from H}_2\text{O}}$$

Except in *very* dilute solutions of strong acids, the amount of H_3O^+ contributed by water ($[\text{H}_3\text{O}^+]_{\text{from H}_2\text{O}}$) is negligible compared with the amount of H_3O^+ from the acid ($[\text{H}_3\text{O}^+]_{\text{from acid}}$). For instance, in worked example 11.7 we saw that in $5.5 \times 10^{-2} \text{ mol L}^{-1}$ HBr the $[\text{OH}^-]$ was $1.8 \times 10^{-13} \text{ mol L}^{-1}$. The only source of OH^- in this acidic solution is from the autoprotolysis of water, and the amounts of OH^- and H_3O^+ formed by the autoprotolysis of water must be equal. Therefore, $[\text{H}_3\text{O}^+]_{\text{from H}_2\text{O}}$ also equals $1.8 \times 10^{-13} \text{ mol L}^{-1}$. If we now look at the total $[\text{H}_3\text{O}^+]$ for this solution, we have the following.

$$\begin{aligned} [\text{H}_3\text{O}^+]_{\text{total}} &= 2.0 \times 10^{-2} \text{ mol L}^{-1} + 1.8 \times 10^{-13} \text{ mol L}^{-1} \\ &\quad \text{(from HCl)} \quad \quad \quad \text{(from H}_2\text{O)} \\ &= 2.0 \times 10^{-2} \text{ mol L}^{-1} \text{ (rounded correctly)} \end{aligned}$$

In any solution of an acid, the autoprotolysis of water is suppressed by the H_3O^+ produced by the acid. This is a demonstration of the common ion effect we first discussed in the chapter on solutions and solubility; in this case, H_3O^+ is the common ion, and the large excess of H_3O^+ from the acid suppresses the autoprotolysis of water.

We can rationalise this by considering the autoprotolysis equilibrium of water.

If we add another source of H_3O^+ to water, we instantaneously increase the reaction quotient Q_w (where $Q_w = [\text{H}_3\text{O}^+][\text{OH}^-]$), so that $Q_w > K_w$. Therefore, the equilibrium shifts towards the reactants to decrease Q_w , resulting in lower amounts of both H_3O^+ and OH^- from the autoprotolysis of water. Similar reasoning also applies to the addition of another source of OH^- to water. Therefore, addition of either H_3O^+ or OH^- to water suppresses the autoprotolysis of water. The maximum possible contribution of $[\text{H}_3\text{O}^+]$ or $[\text{OH}^-]$ from the autoprotolysis of water is $1.0 \times 10^{-7} \text{ mol L}^{-1}$ at 25.0°C , and, in most cases, especially when strong acids or bases are involved, this can be safely ignored. However, as shown in worked example 11.8, there are exceptions.

WORKED EXAMPLE 11.8

Calculating the pH of very dilute strong acid solutions

Calculate the pH of a $1.0 \times 10^{-10} \text{ mol L}^{-1}$ solution of HCl(aq) .

Analysis

At first glance, this appears a simple matter of equating $[\text{H}_3\text{O}^+]$ to the concentration of the acid, as we have done in previous examples concerning strong acid solutions. However, if we do this, we obtain a pH of 10, which is obviously incorrect as it would mean that the solution of HCl is basic! In this case, we need to take *both* possible sources of H_3O^+ into account — HCl and H_2O — and see which one, if any, dominates.

Solution

We start by calculating the contribution of H_3O^+ from both water and HCl . We know that the HCl solution is $1.0 \times 10^{-10} \text{ mol L}^{-1}$, and therefore:

$$[\text{H}_3\text{O}^+]_{\text{from HCl}} = 1.0 \times 10^{-10} \text{ mol L}^{-1}$$

Ordinarily, the addition of acid to water would suppress the autoprotolysis of water through the common ion effect

(H_3O^+ is the common ion), meaning that the contribution of H_3O^+ from this would be less than $1.0 \times 10^{-7} \text{ mol L}^{-1}$. However, in this case, the concentration of acid is very small compared with that resulting from the autoprotolysis of water — in fact, the $[\text{H}_3\text{O}^+]$ from water will suppress the dissociation of the HCl and we can therefore say, to a very good approximation:

$$[\text{H}_3\text{O}^+]_{\text{from H}_2\text{O}} = 1.0 \times 10^{-7} \text{ mol L}^{-1}$$

Hence:

$$\begin{aligned} [\text{H}_3\text{O}^+]_{\text{total}} &= 1.0 \times 10^{-7} \text{ mol L}^{-1} + 1.0 \times 10^{-10} \text{ mol L}^{-1} \\ &= 1.0 \times 10^{-7} \text{ mol L}^{-1} \text{ (rounded correctly)} \end{aligned}$$

and the calculated pH becomes:

$$\begin{aligned} \text{pH} &= -\log[\text{H}_3\text{O}^+] \\ &= -\log(1.0 \times 10^{-7}) = 7.00 \end{aligned}$$

Is our answer reasonable?

A pH of 7 is certainly much more reasonable than a pH of 10. The strong acid is so dilute that, in this case, water is the major contributor of H_3O^+ to the solution.

PRACTICE EXERCISE 11.8

Calculate the pH of a $1.0 \times 10^{-11} \text{ mol L}^{-1}$ solution of NaOH .

From now on, we assume that, except for *very* dilute solutions ($10^{-6} \text{ mol L}^{-1}$ or less), the autoprotolysis of water can be neglected when calculating the pH of strong acids or bases.

11.4 Weak acids and bases

LEARNING OBJECTIVE 11.4 Perform calculations involving weak acids and bases.

Earlier in this chapter, we stated that weak acids and weak bases react incompletely with water to give less than stoichiometric amounts of H_3O^+ and OH^- , respectively. We can quantify the extent to which these reactions occur by looking at the values of their equilibrium constants. If we consider a weak monoprotic acid HA , we can write its reaction with water as follows.

The equilibrium constant expression for this is therefore:

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]}$$

The equilibrium constant for the dissociation of an acid in an aqueous solution is called the **acidity constant** and is given the symbol K_a . We can see that the value of K_a tells us how far the reaction has proceeded towards completion when equilibrium is established.

Similarly, we can write the equation for the reaction of a weak monoprotic base B with water as:

The corresponding equilibrium constant expression is:

$$K_b = \frac{[\text{BH}^+][\text{OH}^-]}{[\text{B}]}$$

This is called the **basicity constant** and is given the symbol K_b .

When polyprotic acids or bases are considered, a separate equilibrium constant must be written for each proton loss or proton gain. For example, the diprotic acid H_2A will undergo two separate proton loss reactions in water, one involving H_2A and the other involving its conjugate base, HA^- . This gives rise to two separate K_a expressions.

Analogous K_b expressions can be written for a polyprotic base.

Because weak acids and weak bases react with water only to a very small extent, both K_a and K_b values are generally significantly less than 1. For example, K_a for acetic acid is 1.8×10^{-5} , while K_b for pyridine is 1.7×10^{-9} . To put these values in perspective, it is instructive to write these numbers in an alternative form — for example, knowing that $10^{-5} = \frac{1}{10^5}$, we can write K_a for acetic acid as follows.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = 1.8 \times 10^{-5} = \frac{1.8}{10^5}$$

When written in this fashion, it is evident that the concentrations on the top line are *much* smaller than the concentration on the bottom. In other words, the concentration of undissociated acid at equilibrium is enormous compared with $[\text{H}_3\text{O}^+]$ and $[\text{CH}_3\text{COO}^-]$. This means that acetic acid is indeed a weak acid. A similar approach can be used to emphasise the weakly basic nature of pyridine.

Because K_a and K_b values are usually significantly less than 1, it is often more convenient to use $\text{p}K_a$ and $\text{p}K_b$ values, where:

$$\begin{aligned}\text{p}K_a &= -\log K_a \\ \text{p}K_b &= -\log K_b\end{aligned}$$

Both $\text{p}K_a$ and $\text{p}K_b$ are analogous to pH, and the defining equations are therefore similar. We can also write each equation in terms of K_a and K_b respectively, and these then become:

$$\begin{aligned}K_a &= 10^{-\text{p}K_a} \\ K_b &= 10^{-\text{p}K_b}\end{aligned}$$

Note that polyprotic acids and bases have more than one $\text{p}K_a$ or $\text{p}K_b$ value.

The strength of a weak acid is determined by its K_a value: the larger the K_a , the stronger the acid and the greater the degree of dissociation at equilibrium. Because of the negative sign in the defining equation for $\text{p}K_a$, the stronger the acid, the *smaller* is its $\text{p}K_a$ value. In fact, the $\text{p}K_a$ values of truly strong acids are negative. The values of K_a and $\text{p}K_a$ for some typical weak acids are given in table 11.4. A more complete list is provided in appendix E. Similar arguments apply to K_b and $\text{p}K_b$ values, some of which are given in table 11.5.

TABLE 11.4 K_a and $\text{p}K_a$ values for weak monoprotic acids at 25 °C

Name of acid	Formula	K_a	$\text{p}K_a$
chloroacetic acid	ClCH_2COOH	1.4×10^{-3}	2.85
nitrous acid	$\text{HNO}_2(\text{HONO})$	7.1×10^{-4}	3.15
hydrofluoric acid	HF	6.8×10^{-4}	3.17
cyanic acid	HOCN	3.5×10^{-4}	3.46
formic acid	HCOOH	1.8×10^{-4}	3.74
barbituric acid	$\text{C}_4\text{H}_4\text{N}_2\text{O}_3$	9.8×10^{-5}	4.01
acetic acid	CH_3COOH	1.8×10^{-5}	4.74
hydrazoic acid	HN_3	1.8×10^{-5}	4.74

butanoic acid	$\text{CH}_3\text{CH}_2\text{CH}_2\text{COOH}$	1.5×10^{-5}	4.82
propanoic acid	$\text{CH}_3\text{CH}_2\text{COOH}$	1.4×10^{-5}	4.89
hypochlorous acid	HOCl	3.0×10^{-8}	7.52

WORKED EXAMPLE 11.9

Interpreting pK_a and finding K_a

Acetylsalicylic acid, better known as aspirin, is a weak acid having a pK_a of 3.49. Calculate the K_a of aspirin. Is it a stronger or weaker acid than acetic acid?

Analysis

To obtain the K_a from the pK_a , we need to use the equation $K_a = 10^{-pK_a}$. This is analogous to the equation $[\text{H}_3\text{O}^+] = 10^{-\text{pH}}$, which we used earlier in this chapter. We determine the relative acid strengths by comparing the values of either pK_a or K_a .

Solution

To find K_a from pK_a , we use the following equation.

$$K_a = 10^{-pK_a}$$

We then substitute $pK_a = 3.49$:

$$K_a = 10^{-3.49} = 3.2 \times 10^{-4}$$

From table 11.4, the pK_a of acetic acid is 4.74 and the K_a is 1.8×10^{-5} . As these are, respectively, larger and smaller than the corresponding values for aspirin, aspirin is a stronger acid than acetic acid.

Is our answer reasonable?

A smaller value of pK_a means more extensive dissociation and therefore a stronger acid. Our calculated K_a is in agreement with this.

PRACTICE EXERCISE 11.9

Three weak acids, HX, HY and HZ, have pK_a values of 4.13, 3.91 and 4.02, respectively. Rank these acids in order from strongest to weakest. What are the K_a values of these acids?

Some molecules contain both an acidic site and a basic site, and this leads to interesting structural consequences. Consider, for example, the amino acid glycine. We would usually write the condensed

structural formula of this molecule as $\text{NH}_2\text{CH}_2\text{COOH}$. However, it actually exists in the solid state as a **zwitterion**, a structure which contains both a positive and negative charge but which is overall neutral.

We will discuss such compounds in more detail in the chapter on amino acids and proteins.

We learned in the chapter on chemical equilibrium how to manipulate equilibrium constant expressions and found that, when two chemical equations were added together, the equilibrium constant for the resulting equation was equal to the product of the equilibrium constants for the two reactions. This approach leads to an important result when applied to an acid and its conjugate base. Consider, for example, formic acid, HCOOH , a weak acid partly responsible for the sting of some ants (the word *formica* is Latin for 'ant'). The acid reacts with water according to the following equilibrium equation.

For this equilibrium equation:

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{HCOO}^-]}{[\text{HCOOH}]}$$

the conjugate base of formic acid, the formate ion, HCOO^- , reacts with water as follows.

Hence:

$$K_b = \frac{[\text{HCOOH}][\text{OH}^-]}{[\text{HCOO}^-]}$$

If we add these equilibrium equations, we obtain the equilibrium equation for the autoprotolysis of water.

If we multiply the expressions for K_a and K_b together, we obtain:

$$\frac{[\text{H}_3\text{O}^+][\text{HCOO}^-]}{[\text{HCOOH}]} \times \frac{[\text{HCOOH}][\text{OH}^-]}{[\text{HCOO}^-]} = [\text{H}_3\text{O}^+][\text{OH}^-] = K_w$$

or

$$K_a K_b = K_w$$

This relationship holds for *any* acid–base conjugate pair, regardless of the strength of the acid or base.

Another useful relationship can be derived by taking the negative logarithm of each side of $K_a K_b = K_w$ and remembering that the logarithm of the product of two numbers is the sum of their logarithms.

$$\text{p}K_a + \text{p}K_b = \text{p}K_w = 14.00 \text{ (at } 25^\circ\text{C)}$$

There are some important consequences of the relationship $K_a K_b = K_w$. One is that it is not necessary to tabulate both K_a and K_b for the members of an acid–base pair; if one K is known, the other can be calculated. For example, K_a for HCOOH and K_b for NH_3 are found in most tables of acid–base equilibrium constants, but these tables usually do not contain K_b for HCOO^- or K_a for NH_4^+ . If we need them, we can calculate them using $K_a K_b = K_w$.

PRACTICE EXERCISE 11.10

The value of K_a for HCOOH is 1.8×10^{-4} . What is the value of K_b for the HCOO^- ion?

Another interesting and useful observation is that *there is an inverse relationship between the strengths of the acid and base members of a conjugate pair*. This is illustrated graphically in figure 11.11. Because the product of K_a and K_b is a constant, the larger the value of K_a , the smaller the value of K_b . In other words, *the stronger the conjugate acid, the weaker its conjugate base*. We can see from the figure that the conjugate base of a strong acid is *very weak*, and the conjugate acid of a strong base is *very weak*. However, do not make the mistake of assuming that the conjugate base of a weak acid is strong. Inspection of figure 11.11 and use of the relationship $pK_a + pK_b = 14.00$ show that, in fact, the conjugate base of a weak acid is weak. For example, the pK_a of acetic acid, a weak acid, is 4.74. Its conjugate base, the acetate ion, must therefore have a pK_b of $(14.00 - 4.74) = 9.26$, a value indicative of a weak base. Similar arguments apply for the conjugate acid of a weak base.

FIGURE 11.11

The relative strengths of conjugate acid–base pairs. The stronger the acid, the weaker its conjugate base. The weaker the acid, the stronger its conjugate base.

pH calculations in solutions of weak acids and bases

In section 11.3, we learned how to calculate the pH of solutions of strong acids and bases. The calculations relied on the fact that, because strong acids and bases dissociate completely in water, the concentration of H_3O^+ or OH^- was equal to the initial concentration of the acid or base.

However, because weak acids and bases react incompletely with water, this is no longer the case. For weak acids and bases, we must use the value of K_a or K_b to determine $[H_3O^+]$ or $[OH^-]$ and hence pH. We will illustrate this by calculating the pH of a 1.0 mol L^{-1} aqueous solution of acetic acid, CH_3COOH .

We begin by writing the balanced chemical equation for the reaction of the acid with water, and obtain the expression for K_a from this.

We cannot directly solve for $[H_3O^+]$ in this form as there are two unknowns: $[CH_3COO^-]$ and $[CH_3COOH]$. However, because the sum of $[CH_3COO^-]$ and $[CH_3COOH]$ must be 1.0 mol L^{-1} , the initial

concentration of the acid, we could solve the problem using a quadratic equation. It is usual, however, to use a concentration table for calculations of this sort. We set this up in the same way as we did in the chapter on chemical equilibrium. We assume that the initial concentration of CH_3COOH is 1.0 mol L^{-1} and the initial concentrations of both H_3O^+ and CH_3COO^- are 0. (Recall that there is a small nonzero concentration of H_3O^+ arising from the autoprotolysis of water, but we can safely neglect this as it is a maximum of $1.0 \times 10^{-7} \text{ mol L}^{-1}$.) As the reaction proceeds to equilibrium, the concentration of CH_3COOH decreases by $-x$, and the concentrations of both H_3O^+ and CH_3COO^- increase by $+x$, owing to the stoichiometry of the reaction. At equilibrium, the concentrations of CH_3COOH , CH_3COO^- and H_3O^+ are $(1.0 - x)$, x and x , respectively. Hence, we obtain the following concentration table. (Concentrations given in the question are highlighted.)

	$\text{H}_2\text{O} + \text{CH}_3\text{COOH}$	$\rightleftharpoons$	$\text{H}_3\text{O}^+ + \text{CH}_3\text{COO}^-$
Initial concentration (mol L^{-1})	1.0		0 0
Change in concentration (mol L^{-1})	$-x$		$+x$ $+x$
Equilibrium concentration (mol L^{-1})	$1.0 - x$		x x

When the values in the last row of the table are substituted into the expression for K_a we obtain:

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = \frac{(x)(x)}{1.0 - x} = \frac{x^2}{1.0 - x} = 1.8 \times 10^{-5}$$

This equation involves a term in x^2 , and it could be solved exactly using the quadratic formula. However, this and many other similar calculations involving weak acids and bases can be simplified. Recall from the chapter on solutions and solubility that, if the concentration from which x is subtracted is at least 400 times as large as K , we can make simplifying assumptions. In this case, the initial concentration of 1.0 mol L^{-1} is indeed at least 400 times as large as K_a , 1.8×10^{-5} . Therefore, we can make the approximation $(1.0 - x) \approx 1.0$. If we now replace $1.0 - x$ with 1.0 in the equation above, we obtain:

$$\frac{x^2}{1.0} = 1.8 \times 10^{-5}$$

We can now solve this directly:

$$\begin{aligned} x^2 &= (1.8 \times 10^{-5})(1.0) \\ x &= \sqrt{(1.8 \times 10^{-5})(1.0)} = 4.2 \times 10^{-3} \text{ mol L}^{-1} \end{aligned}$$

We see that the value of x is indeed negligible compared with 1.0 mol L^{-1} (i.e. if we subtract $4.2 \times 10^{-3} \text{ mol L}^{-1}$ from 1.0 mol L^{-1} and round correctly, we obtain 1.0 mol L^{-1}). Note that using the approximation $(1.0 - x) \approx 1.0$ is equivalent to assuming that the weak acid does not dissociate at all! If we do make this approximation, we can simply solve for $[\text{H}_3\text{O}^+]$ using the following equation, rather than writing out a concentration table.

$$[\text{H}_3\text{O}^+] = \sqrt{K_a[\text{HA}]_{\text{initial}}}$$

Note from the calculation above how this equation arises from the concentration table treatment.

We also note that the same answer (to two significant figures) is obtained by solving the quadratic equation exactly, further justifying our assumption. This value corresponds to approximately 1 molecule in 240 of CH_3COOH being dissociated at equilibrium; CH_3COOH is indeed a weak acid. Having calculated x , and knowing that $x = [\text{H}_3\text{O}^+]$ at equilibrium, we can find the pH of the solution by taking the negative logarithm of this number.

$$\text{pH} = -\log(4.2 \times 10^{-3}) = 2.38$$

The approximation above is valid when the equilibrium constant is small and the concentrations of the solutes are reasonably high — conditions that apply to most situations you will encounter with weak acids and bases. Later in the chapter, we will discuss the conditions under which the approximation is not valid.

Recall that we neglected any contribution of H_3O^+ from the autoprotolysis of water to the total $[\text{H}_3\text{O}^+]$ in the solution. We can show that this assumption is justified by looking at the magnitude of $[\text{H}_3\text{O}^+]$ due to the acid compared with $[\text{H}_3\text{O}^+]$ from water. The maximum possible $[\text{H}_3\text{O}^+]$ contributed by water is

$1.0 \times 10^{-7} \text{ mol L}^{-1}$, and this will be smaller in reality owing to the common ion effect from the presence of the acid. Even if we compare the maximum possible $[\text{H}_3\text{O}^+]$ from water ($1.0 \times 10^{-7} \text{ mol L}^{-1}$) with $[\text{H}_3\text{O}^+]$ from the acid ($4.2 \times 10^{-3} \text{ mol L}^{-1}$), we see that it is negligibly small ($4.2 \times 10^{-3} \text{ mol L}^{-1} + 1.0 \times 10^{-7} \text{ mol L}^{-1} = 4.2 \times 10^{-3} \text{ mol L}^{-1}$) and so our assumption is justified.

We will now look at examples that illustrate typical weak acid and weak base equilibrium problems.

WORKED EXAMPLE 11.10

Calculating $[\text{H}_3\text{O}^+]$ and pH values for a solution of a weak acid from its K_a value

Calcium propanoate, a compound used as a preservative in baked goods (figure 11.12), is a salt of the weak acid propanoic acid, $\text{CH}_3\text{CH}_2\text{COOH}$. A student planned an experiment that would use aqueous propanoic acid at a concentration of 0.10 mol L^{-1} . Calculate the values of $[\text{H}_3\text{O}^+]$ and pH for this solution at 25°C . For propanoic acid at 25°C , $K_a = 1.4 \times 10^{-5}$.

FIGURE 11.12 The calcium salt of propanoic acid, calcium propanoate, is used as a preservative in baked products.

Analysis

First, we write the balanced equation for the reaction of the acid with water and obtain the expression for K_a from this.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{CH}_2\text{COO}^-]}{[\text{CH}_3\text{CH}_2\text{COOH}]}$$

The initial concentration of the acid is 0.10 mol L^{-1} , and the initial concentrations of both ions are 0 mol L^{-1} . The concentration of $\text{CH}_3\text{CH}_2\text{COOH}$ will change by $-x$ and those of $\text{CH}_3\text{CH}_2\text{COO}^-$ and H_3O^+ will increase by $+x$ as the reaction proceeds to equilibrium. We can now construct the concentration table.

Solution

	H_2O	+	$\text{CH}_3\text{CH}_2\text{COOH}$	$\rightleftharpoons$	H_3O^+	+	$\text{CH}_3\text{CH}_2\text{COO}^-$
Initial concentration (mol L^{-1})			0.10		0		0
Change in concentration (mol L^{-1})			$-x$		$+x$		$+x$
Equilibrium concentration (mol L^{-1})			$0.10 - x$		x		x

As propanoic acid is a weak acid, it dissociates only to a small extent and therefore x is very small. We can then make the simplifying approximation that $(0.10 - x) \approx 0.10$, so we take the equilibrium concentration of $\text{CH}_3\text{CH}_2\text{COOH}$ to be 0.10 mol L^{-1} . Substituting these quantities into the K_a expression gives the following.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{CH}_2\text{COO}^-]}{[\text{CH}_3\text{CH}_2\text{COOH}]} = \frac{(x)(x)}{0.10 - x} \approx \frac{x^2}{0.10} = 1.4 \times 10^{-5}$$

We can now solve this for x .

$$x^2 = (1.4 \times 10^{-5})(0.10) = 1.4 \times 10^{-6}$$

$$x = \sqrt{1.4 \times 10^{-6}} = 1.2 \times 10^{-3}$$

We know that $x = [\text{H}_3\text{O}^+]$ and therefore:

$$[\text{H}_3\text{O}^+] = 1.2 \times 10^{-3} \text{ mol L}^{-1}$$

Finally, we calculate the pH.

$$\text{pH} = -\log[\text{H}_3\text{O}^+] = -\log(1.2 \times 10^{-3}) = 2.92$$

Is our answer reasonable?

First, we see that the calculated pH is less than 7, as it must be for a solution of an acid. Also, the pH is higher than it would be if the acid were strong. (A 0.10 mol L^{-1} solution of a strong acid would have $[\text{H}_3\text{O}^+] = 0.10 \text{ mol L}^{-1}$ and $\text{pH} = 1.0$.) If we wish to further check the accuracy of the calculation, we can substitute the calculated equilibrium concentrations into the expression for K_a . If the calculated quantities are correct, we should obtain the numerical value of K_a .

$$\frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{CH}_2\text{COO}^-]}{[\text{CH}_3\text{CH}_2\text{COOH}]} = \frac{(x)(x)}{0.10} = \frac{(1.2 \times 10^{-3})^2}{0.10} = 1.4 \times 10^{-5} = K_a$$

The check works, so we have done the calculation correctly.

We can also check the answer by realising that the equation:

$$x = \sqrt{1.4 \times 10^{-6}}$$

in the calculation is equivalent to writing:

$$[\text{H}_3\text{O}^+] = \sqrt{K_a[\text{HA}]_{\text{initial}}}$$

as we discussed previously. Using this equation gives the same answer as the concentration table treatment, so we can be confident the answer is correct.

PRACTICE EXERCISE 11.11

Angelic acid, the structure of which is shown here, is so named because it can be extracted from the plant *Angelica archangelica*, otherwise known as wild celery. The K_a of angelic acid is 5.0×10^{-5} . Calculate the $[\text{H}_3\text{O}^+]$ and the pH of a $0.0084 \text{ mol L}^{-1}$ solution of angelic acid.

WORKED EXAMPLE 11.11

Calculating the pH of a solution of a weak base

An aqueous solution of hydrazine, N_2H_4 , a weak base, has a concentration of 0.25 mol L^{-1} . What is the pH of the solution? Hydrazine has $K_b = 1.7 \times 10^{-6}$.

Analysis

This example is analogous to worked example 11.10, except that we are now dealing with a weak base and using K_b rather than K_a .

Solution

We begin with the balanced chemical equation and obtain the K_b expression.

$$K_b = \frac{[\text{N}_2\text{H}_5^+][\text{OH}^-]}{[\text{N}_2\text{H}_4]}$$

Again, the concentration of N_2H_4 will change by $-x$ and those of N_2H_5^+ and OH^- will increase by $+x$ as the reaction proceeds to equilibrium. We construct the concentration table as follows.

	H_2O	+	N_2H_4	$\rightleftharpoons$	N_2H_5^+	+	OH^-
Initial concentration (mol L^{-1})			0.25		0		0
Change in concentration (mol L^{-1})			$-x$		$+x$		$+x$
Equilibrium concentration (mol L^{-1})			$0.25 - x$		x		x

Because hydrazine is a weak base, it reacts with water only to a small extent. We can therefore make the analogous approximation that we made for a weak acid; that is, that the equilibrium concentration of the weak base is essentially equal to its initial concentration, and thus $(0.25 - x) \approx 0.25$. We substitute the values from the concentration table into the K_b expression.

$$K_b = \frac{[\text{N}_2\text{H}_5^+][\text{OH}^-]}{[\text{N}_2\text{H}_4]} = \frac{(x)(x)}{0.25 - x} \approx \frac{x^2}{0.25} = 1.7 \times 10^{-6}$$

We solve this for x as follows.

$$\begin{aligned}x^2 &= (1.7 \times 10^{-6})(0.25) = 4.3 \times 10^{-7} \\x &= \sqrt{4.3 \times 10^{-7}} = 6.5 \times 10^{-4}\end{aligned}$$

This value represents the hydroxide ion concentration, from which we can calculate the pOH.

$$\text{pOH} = -\log[\text{OH}^-] = -\log(6.5 \times 10^{-4}) = 3.19$$

The pH of the solution can then be obtained from the relationship:

$$\begin{aligned}\text{pH} + \text{pOH} &= 14.00 \\ \text{pH} &= 14.00 - 3.19 = 10.81\end{aligned}$$

Is our answer reasonable?

As stated in the question, hydrazine is a weak base, so we would expect a $\text{pH} > 7$. We can quickly check to see whether the value of x and our assumed equilibrium concentration of N_2H_4 (0.25 mol L^{-1}) are correct by substituting them into the expression for K_b and comparing the result with the numerical value of K_b . Doing this gives 1.7×10^{-6} , which is the same as K_b , so the value of x is correct.

By analogy to previous calculations involving weak acids, we can also check our answer by realising that the equation:

$$x = \sqrt{4.3 \times 10^{-7}}$$

in the calculation is equivalent to writing:

$$[\text{OH}^-] = \sqrt{K_b[\text{B}]_{\text{initial}}}$$

Using this equation gives the same answer as that obtained from the calculation table method, and so we can be confident our answer is correct.

PRACTICE EXERCISE 11.12

Pyridine, $\text{C}_5\text{H}_5\text{N}$, is a foul-smelling liquid for which $K_b = 1.7 \times 10^{-9}$. What is the pH of a 0.010 mol L^{-1} aqueous solution of pyridine?

In worked examples 11.10 and 11.11, we have calculated the pH given the value of K_a or K_b . We can also use measured values of pH to calculate K_a or K_b values, as shown in worked example 11.12.

WORKED EXAMPLE 11.12

Calculating K_a and pK_a from pH

Lactic acid, $\text{CH}_3\text{CH}(\text{OH})\text{COOH}$, is a monoprotic acid that is present in sour milk and yoghurt. The pH of a 0.100 mol L^{-1} aqueous solution of lactic acid is 2.44 at 25°C . Calculate K_a and pK_a for lactic acid at this temperature.

Analysis

In this case we are given the pH of the solution, from which we can calculate $[\text{H}_3\text{O}^+]$. In essence, this is the reverse of the previous examples. We use the balanced chemical equation to construct a concentration table and then substitute the calculated equilibrium concentrations into the expression for K_a .

Solution

We begin by writing the balanced chemical equation and obtaining the expression for K_a .

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{CH}(\text{OH})\text{COO}^-]}{[\text{CH}_3\text{CH}(\text{OH})\text{COOH}]}$$

In this problem, the only source of the ions H_3O^+ and $\text{CH}_3\text{CH}(\text{OH})\text{COO}^-$ is the acid. As a result, the equilibrium concentration of H_3O^+ must be identical to that of $\text{CH}_3\text{CH}(\text{OH})\text{COO}^-$ because the reaction gives these ions in a 1 : 1 ratio. However, we do not have the values of either $[\text{H}_3\text{O}^+]$ or $[\text{CH}_3\text{CH}(\text{OH})\text{COO}^-]$; all we have is the pH of the 0.100 mol L^{-1} solution. We start by finding $[\text{H}_3\text{O}^+]$ from the pH. This gives us the *equilibrium* value of $[\text{H}_3\text{O}^+]$.

$$\begin{aligned} [\text{H}_3\text{O}^+] &= 10^{-\text{pH}} = 10^{-2.44} \\ &= 3.6 \times 10^{-3} \text{ mol L}^{-1} \end{aligned}$$

Because $[\text{CH}_3\text{CH}(\text{OH})\text{COO}^-] = [\text{H}_3\text{O}^+]$, we know that $[\text{CH}_3\text{CH}(\text{OH})\text{COO}^-] = 3.6 \times 10^{-3} \text{ mol L}^{-1}$ at equilibrium. We now set up the concentration table, given that the initial concentration of lactic acid is 0.100 mol L^{-1} .

	H_2O	+	$\text{CH}_3\text{CH}(\text{OH})\text{COOH}$	$\rightleftharpoons$	H_3O^+	+	$\text{CH}_3\text{CH}(\text{OH})\text{COO}^-$
Initial concentration (mol L^{-1})			0.100		0		0
Change in concentration (mol L^{-1})			-3.6×10^{-3}		$+3.6 \times 10^{-3}$		$+3.6 \times 10^{-3}$
Equilibrium concentration (mol L^{-1})			$0.100 - 3.6 \times 10^{-3} = 0.096$		3.6×10^{-3}		3.6×10^{-3}

This problem differs from the previous worked examples in that we know the value of x ($3.6 \times 10^{-3} \text{ mol L}^{-1}$) but we do not know K_a . We proceed by substituting the equilibrium values into the K_a expression. We know that both $[\text{H}_3\text{O}^+]$ and $[\text{CH}_3\text{CH}(\text{OH})\text{COO}^-] = 3.6 \times 10^{-3} \text{ mol L}^{-1}$, and, from the concentration table, that $[\text{CH}_3\text{CH}(\text{OH})\text{COOH}] = (0.100 - x) = (0.100 - 3.6 \times 10^{-3}) = 0.096 \text{ mol L}^{-1}$. (Note that, because we know the value of x in this case, we do not have to make the assumption that $(0.100 - x) \approx 0.100$.) Therefore:

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{CH}(\text{OH})\text{COO}^-]}{[\text{CH}_3\text{CH}(\text{OH})\text{COOH}]} = \frac{(3.6 \times 10^{-3})(3.6 \times 10^{-3})}{0.096} = 1.4 \times 10^{-4}$$

Thus the K_a for lactic acid is 1.4×10^{-4} . To find pK_a , we take the negative logarithm of K_a .

$$pK_a = -\log K_a = -\log(1.4 \times 10^{-4}) = 3.85$$

Is our answer reasonable?

Weak acids have small acidity constants, so the value we obtained for K_a seems to be reasonable. We should also check the entries in the concentration table to be sure they are reasonable. For example, the change in concentrations of the ions are both positive, meaning both of their concentrations are increasing, as required. Likewise, the concentration of lactic acid decreases, as it must do.

PRACTICE EXERCISE 11.13

Ethanolamine, $\text{NH}_2\text{CH}_2\text{CH}_2\text{OH}$, is a very water-soluble amine that is used to remove H_2S and CO_2 from industrial waste gas streams. Given that the pH of a 0.100 mol L^{-1} aqueous solution of ethanolamine is 11.25, calculate its K_b and pK_b .

pH calculations in solutions of salts of weak acids and bases

We have seen that Cl^- , the conjugate base of the strong acid HCl , is a very weak base and shows essentially no tendency to react with H_3O^+ to form HCl . This means that Cl^- is even less likely to act as a base towards H_2O , and hence we can say that Cl^- has essentially no basic properties. Therefore, an aqueous solution of NaCl has a pH of 7.00 at 25°C . This is true of the conjugate bases of all strong monoprotic acids. Thus, dilute aqueous solutions of salts such as NaBr , NaI , NaNO_3 and, indeed, any sodium salt of a strong monoprotic acid, have pH values of 7.00 at 25°C . However, this is not the case for the salt of a weak acid, such as NaOOCCH_3 , which has a pH > 7 , or the salt of a weak base, such as NH_4Cl , which has a pH < 7 at this temperature. If we dissolve each of these in water, we get complete dissociation into the respective ions as follows.

The CH_3COO^- and NH_4^+ ions are then involved in the following equilibria.

The two solutions are therefore slightly basic and slightly acidic, respectively.

As illustrated in figure 11.11, conjugate base strength increases as acid strength decreases, and therefore the salts of weak acids can be appreciably basic. Similarly, the salts of weak bases are generally slightly acidic. We can see that this is the case by looking at $\text{p}K_{\text{a}}$ and $\text{p}K_{\text{b}}$ values for conjugate pairs. For example, as we have seen, acetic acid, CH_3COOH , has a $\text{p}K_{\text{a}}$ of 4.74, and this means that the acetate ion, CH_3COO^- , has a $\text{p}K_{\text{b}}$ of $14.00 - 4.74 = 9.26$. If we consider HCN , an even weaker acid ($\text{p}K_{\text{a}} = 9.21$), we can see that the cyanide ion, CN^- , has a $\text{p}K_{\text{b}}$ of $14.00 - 9.21 = 4.79$, making it almost as strong a base as ammonia, NH_3 . We can use the $\text{p}K_{\text{a}}$ and $\text{p}K_{\text{b}}$ values to calculate the pH of aqueous solutions containing the salts of weak acids and bases, as shown in worked examples 11.13 and 11.14.

WORKED EXAMPLE 11.13

Calculating the pH of a salt solution

NaOCl , sodium hypochlorite, is the major constituent of household bleach solutions. The OCl^- ion is the conjugate base of the weak acid HOCl (hypochlorous acid). What is the pH of a 0.10 mol L^{-1} aqueous solution of NaOCl at 25°C ? For HOCl , $K_{\text{a}} = 3.0 \times 10^{-8}$.

Analysis

OCl^- is the conjugate base of the weak acid HOCl , and we therefore expect the solution to be slightly basic. As we are given only K_{a} for HOCl and we are asked to find the pH, we use K_{b} , which we can obtain from K_{a} , to solve this problem. As usual, we start with a balanced chemical equation and obtain the expression for the appropriate equilibrium constant from this.

Solution

First, we write the chemical equation for the reaction of OCl^- with water along with the corresponding K_{b} expression.

The data provided in the problem include the K_{a} for HOCl , but we can calculate K_{b} because $K_{\text{a}}K_{\text{b}} = K_{\text{w}}$ for a conjugate pair.

$$K_{\text{b}} = \frac{K_{\text{w}}}{K_{\text{a}}} = \frac{1.0 \times 10^{-14}}{3.0 \times 10^{-8}} = 3.3 \times 10^{-7}$$

Now let us set up the concentration table. The only source of HOCl and OH^- is the reaction of OCl^- , so their concentrations each increase by x and the concentration of OCl^- decreases by x as the reaction proceeds to equilibrium.

	H ₂ O	+	OCI ⁻	⇌	HOCl	+	OH ⁻
Initial concentration (mol L ⁻¹)			0.10		0		0
Change in concentration (mol L ⁻¹)			-x		+x		+x
Equilibrium concentration (mol L ⁻¹)			(0.10 - x)		x		x

At equilibrium, the concentrations of HOCl and OH⁻ are the same, x .

$$[\text{HOCl}] = [\text{OH}^-] = x$$

As OCI⁻ is a weak base, it reacts with water only to a small extent, and therefore x is small. We can then make the approximation that $(0.10 - x) \approx 0.10$ because $0.1 > 400 \times K_b$, and so $[\text{OCI}^-] = 0.10 \text{ mol L}^{-1}$ at equilibrium. We substitute the values into the K_b expression to give the following.

$$K_b = \frac{[\text{HOCl}][\text{OH}^-]}{[\text{OCI}^-]} = \frac{(x)(x)}{0.10 - x} \approx \frac{x^2}{0.10} = 3.3 \times 10^{-7}$$

We solve this for x as follows.

$$x^2 = (0.10)(3.3 \times 10^{-7}) = 3.3 \times 10^{-8}$$

$$x = \sqrt{3.3 \times 10^{-8}} = 1.8 \times 10^{-4} \text{ mol L}^{-1}$$

This value of x represents $[\text{OH}^-]$. We can then calculate the pOH and then the pH.

$$\text{pOH} = -\log[\text{OH}^-] = -\log(1.8 \times 10^{-4}) = 3.74$$

$$\text{pH} = 14.00 - \text{pOH} = 14.00 - 3.74 = 10.26$$

The pH of this solution is 10.26.

Is our answer reasonable?

From the nature of the salt, we expect the solution to be basic. The calculated pH corresponds to a basic solution, so the answer seems reasonable. We can also check the accuracy of the answer by substituting the calculated equilibrium concentrations into the expression for K_b .

$$\frac{[\text{HOCl}][\text{OH}^-]}{[\text{OCI}^-]} = \frac{(x)(x)}{0.10} = \frac{(1.8 \times 10^{-4})^2}{0.10} = 3.2 \times 10^{-7}$$

The result is acceptably close to the value of K_b , so our answers are correct.

PRACTICE EXERCISE 11.14

What is the pH of a 0.10 mol L^{-1} solution of NaNO_2 ? Use the $\text{p}K_a$ of HNO_2 from table 11.4.

WORKED EXAMPLE 11.14

Calculating the pH of a salt solution

Prescription drugs containing amine functional groups (amines are derivatives of ammonia) are sometimes sold as the 'hydrochloride salt'. These are ionic compounds in which the amine N atom has been protonated, resulting in a positively charged ion, with the chloride balancing the charge. This is because such salts are often significantly more water soluble than the neutral 'free base' form of the drug. Thus, pseudoephedrine, a nasal decongestant with the structure shown below left, is usually sold as the hydrochloride salt, with the structure shown below right. What is the pH of a 0.10 mol L^{-1} aqueous solution of pseudoephedrine hydrochloride, the formula of which can be written as either $\text{C}_{10}\text{H}_{15}\text{NO} \cdot \text{HCl}$ or $\text{C}_{10}\text{H}_{16}\text{NOCl}$ at 25°C ? Pseudoephedrine has a $\text{p}K_b$ value of 4.78 at 25°C .

pseudoephedrine, $C_{10}H_{15}NO$

pseudoephedrine hydrochloride, $C_{10}H_{15}NO \cdot HCl$ or $C_{10}H_{16}NOCl$

Analysis

The hydrochloride salt is the conjugate acid of a weak base, and will therefore be a weak acid. We use an analogous approach to that of worked example 11.13, starting, as always, with the balanced equilibrium equation and the appropriate equilibrium constant expression, this time for the reaction of a weak acid. We know that, as Cl^- is the conjugate base of a strong acid, it will have no effect on the pH of the solution and we can neglect it in our calculations.

Solution

We will begin with the balanced equilibrium equation for the reaction of $C_{10}H_{16}NO^+$ with water and write the K_a expression.

$$K_a = \frac{[H_3O^+][C_{10}H_{15}NO]}{[C_{10}H_{16}NO^+]}$$

We are given the pK_b value for pseudoephedrine, but we require the K_a value for its conjugate acid. We know that $pK_a + pK_b = 14.00$, so therefore $pK_a = 14.00 - 4.78 = 9.22$. We can then obtain the value of K_a .

$$K_a = 10^{-9.22} = 6.0 \times 10^{-10}$$

Now we set up the concentration table. The initial concentrations of H_3O^+ and $C_{10}H_{15}NO$ are both set to zero. Next, we indicate that the concentration of $C_{10}H_{16}NO^+$ decreases by x and the concentrations of H_3O^+ and $C_{10}H_{15}NO$ both increase by x as the reaction proceeds to equilibrium.

	H_2O	+	$C_{10}H_{16}NO^+$	$\rightleftharpoons$	H_3O^+	+	$C_{10}H_{15}NO$
Initial concentration (mol L^{-1})			0.10		0		0
Change in concentration (mol L^{-1})			$-x$		$+x$		$+x$
Equilibrium concentration (mol L^{-1})			$0.10 - x$		x		x

At equilibrium, equal amounts of H_3O^+ and $C_{10}H_{15}NO$ are present, and their equilibrium concentrations are each equal to x .

$$[H_3O^+] = [C_{10}H_{15}NO] = x$$

As $C_{10}H_{16}NO^+$ is a weak acid, it reacts with water to a small extent. We can assume that $(0.10 - x) \approx 0.10$ because $0.1 > 400 \times K_a$, and therefore $[C_{10}H_{16}NO^+] = 0.10 \text{ mol L}^{-1}$ at equilibrium. We then substitute quantities into the equilibrium constant expression.

$$K_a = \frac{[H_3O^+][C_{10}H_{15}NO]}{[C_{10}H_{16}NO^+]} = \frac{(x)(x)}{0.10 - x} \approx \frac{x^2}{0.10} = 6.0 \times 10^{-10}$$

We solve this for x as follows.

$$x^2 = (0.10)(6.0 \times 10^{-10}) = 6.0 \times 10^{-11}$$

$$x = \sqrt{6.0 \times 10^{-11}} = 7.7 \times 10^{-6} \text{ mol L}^{-1}$$

Since $x = [H_3O^+]$, the pH of the solution is as follows.

$$\text{pH} = -\log[H_3O^+] = -\log(7.7 \times 10^{-6}) = 5.11$$

Is our answer reasonable?

As we are dealing with a weak acid and the calculated pH is slightly less than 7, the final answer appears to be reasonable. In all problems of this type you should substitute your calculated equilibrium concentrations into the expression for K_a to check your answer.

PRACTICE EXERCISE 11.15

What is the pH of a $0.0750 \text{ mol L}^{-1}$ aqueous solution of NH_4ClO_4 ? Use the pK_b of NH_3 from table 11.5.

Solutions that contain the salt of a weak acid and a weak base

We saw previously that both the NH_4^+ cation and CH_3COO^- anion affect the pH of an aqueous solution. We now address what happens when both the cation and anion in a single salt are able to affect the pH. Whether or not the salt has a net effect on the pH now depends on the relative strengths of its ions, one functioning as an acid and the other as a base. If they are matched in their respective strengths, the salt has no net effect on pH. Consider, for example, a solution of ammonium acetate, $\text{NH}_4\text{OOCCH}_3$, in which the ammonium ion is an acidic cation and the acetate ion is a basic anion. However, K_a of NH_4^+ is 5.6×10^{-10} and K_b of CH_3COO^- just happens to be the same, 5.6×10^{-10} . The cation tends to produce H_3O^+ ions to the same extent that the anion tends to produce OH^- . So, in aqueous ammonium acetate, $[\text{H}_3\text{O}^+] = [\text{OH}^-]$ and the solution has a pH of 7.

Consider, now, ammonium formate, $\text{NH}_4\text{OOCCH}_3$. The formate ion, HCOO^- , is the conjugate base of the weak acid formic acid and has $K_b = 5.6 \times 10^{-11}$. Comparing this value with the (slightly larger) K_a of the ammonium ion, 5.6×10^{-10} , we see that NH_4^+ is slightly stronger as an acid than the formate ion is as a base. As a result, a solution of ammonium formate is slightly acidic. The exact calculation of pH in such solutions is difficult, and we are concerned here only in predicting if the solution is acidic, basic or neutral.

WORKED EXAMPLE 11.15

Predicting how a salt affects the pH of its solution

Is a 0.20 mol L^{-1} aqueous solution of NH_4F acidic, basic or neutral?

Analysis

This is a salt in which the cation is a weak acid (it is the conjugate acid of a weak base, NH_3) and the anion is a weak base (it is the conjugate base of a weak acid, HF). The question is how do the two ions compare in their abilities to affect the pH of the solution? We have to compare their respective K_a and K_b values to compare their strengths.

Solution

K_a of NH_4^+ (calculated from the K_b of NH_3) is 5.6×10^{-10} . Similarly, K_b of F^- is 1.5×10^{-11} (calculated from the K_a of HF , 6.8×10^{-4}). Comparing the two equilibrium constants, we see that K_a for the acid, NH_4^+ , is greater than K_b for the base, F^- . Therefore, the reaction of NH_4^+ with water to give H_3O^+ proceeds to a greater extent than the reaction of F^- with water to give OH^- . This means that, at equilibrium, $[\text{H}_3\text{O}^+] > [\text{OH}^-]$ and we expect the solution to be slightly acidic.

Is our answer reasonable?

There is not much to check here except to be sure that we have done the arithmetic correctly.

PRACTICE EXERCISE 11.16

Is an aqueous solution of ammonium cyanide, NH_4CN , acidic, basic or neutral?

Situations where simplifying assumptions do not work

So far, in our calculations involving weak acids and bases, we have used initial concentrations of acids and bases as though they were equilibrium concentrations. This is only an approximation, but it works most

of the time. Unfortunately, it does not work in all cases, so we will now examine how to solve problems in which the approximation cannot be used.

When a weak acid HA reacts with water, its concentration is reduced as it dissociates. If we let x represent the amount of acid that reacts per litre, the equilibrium concentration becomes:

$$[\text{HA}]_{\text{equilibrium}} = [\text{HA}]_{\text{initial}} - x$$

In previous problems, we have assumed that $[\text{HA}]_{\text{equilibrium}} \approx [\text{HA}]_{\text{initial}}$ because x is small compared with $[\text{HA}]_{\text{initial}}$. However, this is the case only if $[\text{HA}]_{\text{initial}}$ is greater than, or equal to, 400 times the value of K_a . As the value of K_a of the weak acid increases, our assumption becomes less valid because the extent of dissociation of the acid increases, and $[\text{HA}]_{\text{equilibrium}}$ is no longer approximately equal to $[\text{HA}]_{\text{initial}}$.

When our assumption is not valid, we must solve a quadratic equation as we did in the chapter on solutions and solubility. We also assumed that we could safely neglect any contribution to $[\text{H}_3\text{O}^+]$ or $[\text{OH}^-]$ from the autoprotolysis of water. This is the case only if the value of $[\text{H}_3\text{O}^+]$ or $[\text{OH}^-]$ from the acid or base is greater than 1×10^{-5} (i.e. at least 100 times 1×10^{-7} , the maximum possible contribution from water). This will generally be the case, and we assume we can continue to neglect the autoprotolysis of water from here on. We illustrate a situation that requires use of the quadratic formula in worked example 11.16.

WORKED EXAMPLE 11.16

Using the quadratic formula in equilibrium products

Chloroacetic acid, ClCH_2COOH , is used as a herbicide and in the manufacture of dyes and other organic chemicals. It is a weak acid with $K_a = 1.4 \times 10^{-3}$. What is the pH of a 0.010 mol L^{-1} aqueous solution of ClCH_2COOH at 25°C ?

Analysis

Before we begin, we check to see whether we can use our usual simplifying approximation. We do this by calculating $400 \times K_a$ and then comparing the result with the initial concentration of the acid.

$$400 \times K_a = 400(1.4 \times 10^{-3}) = 0.56$$

The initial concentration of ClCH_2COOH is *less than* 0.56 mol L^{-1} , so we know that using the approximation will give a substantial error. We must therefore set up a concentration table and then use a quadratic equation to obtain the solution.

Solution

We begin by writing the balanced chemical equation and the K_a expression.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{ClCH}_2\text{COO}^-]}{[\text{ClCH}_2\text{COOH}]} = 1.4 \times 10^{-3}$$

The initial concentration of the acid will be reduced by an amount, $-x$, as it reacts with water to form the ions. From this, we build the concentration table, assuming, as always, that the initial concentrations of the ions are zero.

	H_2O	+	ClCH_2COOH	$\rightleftharpoons$	H_3O^+	+	$\text{ClCH}_2\text{COO}^-$
Initial concentration (mol L^{-1})			0.010		0		0
Change in concentration (mol L^{-1})			$-x$		$+x$		$+x$
Equilibrium concentration (mol L^{-1})			$0.010 - x$		x		x

Substituting equilibrium concentrations into the equilibrium expression gives the following.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{ClCH}_2\text{COO}^-]}{[\text{ClCH}_2\text{COOH}]} = \frac{(x)(x)}{0.010 - x} = \frac{x^2}{0.010 - x} = 1.4 \times 10^{-3}$$

This time we cannot assume $(0.010 - x) = 0.010$. To solve the problem, we first rearrange the expression to obtain the familiar form of a quadratic equation. We do this by multiplying both sides by $(0.010 - x)$. This gives:

$$x^2 = (0.010 - x)(1.4 \times 10^{-3})$$

We then multiply out the parentheses.

$$x^2 = (1.4 \times 10^{-5}) - (1.4 \times 10^{-3})x$$

$$x^2 + (1.4 \times 10^{-3})x - (1.4 \times 10^{-5}) = 0$$

This is a general quadratic equation of the form:

$$ax^2 + bx + c = 0$$

We now use the quadratic formula:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

We make the substitutions $a = 1$, $b = 1.4 \times 10^{-3}$ and $c = -1.4 \times 10^{-5}$. Entering these into the quadratic formula gives:

$$x = \frac{-1.4 \times 10^{-3} \pm \sqrt{(1.4 \times 10^{-3})^2 - 4(1)(-1.4 \times 10^{-5})}}{2(1)}$$
$$x = 3.1 \times 10^{-3} \text{ mol L}^{-1} \text{ and } x = -4.5 \times 10^{-3} \text{ mol L}^{-1}$$

We know that x cannot be negative because that would give negative concentrations for the ions, which is impossible, so we choose the first value as the correct one. This yields the following equilibrium concentrations.

$$\begin{aligned} [\text{H}_3\text{O}^+] &= 3.1 \times 10^{-3} \text{ mol L}^{-1} \\ [\text{ClCH}_2\text{COO}^-] &= 3.1 \times 10^{-3} \text{ mol L}^{-1} \\ [\text{ClCH}_2\text{COOH}] &= 0.010 - x = 0.010 - 0.0031 \\ &= 0.007 \text{ mol L}^{-1} \end{aligned}$$

Finally, we calculate the pH of the solution.

$$\begin{aligned} \text{pH} &= -\log(3.1 \times 10^{-3}) \\ &= 2.51 \end{aligned}$$

Notice that x is not negligible compared with the initial concentration, so the simplifying approximation would not have been valid. We can calculate the error that would be produced if we made the simplifying approximation in this case. We would obtain the same equation.

$$\begin{aligned} K_a &= \frac{[\text{H}_3\text{O}^+][\text{ClCH}_2\text{COO}^-]}{[\text{ClCH}_2\text{COOH}]} \\ &= \frac{(x)(x)}{0.010 - x} = 1.4 \times 10^{-3} \end{aligned}$$

Making the assumption that $(0.010 - x) \approx 0.010$, we would then obtain the following.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{ClCH}_2\text{COO}^-]}{[\text{ClCH}_2\text{COOH}]} = \frac{x^2}{0.010} = 1.4 \times 10^{-3}$$

Solving this for x would give:

$$\begin{aligned} x^2 &= (0.010)(1.4 \times 10^{-3}) = 1.4 \times 10^{-5} \\ x &= \sqrt{1.4 \times 10^{-5}} = 3.7 \times 10^{-3} \end{aligned}$$

Therefore, making the assumption gives $[\text{H}_3\text{O}^+] = 3.7 \times 10^{-3} \text{ mol L}^{-1}$, approximately a 20% error compared to the correct value of $3.1 \times 10^{-3} \text{ mol L}^{-1}$ from solution of the quadratic equation.

Is our answer reasonable?

As before, a quick check can be performed by substituting the calculated equilibrium concentrations into the equilibrium expression.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{ClCH}_2\text{COO}^-]}{[\text{ClCH}_2\text{COOH}]} = \frac{(x)(x)}{0.010 - x} = \frac{(3.1 \times 10^{-3})^2}{0.007} = 1.4 \times 10^{-3}$$

The value we obtain equals K_a , so the equilibrium concentrations are correct.

PRACTICE EXERCISE 11.17

The weak base trimethylamine, $(\text{CH}_3)_3\text{N}$, has $K_b = 6.3 \times 10^{-5}$. Calculate the pH of a $0.0010 \text{ mol L}^{-1}$ aqueous solution of trimethylamine.

11.5 The molecular basis of acid strength

LEARNING OBJECTIVE 11.5 Explain the relationship between structure and acidity.

Up until this point, we have labelled acids as either strong or weak, but have not explained what determines the strength of a particular acid. In this section, we will show that a variety of factors contribute to the overall strength of an acid.

Binary acids

A binary acid is defined as an acid containing H and only one other element, generally a nonmetal. The simplest binary acids are the monoprotic species HF, HCl, HBr and HI containing group 17 elements. Diprotic binary acids include H₂O and H₂S, whereas NH₃ and CH₄ are examples of, albeit extremely weak, triprotic and tetraprotic binary acids, respectively. The observed order of acid strengths of these acids is (from weakest to strongest).

In order for each of these compounds to act as an acid, a single H—X bond must be broken, so it might be expected there would be some correlation between the H—X bond enthalpy (which can be thought of as the ease with which the bond can be broken) and the acid strength. As can be seen from table 11.6, this is not the case.

TABLE 11.6 Bond enthalpies for cleavage of some H—X bonds

Bond	Bond enthalpy for homolytic cleavage (kJ mol ⁻¹)	Bond enthalpy for heterolytic cleavage (kJ mol ⁻¹)
C—H	412	1744
N—H	388	1688
O—H	463	1633
S—H	338	1468
F—H	565	1554
Cl—H	431	1395
Br—H	366	1353
I—H	299	1314

This is perhaps not surprising when you consider the definition of bond enthalpy. Recall from the chapter on chemical thermodynamics that a bond enthalpy refers to the process shown below, in which the bond in the gas phase molecule undergoes **homolytic cleavage** (the bond breaks evenly so that one electron is given to each of the atoms involved in the bond) to give electrically neutral species.

Such a process is in fact very different from that involved in proton donation from H—X to water, which occurs via **heterolytic cleavage** (the bond breaks unevenly so that both electrons are given to one of the atoms involved in the bond) to form solvated ions, according to the following equation.

A good correlation between the acidity and the heterolytic H—X bond energies in the gas phase does exist, as can be seen in table 11.6; these gas phase data, however, neglect solvent effects and do not therefore constitute an acceptable approximation of reality.

A more realistic approach that includes solvent effects uses the Hess's law cycle, which is shown in figure 11.13.

The value of ΔH_{acid} , the enthalpy change for the dissociation of the acid in its standard state (gas for all acids in table 11.7 except H₂O) in water, can be calculated for the binary acids listed in table 11.7 using available thermochemical data; $\Delta_{\text{bond}}H$ is the H—X bond energy (homolytic cleavage), $E_i(H)$ is the

ionisation energy of the gaseous hydrogen atom (1312 kJ mol^{-1}), E_{ea} is the electron affinity of $\text{X}(\text{g})$, and $\Delta_{\text{hyd}}H(\text{HX})$ is the hydration enthalpy (see the chapter on solutions and solubility) of gaseous HX .

FIGURE 11.13 A Hess's law cycle for the dissociation of an acid in aqueous solution

TABLE 11.7

Enthalpy and energy changes involved in the dissociation of a variety of acids in aqueous solution at 25 °C

Acid (HX)	$\Delta_{\text{bond}}H$ (kJ mol^{-1})	$E_{\text{i}}(\text{H}) + E_{\text{ea}}(\text{X})$ (kJ mol^{-1})	$\Delta_{\text{hyd}}H(\text{HX})$ (kJ mol^{-1})	ΔH_{acid} (kJ mol^{-1})
CH_4 (X = CH_3)	412	1303	-1583	132
NH_3 (X = NH_2)	388	1241	-1603	26
H_2O (X = OH)	463	1134	-1623	15 ^(a)
H_2S (X = SH)	338	1090	-1443	-15
HF (X = F)	565	990	-1613	-58
HCl (X = Cl)	431	963	-1470	-76
HBr (X = Br)	366	987	-1439	-86
HI (X = I)	299	1017	-1394	-78

^(a)To provide a meaningful comparison with the other acids, H_2O must be vaporised, a process which requires 41 kJ mol^{-1} . The final value of 15 kJ mol^{-1} includes this contribution.

Note: This approach is based on that of Fridgen, T. D., *J. Chem. Educ.*, 2008, 85, 1220.

It can be seen, from the data in table 11.7, that the trends in the ΔH_{acid} values correlate well with the acid strengths; as ΔH_{acid} becomes less positive (more negative), the acid strength increases. It can also be seen that no single contributing factor to ΔH_{acid} is primarily responsible for the observed trend in acid strengths. While it may be tempting to attribute the increasing acidity in the monoprotic acids from HF to HI to the significant decrease in $\Delta_{\text{bond}}H$, this is almost exactly opposed by the decrease in $\Delta_{\text{hyd}}H$ values. Similarly, an increase in electron affinity of X does appear to correlate well with an increase in acidity, but this breaks down for HBr and HI. It should also be noted that the above approach neglects entropic effects, which will undoubtedly contribute to the overall energetics of the acid dissociation process.

Having said this, two general observations concerning the acid strength of binary acids can be made.

1. The acid strength of binary acids increases going across a period (e.g. $\text{CH}_4 < \text{NH}_3 < \text{H}_2\text{O} < \text{HF}$).
2. The acid strength of binary acids increases going down a group (e.g. $\text{HF} < \text{HCl} < \text{HBr} < \text{HI}$).

The first observation has been attributed to the increasing electronegativity of X, rendering the H—X bond more polar, while the second has been explained by the increasing size of X, making the H—X bond longer and, therefore, weaker. As the data in table 11.7 show, however, such simple interpretations should be treated with caution, and are generally best avoided.

PRACTICE EXERCISE 11.18

Using only the periodic table, choose the stronger acid of each of the following pairs.

- (a) H_2Se or HBr
 (b) H_2Se or H_2Te
 (c) CH_3OH or CH_3SH

Oxoacids

Acids composed of hydrogen, oxygen and some other element are called oxoacids (see table 11.8). Those that are strong acids in water are marked in the table by asterisks.

TABLE 11.8 Some oxoacids of nonmetals and metalloids^(a, b)

Formula	Name	Formula	Name
Group 14		Group 17	
H_2CO_3 ((HO) ₂ CO)	carbonic acid ^(c)	HOF	hypofluorous acid ^(f)
Group 15		$^*\text{HClO}_4$ ((HO)ClO ₃)	perchloric acid
$^*\text{HNO}_3$ (HONO ₂)	nitric acid	$^*\text{HClO}_3$ ((HO)ClO ₂)	chloric acid
HNO_2 (HONO)	nitrous acid	HClO_2 (HOClO)	chlorous acid
H_3PO_4 ((HO) ₃ PO)	phosphoric acid	HOCl	hypochlorous acid
H_3PO_3 ((HO) ₂ P(H)(O))	phosphonic acid	$^*\text{HBrO}_4$ ((HO)BrO ₃)	perbromic acid ^(g)
H_3AsO_4 ((HO) ₃ AsO)	arsenic acid	$^*\text{HBrO}_3$ (HO)BrO ₂)	bromic acid
H_3AsO_3	arsenous acid ^(d)	HOBr	hypobromous acid
Group 16		HIO_4 ((HO)IO ₃)	periodic acid
$^*\text{H}_2\text{SO}_4$ ((HO) ₂ SO ₂)	sulfuric acid	H_5IO_6 ((HO) ₅ IO) ^(h)	orthoperiodic acid
H_2SO_3 ((HO) ₂ SO)	sulfurous acid ^(e)	HOI	hypoiodous acid
$^*\text{H}_2\text{SeO}_4$ ((HO) ₂ SeO ₂)	selenic acid	HIO_3 ((HO) ₂ IO)	iodic acid
H_2SeO_3 ((HO) ₂ SeO)	selenous acid		

^(a) The molecular formulae of the acids in parentheses emphasise the actual structure of each acid. All oxoacids have an —OH group bonded to some central atom.

^(b) Strong acids are marked with asterisks

^(c) Predominantly $\text{CO}_2(\text{aq})$

^(d) The structure of arsenous acid is currently unknown.

^(e) An aqueous solution actually contains just dissolved sulfur dioxide, $\text{SO}_2(\text{aq})$.

^(f) Unstable at room temperature

^(g) Pure perbromic acid is unstable; a dihydrate is known

^(h) H_5IO_6 is formed from $\text{HIO}_4 + 2\text{H}_2\text{O}$

A feature common to the structures of all oxoacids is the presence of O—H groups bonded to some central atom. For example, the structures of two oxoacids of the group 16 elements are as follows.

As with the binary acids, several observations about the acid strengths of oxoacids can be made.

1. *Within groups of oxoacids with the same number of oxygen atoms, the acid strength increases going up a group.* This is best illustrated by oxoacids containing group 17 elements. The hypohalous acids, all of which are weak, increase in strength in the order $\text{HOI} < \text{HOBr} < \text{HOCl}$, with $\text{p}K_{\text{a}}$ values of 10.64, 8.68 and 7.52, respectively. (Note that HOF is unstable, decomposing rapidly at room temperature.) For the strong group 17 oxoacids with the general formula HXO_4 , the order of acid strength is $\text{HIO}_4 < \text{HBrO}_4 < \text{HClO}_4$. (Note that HFO_4 is unknown, as F cannot accommodate more than an octet of electrons.) Similarly, in the group 16 acids, we find that H_2SeO_4 is weaker than H_2SO_4 (the third member of this series, ' H_2TeO_4 ' actually exists as $\text{Te}(\text{OH})_6$ and does not therefore provide a valid comparison); in group 15, H_3AsO_4 ($\text{p}K_{\text{a}} = 2.25$) is slightly weaker than H_3PO_4 ($\text{p}K_{\text{a}} = 2.15$).

PRACTICE EXERCISE 11.19

Which would be predicted to be the stronger acid, H_3AsO_3 or H_3PO_3 ?

2. *Within groups of oxoacids with the same number of oxygen atoms, the acid strength increases across a period.* This can be seen in oxoacids containing period 3 elements, where acid strength increases in the order $\text{H}_3\text{PO}_4 < \text{H}_2\text{SO}_4 < \text{HClO}_4$.
3. *Acid strength increases as the number of lone oxygen atoms increases.* (A lone oxygen atom is one that is bonded only to the central atom and not a hydrogen atom.) There are numerous examples that demonstrate this observation. For example, nitrous acid, HNO_2 , which contains one lone oxygen atom, is a weak acid ($\text{p}K_{\text{a}} = 3.15$) while nitric acid, HNO_3 , is a strong acid.

A similar situation is seen with selenous acid, H_2SeO_3 , and selenic acid, H_2SeO_4 , where the latter, having two lone oxygen atoms, is a much stronger acid.

Among oxoacids of the halogens, we find the same trend in acid strengths. For the oxoacids of chlorine, for instance, we find the following trend.

Comparing their structures we have the following.

The acid-strengthening effect of lone oxygen atoms is not limited to inorganic oxoacids. Consider, for example, ethanol and acetic acid.

Ethanol displays negligible acid properties in water ($pK_a = 15.9$). However, incorporation of a lone oxygen atom as a replacement for two protons yields acetic acid, which is eleven orders of magnitude (one hundred billion times) more acidic ($pK_a = 4.74$). This enormous increase in acidity has been ascribed in part to the differing stabilities of the respective conjugate bases, which is governed by their ability to delocalise the negative charge arising from the loss of a proton. The acetate ion can be drawn as two equivalent resonance structures (see the chapter on chemical bonding and molecular structure), with the negative charge on either of the carboxylate O atoms. The actual structure of the acetate ion lies somewhere between these two forms, with the negative charge delocalised over the two O atoms and the carboxylate carbon atom.

This ‘spreading out’ or **resonance stabilisation** of the negative charge results in a lowering in energy relative to the situation where the charge is localised on a single atom. The ethoxide ion cannot undergo such resonance stabilisation, and we therefore expect ethanol to be a weaker acid than acetic acid. An analogous situation occurs in the oxoacids of main-group elements. Consider the acids H_2SO_4 and H_3PO_4 .

As you can see in their structures, H_2SO_4 has two lone oxygen atoms and H_3PO_4 has only one. Loss of a proton from each gives the following species.

In oxoanions such as these, the lone oxygen atoms carry most of the negative charge, rather than the oxygen atoms bonded to hydrogen atoms. This charge actually spreads over the lone oxygen atoms. In HSO_4^- , therefore, each lone oxygen atom carries a charge of about $\frac{1}{3}-$. By the same reasoning, in H_2PO_4^- each lone oxygen atom carries a charge of about $\frac{1}{2}-$. The smaller negative charge on the lone oxygen atoms in HSO_4^- makes this ion less able to attract H_3O^+ ions, so HSO_4^- is a weaker base than H_2PO_4^- . In other words, HSO_4^- cannot become H_2SO_4 again as readily as H_2PO_4^- can become H_3PO_4 . There are thus two factors that make H_2SO_4 a stronger acid than H_3PO_4 in water. One is the greater tendency of H_2SO_4 to donate a proton and the other is the lesser tendency of HSO_4^- to accept a proton.

PRACTICE EXERCISE 11.20

Predict the stronger acid in each pair.

(b) H_3AsO_3 or H_3AsO_4

CHEMICAL CONNECTIONS

The strongest acid and the strongest base

In this chapter, we have discussed the concept of acid and base strength, and we have related this to the extent to

which the acid or base donates a proton to, or accepts a proton from, water. The obvious question that then arises is: what is the strongest acid and what is the strongest base? In water, the answer to this question is, as we have seen, H_3O^+ and OH^- . However, if we use different experimental

conditions, then we find that much stronger acids and bases exist. Of these, both the strongest acid and strongest base have an Australasian connection.

In 2004, Professor Christopher Reed, an expatriate New Zealand Professor of Chemistry at the University of California at Riverside, in the USA, published a paper with a number of colleagues titled 'The strongest isolable acid'. The acid in question is a carborane, a molecule with a framework comprising carbon and boron atoms, and has the chemical formula $\text{H}(\text{CHB}_{10}\text{Cl}_{11})$. The structure of this acid, which is a solid at room temperature, is shown in figure 11.14. The extraordinary acid strength of $\text{H}(\text{CHB}_{10}\text{Cl}_{11})$ was quantified using NMR (nuclear magnetic resonance) and IR (infrared) spectroscopies and these techniques showed it to be at least 1 million times stronger than sulfuric acid.

Ten years later, in 2014, Reed and coworkers reported an even stronger acid, $\text{H}(\text{CHB}_{10}\text{F}_{11})$, which was found to protonate CO_2 to give the $\text{H}(\text{CO}_2)_2^+$ ion. $\text{H}(\text{CHB}_{10}\text{F}_{11})$ remains the strongest known acid at the time of publication.

The strongest known base is the ortho-diethynylbenzene dianion, $\text{C}_{10}\text{H}_4^{2-}$, which has the structure shown below.

In 2016, workers from the Queensland University of Technology, the University of Wollongong, the Australian National University, and the University of Sydney, using a combination of mass spectrometry and sophisticated computational techniques, demonstrated that, in the gas phase, the ortho-diethynylbenzene dianion was a stronger base than LiO^- , the previous strongest gas-phase base.

In contrast to the strongest acid discussed above, the gas-phase ortho-diethynylbenzene dianion cannot be put in a bottle, so its extreme basicity cannot be exploited in the chemistry laboratory. It was, however, 'isolated' in a mass spectrometer, making it a real chemical species.

Extraordinarily strong acids and bases (superacids and superbases) are not merely scientific curiosities. Indeed, the Hungarian-born US chemist George Olah was awarded the Nobel Prize in chemistry in 1994 for his seminal work in the field of superacids, results of which found significant applications in the petrochemical industry.

FIGURE 11.14

Representation of the structure of a carborane acid with the chemical formula $\text{H}(\text{CHB}_{10}\text{Cl}_{11})$. The chlorine atoms are green, the boron atoms are pink, the carbon atom is black and the hydrogen atoms are white.

11.6 Buffer solutions

LEARNING OBJECTIVE 11.6 Perform calculations involving buffer solutions.

The control and maintenance of pH is crucial in many chemical and biological systems. For example, if the pH of your blood, which is typically 7.35 to 7.42, were to change to either 7.00 or 8.00, you would die. Fortunately, nature has developed a sophisticated chemical system, called a buffer, which maintains blood pH within the vital limits. Figure 11.15 shows another application of a buffer.

A **buffer solution** is one that contains appreciable amounts of both a weak acid and its conjugate base, or a weak base and its conjugate acid. As a result of this, a buffer solution resists change in pH after the addition of small amounts of either acid or base, and also on moderate dilution. The pH values over which a buffer is effective at maintaining the pH are determined by either the $\text{p}K_a$ or $\text{p}K_b$ of the weak acid or weak base, respectively, and the ratio of the concentrations of conjugate pairs present in the solution.

pH calculations in buffer solutions

We will first consider an aqueous buffer solution containing equal amounts of a weak acid HA and its conjugate base A^- . A buffer solution works by being able to react to neutralise added H_3O^+ or OH^- .

FIGURE 11.15

A practical application of a buffer. Baking soda, which is sodium bicarbonate, is sometimes added to swimming pools to control the pH of the water.

If we add a source of H_3O^+ to the above solution, it will react with A^- to form HA.

If we add OH^- to the buffer solution, it will react with HA to form A^- .

Both reactions serve to ‘mop up’ any added acid or base, which means that the pH of the solution remains relatively constant. We can calculate the pH of buffer solutions, both before and after the addition of either acid or base, by application of the methods we have learned so far. Consider, for example, a buffer solution containing acetic acid, CH_3COOH , and sodium acetate, NaOOCCH_3 . Addition of acid to this solution will cause the following reaction to occur.

Added base will be neutralised as follows.

Worked example 11.17 shows how we carry out calculations involving the pH of buffer solutions.

WORKED EXAMPLE 11.17

Calculating the pH of a buffer

To study the effects of a weakly acidic medium on the rate of corrosion of a metal alloy, a student prepared an aqueous buffer solution by dissolving 0.11 mol of NaOOCCH_3 in the minimum volume of water, adding 0.090 mol of CH_3COOH , and making the resulting solution up to 1.00 L with water. What is the pH of this solution at 25 °C?

Analysis

The buffer solution contains both the weak acid CH_3COOH and its conjugate base CH_3COO^- , and we are given the concentrations of both. We can solve the problem by using either K_a for CH_3COOH or K_b for CH_3COO^- . We will show in detail how to use the former, and will look at the latter in practice exercise 11.21. We begin by looking up the value of K_a for CH_3COOH . Then we will set up a concentration table and solve for $[\text{H}_3\text{O}^+]$ using the simplifying approximations developed earlier.

Solution

We begin with the balanced equilibrium equation and the expression for K_a .

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = 1.8 \times 10^{-5}$$

We set up the concentration table and take the initial concentrations of CH_3COOH and CH_3COO^- to be the values given in the problem. We assume the initial $[\text{H}_3\text{O}^+] = 0$ and therefore this must increase by $+x$ as the reaction proceeds to equilibrium. The other changes follow from that. The completed table is shown below.

	H_2O	+	CH_3COOH	$\rightleftharpoons$	H_3O^+	+	CH_3COO^-
Initial concentration (mol L^{-1})			0.090		0		0.11
Change in concentration (mol L^{-1})			$-x$		$+x$		$+x$
Equilibrium concentration (mol L^{-1})			$0.090 - x$		x		$0.11 + x$

While this concentration table might look similar to those we have used in weak acid calculations, it differs in one very important aspect. Because appreciable amounts of the conjugate base are present in the initial solution, this will then function as a common ion. The result of this will be that the dissociation of the weak acid will be suppressed. (This is analogous to the lower solubility of slightly soluble salts in solutions containing a common ion, which we described in the chapter on solutions and solubility.) Therefore, the quantity x will be very small and we can safely assume that $(0.090 - x) \approx 0.090$ and $(0.11 + x) \approx 0.11$. Substituting these quantities into the K_a expression gives the following.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = \frac{(x)(0.11 + x)}{0.090 - x} \approx \frac{(x)(0.11)}{0.090} = 1.8 \times 10^{-5}$$

We solve for x as follows.

$$\begin{aligned} 0.11x &= (0.090)(1.8 \times 10^{-5}) \\ x &= \frac{(0.090)(1.8 \times 10^{-5})}{0.11} = 1.5 \times 10^{-5} \end{aligned}$$

Because x equals $[\text{H}_3\text{O}^+]$, we now have $[\text{H}_3\text{O}^+] = 1.5 \times 10^{-5} \text{ mol L}^{-1}$. We then calculate the pH.

$$\text{pH} = -\log[\text{H}_3\text{O}^+] = -\log(1.5 \times 10^{-5}) = 4.82$$

Thus the pH of the buffer is 4.82.

Is our answer reasonable?

We can check the answer in the usual way by substituting our calculated equilibrium values into the expression for K_a .

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = \frac{(1.5 \times 10^{-5})(0.11)}{0.090} = 1.8 \times 10^{-5}$$

This equals K_a , so the values we have obtained are correct equilibrium concentrations.

PRACTICE EXERCISE 11.21

Calculate the pH of the buffer solution described in worked example 11.17 by using the K_b for CH_3COO^- . Be sure to write the equilibrium equation as the reaction of CH_3COO^- with water. Then use the equilibrium equation

as a guide in setting up the equilibrium expression for K_b . If you work through the problem correctly, you should obtain the same answer as above.

We can rearrange the expression for K_a into a form that is particularly useful for calculations involving buffer solutions, and which also removes the need to write a concentration table for each calculation.

We know that, for the equilibrium:

we can write K_a as shown.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]}$$

If we multiply both sides of the equation by $[\text{HA}]$ and divide both sides by $[\text{A}^-]$, we obtain:

$$[\text{H}_3\text{O}^+] = K_a \frac{[\text{HA}]}{[\text{A}^-]}$$

If we take the negative logarithm (p) of both sides, realising that the logarithm of a product of two numbers is the sum of the logarithms of those numbers, and that $-\log \frac{x}{y} = \log \frac{y}{x}$, we obtain:

$$\text{pH} = \text{p}K_{\text{a}} + \log \frac{[\text{A}^-]}{[\text{HA}]}$$

This rearrangement of the K_{a} expression is called the **Henderson–Hasselbalch equation**. This form of the K_{a} expression emphasises the fact that the pH of a buffer solution depends on both the $\text{p}K_{\text{a}}$ of the weak acid and the ratio of conjugate base to acid. Recalling that $c = \frac{n}{V}$, we can rewrite the equation as:

$$\text{pH} = \text{p}K_{\text{a}} + \log \left(\frac{\frac{n_{\text{A}^-}}{V}}{\frac{n_{\text{HA}}}{V}} \right)$$

Because the volume of the buffer solution is constant, the V terms will cancel, and therefore:

$$\text{pH} = \text{p}K_{\text{a}} + \log \frac{n_{\text{A}^-}}{n_{\text{HA}}}$$

Therefore, we can express this relationship in terms of either a concentration ratio or a mole ratio. Note that, under the special condition where $[\text{HA}] = [\text{A}^-]$ (or $n_{\text{HA}} = n_{\text{A}^-}$), $\frac{[\text{A}^-]}{[\text{HA}]} = 1$, $\log(1) = 0$, and therefore $\text{pH} = \text{p}K_{\text{a}}$.

A further consequence of the relationship derived above is that the pH of a buffer should not change if the buffer undergoes moderate dilution. Dilution changes the volume of a solution but it does not change the amounts of the solutes, so their mole ratio remains constant and so does $[\text{H}_3\text{O}^+]$.

WORKED EXAMPLE 11.18

Calculating the pH of an ammonia/ammonium ion buffer

To study the influence of an alkaline medium on the rate of a reaction, a student prepared a buffer solution by dissolving 0.12 mol of NH_3 and 0.095 mol of NH_4Cl in the minimum volume of water, and making the solution up to 250 mL with water. What is the pH of the buffer at 25 °C?

Analysis

The pH of the buffer is determined by the mole ratio of the members of the acid–base pair; so to calculate the pH we use the amounts of NH_3 and NH_4^+ directly in the Henderson–Hasselbalch equation. We also require the $\text{p}K_{\text{a}}$ of NH_4^+ .

Solution

Given that $\text{p}K_{\text{a}}(\text{NH}_4^+) = 9.26$, we can insert the values directly into the Henderson–Hasselbalch equation.

$$\text{pH} = \text{p}K_{\text{a}} + \log \frac{n_{\text{A}^-}}{n_{\text{HA}}} = 9.26 + \log \frac{0.12}{0.095} = 9.36$$

Note that we assumed that the initial concentrations of the acid and conjugate base are the equilibrium concentrations. Because of the common ion effect, as discussed above, we are usually justified in doing this.

Is our answer reasonable?

The ratio $\frac{[\text{A}^-]}{[\text{HA}]}$ (or $\frac{n_{\text{A}^-}}{n_{\text{HA}}}$, depending on which version of the equation is used), determines whether the pH of the buffer solution will be greater than, less than, or, as we have seen, equal to the $\text{p}K_{\text{a}}$. If the ratio is greater than 1, then the log of the ratio will be positive, and we would therefore expect the pH to be greater than the $\text{p}K_{\text{a}}$; that is:

$$\text{pH} = \text{p}K_{\text{a}} + (\text{positive})$$

This is to be expected, as a ratio of greater than 1 means that there is more conjugate base (A^-) than acid (HA) present in the solution.

Similarly, if the ratio is less than 1, then the log of the ratio will be negative, and we would expect the pH to be less than the $\text{p}K_{\text{a}}$; that is:

$$\text{pH} = \text{p}K_{\text{a}} + (\text{negative})$$

This again makes sense, as a ratio of less than 1 means more acid (HA) is present than conjugate base (A^-).

In this example, the ratio is greater than 1, so our answer should be greater than the $\text{p}K_{\text{a}}$, which it is.

PRACTICE EXERCISE 11.22

Determine the pH of the buffer in worked example 11.18 when $[\text{NH}_3] = 0.08 \text{ mol L}^{-1}$ and $[\text{NH}_4\text{Cl}] = 0.15 \text{ mol L}^{-1}$.

Buffer solutions function most efficiently when the ratio $\frac{[A^-]}{[HA]}$ is close to 1. When this is the case, the concentrations of both the weak acid and its conjugate base are essentially equal, and the buffer can therefore resist change in pH on the addition of either acid or base. As we showed above, when $\frac{[A^-]}{[HA]} = 1$, $pH = pK_a$, and therefore the pK_a of the weak acid determines where, on the pH scale, a buffer can work best. Thus, to prepare a specific buffer for use at a particular pH, we first select a weak acid with a pK_a near the desired pH. Then, by experimentally adjusting the ratio $\frac{[A^-]}{[HA]}$, we can make a final adjustment to obtain the desired pH.

If the ratio $\frac{[A^-]}{[HA]}$ is significantly different from 1, then the concentrations of the weak acid and its conjugate base in solution are no longer similar. If, for example, $[HA] > [A^-]$, the buffer will resist change in pH well on the addition of base, but it will be less effective at resisting change in pH on addition of acid, as there is less A^- present for the added acid to react with. Once all the A^- has reacted, the pH of the solution will change rapidly. As long as the ratio $\frac{[A^-]}{[HA]}$ in a buffer solution is between $\frac{1}{10}$ and $\frac{10}{1}$, the buffer will maintain pH effectively. If we substitute these values into the Henderson–Hasselbalch equation, we obtain $pH = pK_a - 1$ and $pH = pK_a + 1$, respectively. This means that the operational range of any buffer is 1 pH unit either side of the pK_a of the weak acid, i.e. $pH = pK_a \pm 1$.

WORKED EXAMPLE 11.19

Preparing a buffer solution with a predetermined pH

A solution buffered at a pH of 5.00 is needed in an experiment. Can we use acetic acid and sodium acetate to prepare the buffer? If so, what amount of $NaOOCCH_3$ must be added to 1.0 L of an aqueous solution that contains 1.0 mol CH_3COOH at 25 °C?

Analysis

There are two parts to this problem. To answer the first, we check the pK_a of acetic acid to see if it is in the desired range of $pH = pK_a \pm 1$. If it is, we can calculate the necessary mole ratio. Once we have this, we can proceed to calculate the amount of CH_3COO^- needed and then the amount of $NaOOCCH_3$.

Solution

The pK_a of acetic acid (4.74) falls in the desired range and therefore acetic acid can be used with the acetate ion to make the buffer.

We find the required mole ratio of solutes by using the Henderson–Hasselbalch equation.

$$pH = pK_a + \log \frac{n_{A^-}}{n_{HA}}$$

$$5.00 = 4.74 + \log \frac{n_{CH_3COO^-}}{n_{CH_3COOH}}$$

Therefore:

$$\log \frac{n_{CH_3COO^-}}{n_{CH_3COOH}} = 0.26$$

and hence:

$$\frac{n_{CH_3COO^-}}{n_{CH_3COOH}} = 1.82$$

$$n_{CH_3COO^-} = 1.82 \times n_{CH_3COOH}$$

We know that $n_{CH_3COOH} = 1.0 \text{ mol}$ and $n_{CH_3COO^-} = 1.82 \text{ mol}$.

Because each mole of $NaOOCCH_3$ contains 1 mol of CH_3COO^- , we require 1.82 mol of $NaOOCCH_3$.

Is our answer reasonable?

A 1 : 1 mole ratio of CH_3COO^- to CH_3COOH would give $pH = pK_a = 4.74$. The desired pH of 5.00 is slightly more basic than 4.74, so the amount of conjugate base should be larger than the amount of conjugate acid. Our answer of 1.82 mol of $NaOOCCH_3$ appears to be reasonable.

PRACTICE EXERCISE 11.23

As part of a study into the rate of a particular chemical reaction, a student requires an aqueous buffer with a pH of 9.40. Why would a mixture of ammonia, NH_3 , and ammonium chloride, NH_4Cl , be suitable for buffering at this pH? What

mole ratio of ammonia to ammonium chloride is needed? What mass of NH_4Cl would have to be added to a solution that contains 0.10 mol NH_3 at 25 °C?

In the examples outlined so far, we have prepared buffer solutions by mixing a weak acid with the salt of its conjugate base, and vice versa. Buffer solutions can also be prepared by adding less than stoichiometric

amounts of a strong base to a solution of a weak acid, or less than stoichiometric amounts of a strong acid to a solution of a weak base. Both of these processes will give rise to a solution containing appreciable amounts of a weak acid and its conjugate base. The preparation of such a buffer solution is illustrated in worked example 11.20.

WORKED EXAMPLE 11.20

Preparing a buffer solution using a weak acid and a strong base

What will be the pH of the buffer solution resulting from the addition of 20.00 mL of 0.14 mol L⁻¹ NaOH(aq) to 100.0 mL of 0.050 mol L⁻¹ CH₃COOH(aq)?

Analysis

We are adding NaOH(aq) to an aqueous solution of CH₃COOH. This will result in the formation of the CH₃COO⁻ conjugate base. We will therefore start with a balanced chemical equation, determine the amount of NaOH added, and then calculate the amounts of both CH₃COOH and CH₃COO⁻ in the solution after the addition of the base. We can then use the Henderson–Hasselbalch equation to obtain the pH of the solution.

Solution

The reaction that will occur on addition of NaOH to CH₃COOH is:

We calculate the amount of CH₃COOH in the initial solution and the amount of NaOH added.

$$n_{\text{CH}_3\text{COOH}} = cV = 0.050 \text{ mol L}^{-1} \times 0.1000 \text{ L} = 0.0050 \text{ mol}$$

$$n_{\text{NaOH}} = cV = 0.14 \text{ mol L}^{-1} \times 0.02000 \text{ L} = 0.0028 \text{ mol}$$

From the balanced chemical equation, we can see that 0.0028 mol of NaOH will react completely with 0.0028 mol of CH₃COOH to form 0.0028 mol of CH₃COO⁻. This means that the final buffer solution will contain 0.0028 mol CH₃COO⁻ and (0.0050 – 0.0028) = 0.0022 mol CH₃COOH.

We can now plug these values into the Henderson–Hasselbalch equation.

$$\text{pH} = \text{p}K_{\text{a}} + \log \frac{n_{\text{A}^-}}{n_{\text{HA}}} = 4.74 + \log \frac{0.0028}{0.0022} = 4.84$$

Is our answer reasonable?

We have calculated that the final solution contains slightly more conjugate base than weak acid. This means we would expect the pH to be slightly greater than the pK_a (4.74), as the value of the log term in the equation will be small and positive. Our answer is therefore reasonable.

Once we have prepared a buffer solution, we can calculate the pH change on addition of a specified amount of strong acid or base by assuming that the added strong acid or base reacts quantitatively with the weak acid or base component of the buffer solution. This is illustrated in worked example 11.21.

WORKED EXAMPLE 11.21

Calculating the pH change in a buffer solution

What pH change will occur after the addition of 0.10 L of 0.10 mol L⁻¹ HCl(aq) to 1.0 L of an aqueous buffer solution containing 0.10 mol CH₃COOH and 0.10 mol NaOOCCH₃ at 25 °C?

How does this compare with the pH change that would occur after the addition of the same amount of HCl to 1.0 L of pure water?

Analysis

We are asked for a pH *change*, which means we must calculate the pH of the initial buffer solution. We then calculate the amount of HCl added and assume that this reacts completely with CH₃COO⁻ to form CH₃COOH. We then use the new amounts of CH₃COO⁻ and CH₃COOH in the Henderson–Hasselbalch equation to calculate the final pH. The question involving pure water is a straightforward calculation of the pH of a strong acid.

Solution

The initial pH is obtained from the initial [CH₃COOH] and [CH₃COO⁻] values using the Henderson–Hasselbalch equation.

$$\text{pH} = \text{p}K_{\text{a}} + \log \frac{[\text{A}^-]}{[\text{HA}]} = 4.74 + \log \frac{0.1}{0.1} = 4.74$$

We now carry out a stoichiometric calculation to determine the equilibrium $n_{\text{CH}_3\text{COOH}}$ and $n_{\text{CH}_3\text{COO}^-}$ values. The reaction that will occur on addition of the strong acid is shown below.

We assume this reaction goes to completion, so that:

$$n_{\text{HCl(added)}} = n_{\text{CH}_3\text{COO}^-(\text{used})} = n_{\text{CH}_3\text{COOH(formed)}}$$

$$n_{\text{HCl(added)}} = c \times V = 0.10 \text{ mol L}^{-1} \times 0.10 \text{ L} = 0.010 \text{ mol}$$

Therefore, 0.010 mol HCl(aq) reacts with 0.010 mol CH₃COO⁻(aq) to form 0.010 mol CH₃COOH(aq). Initially we

had 0.10 mol CH_3COOH and 0.10 mol CH_3COO^- , and so the final amounts following addition of the strong acid are as follows.

$$n_{\text{CH}_3\text{COOH}(\text{final})} = 0.10 \text{ mol} + 0.010 \text{ mol} = 0.11 \text{ mol}$$

$$n_{\text{CH}_3\text{COO}^-(\text{final})} = 0.10 \text{ mol} - 0.010 \text{ mol} = 0.090 \text{ mol}$$

We now substitute these values into the Henderson-Hasselbalch equation.

$$\text{pH} = 4.74 + \log \frac{0.090}{0.11} = 4.65$$

Therefore, the *change* in pH is -0.09 pH units, the negative sign showing that this is a decrease in pH.

When we add 0.10 L of 0.10 mol L^{-1} HCl to 1.0 L of water, the final solution contains 0.010 mol HCl in 1.1 L. As HCl is

a strong acid, it reacts completely with water to form H_3O^+ and hence:

$$[\text{H}_3\text{O}^+] = \frac{0.010 \text{ mol}}{1.1 \text{ L}} = 0.0091 \text{ mol L}^{-1}$$

Thus:

$$\text{pH} = -\log[\text{H}_3\text{O}^+] = -\log(0.0091) = 2.04$$

We started with pure water, and so the initial pH was 7.00. Hence, the pH change is -4.96 pH units.

Is our answer reasonable?

We started with the buffer solution at pH 4.74 and added a small amount of strong acid to it. We expect that the final pH should be slightly less than this, which it is.

CHEMICAL CONNECTIONS

Buffers in biological systems

As we stated at the start of section 11.6, it is crucial that the pH of our blood is kept within certain limits. Indeed, this is true not only of our blood, but of the majority of our bodily fluids — the pH of the fluid inside our cells (the intracellular fluid) needs to be maintained at a nearly constant value while chemical reactions involving the consumption and release of H_3O^+ ions are occurring at rapid rates. So how does nature accomplish this? Not surprisingly, through the use of buffers.

The $\text{H}_2\text{PO}_4^-/\text{HPO}_4^{2-}$ buffer system is particularly important in the intracellular fluid, as well as in the urine. The H_2PO_4^- anion has a pK_a of 7.20, meaning that the $\text{H}_2\text{PO}_4^-/\text{HPO}_4^{2-}$ system will act as an effective buffer around this pH, as both H_2PO_4^- and HPO_4^{2-} will be present in significant amounts.

The $\text{H}_2\text{CO}_3/\text{HCO}_3^-$ buffer system aids in regulating the pH of blood and the extracellular fluid (the fluid outside our cells). Although we write the formula H_2CO_3 and call the molecule 'carbonic acid', as you will see in the chapter on the *p*-block elements, H_2CO_3 should be thought of as predominantly $\text{CO}_2(\text{g})$ dissolved in water. The apparent pK_a of H_2CO_3 is 6.35, which means it should not be a good buffer at all for pH values around 7.4. However, the actual buffering process is rather complicated; the fact that the body can independently regulate both the partial pressure of CO_2 (and hence $[\text{H}_2\text{CO}_3]$) and $[\text{HCO}_3^-]$ renders this buffer system ideal for blood.

Other buffers in our body include the $\text{NH}_4^+/\text{NH}_3$ system, bone, in the form of CaCO_3 , and a variety of proteins, of which one important example is haemoglobin. Proteins act as buffers around physiological pH because of the presence of the amino acid histidine (His). The sidechain of this amino acid contains an imidazole ring, which acts as a weak base through use of its non-protonated N atom to accept a proton from water. The pK_a of the conjugate acid of imidazole is 7.00, which makes this group perfect for buffering biological systems. Therefore, proteins with high numbers of histidine residues can be very good buffers around pH 7.

All of the buffers discussed above are necessary to keep what in reality are tiny concentrations of H_3O^+ constant, thereby keeping us alive.

PRACTICE EXERCISE 11.24

Calculate the pH change on the addition of 0.10 L of 0.10 mol L^{-1} NaOH(aq) to 1.0 L of an aqueous buffer solution containing 0.080 mol $\text{NH}_3(\text{aq})$ ($\text{pK}_b = 4.74$) and 0.12 mol $\text{NH}_4\text{Cl}(\text{aq})$ at 25°C .

Worked example 11.21 illustrates the effectiveness of a buffer solution. When the strong acid is added to water, the solution becomes 4.96 pH units more acidic, whereas the buffer solution is little affected, becoming only 0.09 pH units more acidic.

If enough strong acid is added to react with all of the base component of a buffer solution, the mixture is no longer able to neutralise any more strong acid. We can illustrate this with reference to worked example 11.21. Initially there is 0.10 mol CH_3COO^- in the buffer solution; if 0.10 mol HCl is added, this will react completely with the 0.10 mol CH_3COO^- to give 0.10 mol CH_3COOH . When this happens, the concentration of CH_3COO^- is very small (all of the CH_3COO^- in solution at this point will come from dissociation of CH_3COOH) and the solution no longer functions as a buffer towards the addition of more acid. Similarly, if we added 0.10 mol NaOH to the original buffer solution in the example, it would react completely with the 0.10 mol CH_3COOH present to form 0.10 mol CH_3COO^- , thereby leaving essentially no CH_3COOH in the solution to react with any further added NaOH. This means that there is a limit to the amount of added acid or base that a buffer solution can absorb. The **buffer capacity** of any buffer is a measure of the amount of H_3O^+ or OH^- that can be added without significant change in the pH. In the example, the addition of ~ 0.10 mol HCl or ~ 0.10 mol NaOH would exhaust the capacity of the buffer solution.

11.7 Acid–base titrations

LEARNING OBJECTIVE 11.7 Analyse acid–base titrations.

We often encounter solutions of acid or bases with unknown concentrations in chemistry. One method of determining the concentration of an acid or a base is to carry out an **acid–base titration** (figure 11.16). This involves gradual addition of an acid or base of known concentration (the **titrant**) from a **burette** to an accurately known volume of the unknown solution. An **acid–base indicator** changes colour when the **endpoint** of the titration is reached, and, if we have chosen the indicator correctly, the endpoint will be a good approximation of the **equivalence point** of the titration. The equivalence point is the point at which the reaction stoichiometry is satisfied, or, in other words, where the amount of titrant added exactly equals the amount of acid or base initially present. The equivalence point is sometimes called the stoichiometric point. In all acid–base titrations, regardless of the strengths of the acid or base involved, the essential reaction that occurs is shown below.

FIGURE 11.16 An acid–base titration

Knowledge of both the stoichiometry of the reaction and the volume of acid or base added allows us to calculate the concentration of the unknown solution. We will now examine acid–base titrations in a little more detail, with particular emphasis on the variations in pH that occur as the titrations proceed.

Strong acid – strong base and strong base – strong acid titrations

Figure 11.17 shows a plot of pH versus volume of titrant added for the titration of 25.00 mL of 0.200 mol L⁻¹ HCl(aq) with 0.200 mol L⁻¹ NaOH(aq). We call such a plot a **titration curve**, and it has the same general shape for the titration of any strong acid with any strong base. Likewise, the titration curve for the titration of 25.00 mL of 0.200 mol L⁻¹ NaOH with 0.200 mol L⁻¹ HCl is depicted in figure 11.18, and this too is general for the titration of any strong base with any strong acid.

FIGURE 11.17

Titration curve for the titration of a strong acid with a strong base. Here we follow how the pH changes during the titration of 25.00 mL of 0.200 mol L⁻¹ HCl(aq) with 0.200 mol L⁻¹ NaOH(aq).

FIGURE 11.18

Titration curve for the titration of a strong base with a strong acid (25.00 mL of 0.200 mol L⁻¹ NaOH(aq) with 0.200 mol L⁻¹ HCl(aq))

We will consider the strong acid – strong base (note that the titrant comes last when describing a titration) titration curve in detail, realising that analogous arguments apply for the strong base – strong acid titration.

There are four important points and regions to consider for a strong acid – strong base titration curve:

1. the initial pH
2. the acidic region
3. the equivalence point
4. the alkaline region.

The initial pH

The initial pH in a strong acid – strong base titration is the pH of the solution of strong acid being titrated. Because the acid is strong, it will react completely with water to generate H₃O⁺, and therefore we can calculate the pH by taking the negative logarithm of the acid concentration. For the titration curve in figure 11.17, the initial pH will be:

$$\text{pH} = -\log[\text{H}_3\text{O}^+] = -\log(0.200) = 0.70$$

The acidic region

In the acidic region, we are adding OH^- to a solution of H_3O^+ , and the essential reaction that occurs is:

As you can see from figure 11.17, the pH initially changes very slowly on addition of $\text{NaOH}(\text{aq})$, and it is not until the equivalence point is approached that the pH starts to increase significantly. In the acidic region, the solution contains H_3O^+ and Cl^- ions from the acid, and Na^+ ions from the added base, and the pH is governed by the amount of unreacted H_3O^+ in the solution. The concentration of H_3O^+ decreases as NaOH is added, and, at any point in this region, it can be calculated from the following equation where $c_{\text{H}_3\text{O}^+(\text{initial})}$ is the initial concentration of the acid, $c_{\text{OH}^-(\text{added})}$ is the concentration of the NaOH solution, V_{initial} is the initial volume of the acid solution, V_{added} is the volume of the NaOH solution added and V_{total} is the total volume of the solution ($V_{\text{total}} = V_{\text{initial}} + V_{\text{added}}$).

$$\begin{aligned} [\text{H}_3\text{O}^+] &= \frac{n_{\text{H}_3\text{O}^+(\text{initial})} - n_{\text{OH}^-(\text{added})}}{V_{\text{total}}} \\ &= \frac{(c_{\text{H}_3\text{O}^+(\text{initial})} \times V_{\text{initial}}) - (c_{\text{OH}^-(\text{added})} \times V_{\text{added}})}{V_{\text{total}}} \end{aligned}$$

Although this equation looks somewhat formidable, careful inspection reveals that it is merely $c = \frac{n}{V}$ in another form; the top line is the amount of H_3O^+ in the solution, calculated by subtracting the amount of OH^- added from the amount of H_3O^+ present initially. Notice that, even though the pH changes little on addition of NaOH in the acidic region, the resulting solution is not a buffer solution — the pH of this solution will change significantly on moderate dilution, in contrast to a solution containing significant amounts of a weak acid and its conjugate base.

The equivalence point

We defined the equivalence point as the point where the reaction stoichiometry is satisfied. This means that we have added exactly the same amount of OH^- as there was H_3O^+ in the initial solution of acid. As we originally had 25.00 mL of 0.200 mol L^{-1} HCl , this point occurs when we have added 25.00 mL of 0.200 mol L^{-1} NaOH . Therefore, at this point on the titration curve, the reaction shown below has gone to completion, and the solution contains only Na^+ and Cl^- ions in water.

The pH of the solution at the equivalence point is exactly 7.00, because Cl^- is the conjugate base of a very strong acid and therefore has essentially no basic properties. The pH at the equivalence point will *always* be 7.00 for the titration of any strong monoprotic acid with a strong base.

The alkaline region

Beyond the equivalence point, we are adding excess $\text{NaOH}(\text{aq})$ to a solution containing $\text{Na}^+(\text{aq})$ and $\text{Cl}^-(\text{aq})$, so there is no chemical reaction occurring. The pH in this region is governed by the amount of excess $\text{NaOH}(\text{aq})$ added to the solution and will always be > 7 . The concentration of OH^- , and hence the pH, can be calculated from the following equation where $c_{\text{OH}^-(\text{initial})}$ is the concentration of the NaOH solution, V_{added} is the total volume of NaOH solution added, $V_{\text{equiv.}}$ is the volume of NaOH solution added at the equivalence point (in this case, 25.00 mL) and V_{total} is the total volume of the solution.

$$\begin{aligned} [\text{OH}^-] &= \frac{n_{\text{OH}^-(\text{total})} - n_{\text{OH}^-(\text{equiv.})}}{V_{\text{total}}} \\ &= \frac{(c_{\text{OH}^-(\text{initial})} \times V_{\text{added}}) - (c_{\text{OH}^-(\text{initial})} \times V_{\text{equiv.}})}{V_{\text{total}}} \end{aligned}$$

The top line gives the amount of OH^- in excess of that required to reach the equivalence point; this is obtained by subtracting the amount of OH^- used to reach the equivalence point from the total amount of OH^- added.

Weak acid – strong base and weak base – strong acid titrations

Figure 11.19 shows the titration curve for the titration of 25.00 mL of 0.200 mol L^{-1} $\text{CH}_3\text{COOH}(\text{aq})$ with 0.200 mol L^{-1} $\text{NaOH}(\text{aq})$, while the titration curve for the titration of 25.00 mL of 0.200 mol L^{-1} NH_3 with

0.200 mol L⁻¹ HCl is given in figure 11.20. We will focus on the weak acid – strong base curve, realising that analogous arguments can be made for the weak base – strong acid case. As you can see, the weak acid – strong base curve looks rather different from the strong acid – strong base curve (figure 11.17), especially in the acidic region. We will again consider in detail the four important points and regions on this curve.

FIGURE 11.19

Titration curve for the titration of a weak acid with a strong base. In this titration, we follow the pH as 25.00 mL of 0.200 mol L⁻¹ CH₃COOH(aq) is titrated with 0.200 mol L⁻¹ NaOH(aq).

FIGURE 11.20

Titration curve for the titration of a weak base with a strong acid. Here we follow the pH as 25.00 mL of 0.200 mol L⁻¹ NH₃(aq) is titrated with 0.200 mol L⁻¹ HCl(aq).

The initial pH

The initial pH of 2.72 in this titration is significantly higher than that for the strong acid – strong base titration. This is to be expected as CH₃COOH is a weak acid and dissociates only to a small extent. We can calculate the initial pH of the acid solution in a weak acid – strong base titration with the method that was used for the calculation of the pH of a solution of a weak acid. We therefore set up a concentration table for a 0.200 mol L⁻¹ CH₃COOH solution. The balanced chemical equation is shown below.

The equilibrium constant expression is as follows.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = 1.8 \times 10^{-5}$$

The concentration table can then be written as follows.

	H ₂ O	+	CH ₃ COOH	⇌	H ₃ O ⁺	+	CH ₃ COO ⁻
Initial concentration (mol L ⁻¹)			0.200		0		0
Change in concentration (mol L ⁻¹)			-x		+x		+x
Equilibrium concentration (mol L ⁻¹)			0.200 - x		x		x

We make the usual assumption that x is small compared with 0.200, therefore $(0.200 - x) \approx 0.200$. Substituting the equilibrium concentrations into the equilibrium constant expression then gives the following.

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = \frac{(x)(x)}{0.200 - x} \approx \frac{x^2}{0.200} = 1.8 \times 10^{-5}$$

Solving for x gives:

$$x^2 = (0.200)(1.8 \times 10^{-5}) = 3.6 \times 10^{-6}$$

$$x = \sqrt{3.6 \times 10^{-6}} = 1.9 \times 10^{-3}$$

As $x = [\text{H}_3\text{O}^+]$, we obtain the pH of the solution by:

$$\text{pH} = -\log[\text{H}_3\text{O}^+] = -\log(1.9 \times 10^{-3}) = 2.72$$

The acidic region

The general shape of the titration curve in this region differs from that for the strong acid – strong base titration in that there is an initial rapid increase in pH. The curve also lies at higher pH values than the analogous points of the strong acid – strong base titration. While the only reaction of note in the strong acid – strong base titration was $\text{H}_3\text{O}^+(\text{aq}) + \text{OH}^-(\text{aq}) \rightarrow 2\text{H}_2\text{O}(\text{l})$, the situation is more complicated when weak acids or bases are involved. In this case, initial addition of $\text{NaOH}(\text{aq})$ to $\text{CH}_3\text{COOH}(\text{aq})$ forms $\text{CH}_3\text{COO}^-(\text{aq})$ according to the following equation.

Initially, the pH of the solution changes rapidly, but, once the concentration of CH_3COO^- has increased sufficiently, the solution contains appreciable amounts of a weak acid and its conjugate base — in other words, we have a buffer solution. We saw this type of behaviour in worked example 11.20. The pH in this region will therefore be governed by the ratio $\frac{[\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]}$ through the Henderson–Hasselbalch equation $\text{pH} = \text{p}K_a + \log \frac{[\text{A}^-]}{[\text{HA}]}$. At the point halfway to the equivalence point, this ratio will be 1, and therefore $\text{pH} = \text{p}K_a$. Therefore, a titration of a weak acid with a strong base tells us not only the concentration of the weak acid but also its $\text{p}K_a$; we simply take the pH reading at the volume halfway to the equivalence point. While we can calculate the pH at any point in the acidic region using the Henderson–Hasselbalch equation, it can be more conveniently written in terms of concentrations and volumes of the solutions involved in the titration. The amount of CH_3COO^- is equal to the amount of NaOH added, and the amount of CH_3COOH in the solution at any point is equal to the initial amount of CH_3COOH minus the amount of NaOH added, so we can rewrite this equation as shown below where $c_{\text{OH}^-(\text{initial})}$ is the initial concentration of the NaOH solution, $V_{\text{OH}^-(\text{added})}$ is the volume of the NaOH solution added, $c_{\text{HA}(\text{initial})}$ is the initial concentration of the acid solution and V_{initial} is the initial volume of the acid solution.

$$\begin{aligned} \text{pH} &= \text{p}K_a + \log \frac{[\text{A}^-]}{[\text{HA}]} \\ &= \text{p}K_a + \log \frac{n_{\text{OH}^-(\text{added})}}{n_{\text{HA}(\text{initial})} - n_{\text{OH}^-(\text{added})}} \\ &= \text{p}K_a + \log \frac{(c_{\text{OH}^-(\text{initial})} \times V_{\text{OH}^-(\text{added})})}{(c_{\text{HA}(\text{initial})} \times V_{\text{initial}}) - (c_{\text{OH}^-(\text{initial})} \times V_{\text{OH}^-(\text{added})})} \end{aligned}$$

Note that this equation is not exact, as it does not take into account the dissociation of the acid or the reaction of the conjugate base with water. However, as both of these reactions are suppressed by

the common ion effect in a buffer solution, it gives a very good approximation, especially when the concentrations of the acid and conjugate base are similar. You should not attempt to memorise the previous equation, as it can be derived from the Henderson–Hasselbalch equation, which itself is derived from the K_a expression for a weak acid.

As we approach the equivalence point of the titration, the reaction shown below proceeds further towards completion and the pH starts to increase rapidly.

This is because we have exhausted the capacity of the buffer solution; nearly all the CH_3COOH has been used up, and there is no longer sufficient acid present to be able to react with any added OH^- .

The equivalence point

At the equivalence point, the reaction below has proceeded to completion and the solution contains $0.100 \text{ mol L}^{-1} \text{Na}^+(\text{aq})$ and $0.100 \text{ mol L}^{-1} \text{CH}_3\text{COO}^-(\text{aq})$.

In other words, at this point we have a 0.1 mol L^{-1} aqueous solution of NaOOCCH_3 . We have seen previously that CH_3COO^- , being the conjugate base of a weak acid, is appreciably basic, and therefore the following reaction will occur.

This means that, at the equivalence point, there is a small amount of OH^- in the solution, and therefore the pH is greater than 7.00 (in this case it is 8.88, as we show below). In the titration of any weak acid with any strong base, the pH at the equivalence point is always greater than 7, because the conjugate base of the weak acid is measurably basic. The exact pH depends on both the K_b and the concentration of the conjugate base; the weaker the acid, the stronger its conjugate base, and therefore the more basic the solution at the equivalence point. Calculation of the pH at the equivalence point follows the method we outlined previously for the determination of the pH of a salt of a weak acid. The balanced chemical equation we need to consider is as follows.

We will use K_b to determine $[\text{OH}^-]$, and hence pH.

$$K_b = \frac{[\text{CH}_3\text{COOH}][\text{OH}^-]}{[\text{CH}_3\text{COO}^-]} = 5.6 \times 10^{-10}$$

The concentration table is as follows. Note that the initial concentration of CH_3COO^- is 0.100 mol L^{-1} ; this is because at the equivalence point the solution has twice its starting volume due to the added NaOH solution.

	H_2O	+	CH_3COO^-	$\rightleftharpoons$	CH_3COOH	+	OH^-
Initial concentration (mol L^{-1})			0.100		0		0
Change in concentration (mol L^{-1})			$-x$		$+x$		$+x$
Equilibrium concentration (mol L^{-1})			$0.100 - x$		x		x

We make the assumption that x will be small compared with 0.100, because CH_3COO^- is a weak base. Therefore $(0.100 - x) \approx 0.100$. We then substitute values into the K_b expression.

$$K_b = \frac{[\text{CH}_3\text{COOH}][\text{OH}^-]}{[\text{CH}_3\text{COO}^-]} = \frac{(x)(x)}{0.100 - x} \approx \frac{x^2}{0.100} = 5.6 \times 10^{-10}$$

Solving this for x gives the following.

$$x^2 = (0.100)(5.6 \times 10^{-10}) = 5.6 \times 10^{-11}$$

$$x = \sqrt{5.6 \times 10^{-11}} = 7.5 \times 10^{-6}$$

As $x = [\text{OH}^-]$, we obtain the pH of the solution as follows.

$$\begin{aligned}\text{pOH} &= -\log[\text{OH}^-] = -\log(7.5 \times 10^{-6}) = 5.12 \\ \text{pH} &= 14.00 - \text{pOH} = 14.00 - 5.12 = 8.88\end{aligned}$$

Analogous arguments apply for the titration of a weak base with a strong acid, and the pH at the equivalence point in such titrations is < 7 . The exact pH can be calculated using the K_a for the conjugate acid of the weak base.

The alkaline region

Beyond the equivalence point, we are simply adding excess OH^- to a solution of a weak base, and the pH in this region is controlled by the excess amount of NaOH. The titration curve in this region is essentially identical to that for a strong acid – strong base titration, and the pH at any point in this region may therefore be calculated using the same method as described previously for such titrations.

Diprotic acids

When a weak diprotic acid such as ascorbic acid (vitamin C) is titrated with a strong base, there are two protons available to react with the base and there are therefore two equivalence points. Provided that the values of $\text{p}K_{a1}$ and $\text{p}K_{a2}$ differ by several powers of 10, the neutralisation takes place stepwise and the resulting titration curve shows two sharp increases in pH as shown in figure 11.21. Calculations involving acids containing two or more acidic protons can be difficult, especially if the values of $\text{p}K_{a1}$ and $\text{p}K_{a2}$ are similar, and lie outside the scope of this text.

FIGURE 11.21

Titration of a diprotic acid, H_2A , by a strong base. As each equivalence point is reached, there is a sharp rise in the pH.

Speciation diagrams

It is often useful to know the relative amounts of a weak acid and its conjugate base that are present in an aqueous solution having a particular pH. We can do this with the aid of a speciation diagram, which is a plot of mole ratio versus pH. From the speciation diagram for acetic acid in figure 11.22, we can see at a glance that undissociated CH_3COOH predominates at pH values less than 4.74 (the $\text{p}K_a$ of acetic acid). At the point where $\text{pH} = \text{p}K_a$, there are equal amounts of CH_3COOH and CH_3COO^- , and the two lines therefore intersect. At higher pH values, the conjugate base, CH_3COO^- , is present in greater amounts than the undissociated acid; beyond pH 8, there is essentially no CH_3COOH present in the solution.

FIGURE 11.22

Speciation diagram for the dissociation of CH_3COOH in aqueous solution

Speciation diagrams are relatively simple for monoprotic acids, but become somewhat more complicated, and consequently somewhat more useful, for polyprotic acids. Figure 11.23 shows the speciation diagram for H_3PO_4 , a triprotic acid, which yields the anions $\text{H}_2\text{PO}_4^{2-}$, HPO_4^{2-} and PO_4^{3-} on successive deprotonations. The $\text{p}K_a$ values are shown.

$$\text{p}K_a(\text{H}_3\text{PO}_4) = 2.15$$

$$\text{p}K_a(\text{H}_2\text{PO}_4^-) = 7.20$$

$$\text{p}K_a(\text{HPO}_4^{2-}) = 12.3$$

FIGURE 11.23

Speciation diagram for the dissociation of H_3PO_4 in aqueous solution

It can be seen that H_3PO_4 predominates in very acidic regions, but, by pH 4, it has mostly been deprotonated to form H_2PO_4^- . As we proceed past the $\text{p}K_a$ of H_2PO_4^- (7.20), its conjugate base, HPO_4^{2-} , is present in the largest amount until the pH increases past 12.3, the $\text{p}K_a$ of HPO_4^{2-} . Under these conditions, PO_4^{3-} then becomes the dominant species in solution.

Speciation diagrams are extremely useful not only in situations involving polyprotic acids, but also in systems where metal ions react with ligands (see the chapter on transition metal chemistry), which themselves contain acidic protons. The calculations involved can be rather complex, especially in systems involving a number of components, but can usually be carried out satisfactorily using spreadsheets.

Acid–base indicators

The indicators used in acid–base titrations are themselves weak acids, which we can represent by the formula HIn . A requirement of an acid–base indicator is that its ‘acid form’ HIn and conjugate ‘base form’ In^- have different colours. In solution, the indicator is involved in a typical acid–base equilibrium.

The corresponding acid ionisation constant K_{In} is given by the following equation.

$$K_{In} = \frac{[H_3O^+][In^-]}{[HIn]}$$

In a strongly acidic solution, when $[H_3O^+]$ is high, the equilibrium is shifted to the left, and most of the indicator exists in its acid form. Under these conditions, the colour we observe is that of HIn . If base is added to the solution, the $[H_3O^+]$ drops and the equilibrium shifts to the right, towards In^- . The colour we then observe is that of the base form of the indicator (figure 11.24).

FIGURE 11.24 Colours of the acid form and base form of some common acid–base indicators

How acid–base indicators work

In a typical acid–base titration, as we pass the equivalence point, there is a sudden and large change in the pH. For example, in the titration of HCl with $NaOH$ described earlier (figure 11.17), the pH just before the equivalence point (when 24.97 mL of the base has been added) is 3.92. Just one drop later (when 25.03 mL of base has been added), we have passed the equivalence point and the pH has risen to 10.08. This large swing in pH causes a sudden shift in the position of equilibrium for the indicator, and we go

from a condition where most of the indicator is in its acid form to a condition in which most is in the base form. As a result, the solution changes colour and we say that the endpoint has been reached.

Selecting the best indicator for an acid–base titration

The explanation in the preceding paragraph assumes that the *midpoint* of the colour change range of the indicator corresponds to the pH at the equivalence point. At this midpoint, we expect that there are equal amounts of both forms of the indicator, which means that $[In^-] = [HIn]$. If this condition is true, then from the equation below we find that $pK_{In} = \text{pH}$ at the equivalence point.

$$\text{pH} = pK_{In} + \log \frac{[In^-]}{[HIn]}$$

This important result tells us that, once we know the pH of the solution at the equivalence point, we also know the pK_{In} that the indicator should have to function most effectively. Thus, we want an indicator with a pK_{In} equal to (or as close as possible to) the pH at the equivalence point. This will ensure that the observed endpoint will be as close as possible to the equivalence point. Phenolphthalein, for example, changes a solution from colourless to pink as the pH of the solution changes over a range of 8.2 to 10.0 (see table 11.9). Phenolphthalein is therefore a nearly perfect indicator for the titration of a weak acid by a strong base, where the pH at the equivalence point is on the basic side (figure 11.19).

TABLE 11.9 Common acid–base indicators

Indicator	Approximate pH range for colour change	Colour change (lower to higher pH)
methyl green	0.2–1.8	yellow to blue
thymol blue	1.2–2.8	red to yellow
methyl orange	3.2–4.4	red to yellow
ethyl red	4.0–5.8	colourless to red
methyl purple	4.8–5.4	purple to green
bromocresol purple	5.2–6.8	yellow to purple
bromothymol blue	6.0–7.6	yellow to blue
phenol red	6.4–8.2	yellow to red/violet
litmus	4.7–8.3	red to blue
cresol red	7.0–8.8	yellow to red
thymol blue	8.0–9.6	yellow to blue
phenolphthalein	8.2–10.0	colourless to pink
thymolphthalein	9.4–10.6	colourless to blue
alizarin yellow R	10.1–12.0	yellow to red
clayton yellow	12.2–13.2	yellow to amber

Phenolphthalein also works very well for the titration of a strong acid with a strong base. As discussed earlier, just one drop of titrant can bring the pH from below 7 to nearly 10, which spans the pH range for phenolphthalein.

When we perform a titration, we want to use as little indicator as possible. The reason for this is that indicators are weak acids and also react with the titrant. If we were forced to use a lot of indicator, it would affect our measurements and make the titration less accurate. Therefore, the best indicators are those with the most intense colours. Then, even extremely small amounts can give striking colour changes without consuming too much of the titrant.

11.8 Lewis acids and bases

LEARNING OBJECTIVE 11.8 Identify Lewis acids and bases.

We stated earlier in this chapter that there was more than one definition of acids and bases, and, while we have used the Brønsted–Lowry definition throughout this chapter, there is a more general definition first proposed in 1923 by the US chemist Gilbert Lewis.

- A **Lewis acid** is an electron-pair acceptor.
- A **Lewis base** is an electron-pair donor.

To illustrate these definitions, we will consider the reaction between BF_3 and NH_3 .

In this reaction, NH_3 formally donates an electron pair to BF_3 , resulting in formation of a B–N covalent bond, as shown in figure 11.25.

FIGURE 11.25

The Lewis acid–base reaction of BF_3 with NH_3 . A covalent bond between B and N is formed, with both electrons in the bond formally deriving from the Lewis basic N atom.

Thus, BF_3 is a Lewis acid and accepts an electron pair from the Lewis base NH_3 in this reaction to form a single covalent bond between the B and N atoms. This covalent bond differs from those that we have seen in earlier chapters, in that both electrons are donated by one atom, rather than each atom providing one electron. Such bonds are sometimes called dative or coordinate bonds, to distinguish this fact. In structural diagrams, these bonds are sometimes depicted as an arrow, as shown below.

A count of the electrons around the B and N atoms in the product, assuming that the electrons in the B–N bond are shared equally, will confirm that the B atom has a formal negative charge and the N atom is positively charged. We can therefore write a zwitterionic structure for the product. Compounds such as F_3BNH_3 , which are products of the reaction between a Lewis acid and a Lewis base, are sometimes called Lewis adducts, or simply **adducts**. As we will see in the chapter on transition metal chemistry, the chemistry of transition metal ions is dominated by Lewis adducts called coordination complexes. The formation of these involves the reaction of a Lewis acidic transition metal ion with one or more Lewis basic species called ligands, each containing lone pairs of electrons. For example, the coordination complex $[\text{Ni}(\text{NH}_3)_4]^{2+}$ is formed from reaction of Ni^{2+} with four NH_3 ligands, according to the following equation.

Organic chemistry is replete with examples of Lewis acids and bases. Much of organic chemistry is concerned with the making and breaking of covalent bonds involving carbon, and such reactions can be considered from a Lewis acid – Lewis base perspective. For example, the reaction of a ketone with a primary amine gives an imine and involves the formation of a $\text{C}=\text{N}$ bond. The first step of this reaction involves the reaction of the Lewis basic amine with the Lewis acidic ketone, as follows.

The similarity to the reaction of BF_3 with NH_3 discussed above is obvious. The nomenclature of organic chemistry dictates that Lewis acids are called **electrophiles** and Lewis bases are called **nucleophiles**.

As the Lewis definition of acids and bases is the most general of the three we have met so far, it follows that all Brønsted–Lowry acids and bases must be Lewis acids and bases. However, the reverse does not necessarily hold; for example, the Lewis acid BF_3 has no protons to donate and therefore cannot be a Brønsted–Lowry acid.

The strengths of Lewis acids and bases are not as readily quantified as those of their Brønsted–Lowry counterparts. While the latter are measured relative to a single solvent (water), the large variety of solvents in which Lewis acids and bases are used makes a single scale of strengths difficult to achieve. However, it is known that a mixture of the Brønsted–Lowry acid HF and the Lewis acid antimony pentafluoride, SbF_5 , is capable of protonating extremely weak bases, such as alkanes, and is in fact one of the strongest acids known. Such mixtures are called superacids; in fact, we have already seen an example of a superacid in a chemical connections feature earlier in the chapter.

Recognising Lewis acids and bases

A Lewis base must have valence electrons available for bond formation. Any molecule with a Lewis structure that shows nonbonding electron pairs can act as a Lewis base. Ammonia, phosphorus trichloride and dimethyl ether, each of which contains lone pairs, are Lewis bases. Anions can also act as Lewis bases.

For example, in the reaction below the fluoride ion, with eight valence electrons in its $2s$ and $2p$ orbitals, acts as a Lewis base.

A Lewis acid must be able to accept electrons to form a new bond. Because bond formation can occur in several ways, compounds with several different structural characteristics can act as Lewis acids. Nevertheless, most Lewis acids fall into the following categories.

1. *A molecule that has vacant valence orbitals.* A good example is BF_3 , which uses a vacant $2p$ orbital on boron to form an adduct with ammonia. The elements in the p block beyond period 2 of the periodic table have d orbitals which can potentially accept an electron pair, thus allowing them to act as Lewis acids. The silicon atom in SiF_4 is an example.
2. *A molecule with delocalised π bonds involving oxygen.* Examples are CO_2 , SO_2 and SO_3 . Each of these molecules can form a σ bond between its central atom and a Lewis base, at the expense of a π bond. For example, the hydroxide anion, a good Lewis base, attacks the carbon atom of CO_2 to form hydrogen carbonate, with the loss of one π bond.

In this reaction, the oxygen atom of the hydroxide ion donates a pair of electrons to make a new C—O bond. Because all the valence orbitals of the carbon atom in CO_2 are involved in bonding to oxygen, one of the C—O π bonds must be broken to make an orbital available to overlap with the occupied orbital of the hydroxide anion.

3. *A metal cation.* Removing electrons from a metal atom always generates vacant valence orbitals. As described previously, many transition metal cations form complexes with ligands in aqueous solution. In these complexes, the ligands act as Lewis bases, donating pairs of electrons to form metal–ligand bonds. The metal cation accepts these electrons, so it acts as a Lewis acid. Metal cations from the p block also act as Lewis acids. For example, $\text{Pb}^{2+}(\text{aq})$ (group 14) forms a Lewis acid–base adduct with four CN^- anions, each of which donates a pair of electrons.

Worked example 11.22 provides practice in recognising Lewis acids and bases.

WORKED EXAMPLE 11.22
Lewis acids and bases

Identify the Lewis acids and bases in each of the following reactions and draw the structures of the resulting adducts.

- (a) $\text{AlCl}_3 + \text{Cl}^- \rightarrow \text{AlCl}_4^-$
 (b) $\text{Co}^{3+} + 6\text{NH}_3 \rightarrow [\text{Co}(\text{NH}_3)_6]^{3+}$
 (c) $\text{SO}_2 + \text{OH}^- \rightarrow \text{HSO}_3^-$

Analysis

Every Lewis base has one or more lone pairs of valence electrons. A Lewis acid can have vacancies in its valence shell, or it can sacrifice a π bond to make a valence orbital available for adduct formation. To decide whether a molecule or ion acts as a Lewis acid or base, examine its Lewis structure for these features. Review the chapter on chemical bonding and molecular structure for procedures used to determine Lewis structures.

Solution

- (a) Both reactants contain chlorine atoms with lone pairs, so either might act as a Lewis base if a suitable Lewis acid is present. The aluminium atom of AlCl_3 has a vacant $3p$ orbital perpendicular to the molecular plane. The empty p orbital accepts a pair of electrons from the Cl^- anion to form the fourth $\text{Al}-\text{Cl}$ bond. The Lewis acid is AlCl_3 , and the Lewis base is Cl^- .

- (b) As already noted, ammonia is a Lewis base because it has a lone pair of electrons on the nitrogen atom. Like other transition metal cations, Co^{3+} is a Lewis acid and uses vacant $3d$ orbitals to form bonds to NH_3 .

- (c) Sulfur dioxide contains delocalised π bonds, indicating the potential for Lewis acidity. The sulfur atom of SO_2 has a set of $3d$ orbitals that can be used to form an adduct. In this case, the hydroxide ion acts as a Lewis base. The anion uses one lone pair of electrons to form a new bond to sulfur.

Is our answer reasonable?

The Lewis structures confirm that each species identified as a Lewis base possesses lone pairs of electrons and that the Lewis acids have orbitals available to accept electrons.

PRACTICE EXERCISE 11.25

The reaction of SbCl_5 with Cl^- gives the SbCl_6^- ion. Identify the Lewis acid and Lewis base in this reaction, and draw a reaction scheme showing all electron transfers.

Polarisability

Polarisability, described in the chapter on chemical bonding and molecular structure, is a measure of the ease with which the electron cloud of an atom, ion or molecule can be distorted by an electrical charge. An electron cloud is polarised towards a positive charge and away from a negative charge, as shown in figure 11.26. Pushing the electron cloud to one side of an atom causes a polarisation of charge. The side with the concentrated electron density has a small negative charge; the protons in the nucleus give the opposite side a small positive charge.

FIGURE 11.26

The electron cloud of an atom is polarised towards a positive charge and away from a negative charge. A smaller atom binds its valence electrons more tightly and is less polarisable than a larger atom, which binds its electrons loosely.

Polarisability shows periodic variations that correlate with periodic trends in how tightly valence electrons are bound to the nucleus (figure 11.27).

1. Polarisability decreases from left to right in any period of the periodic table. As the effective nuclear charge (Z_{eff}) increases, the nucleus holds the valence electrons more tightly.
2. Polarisability increases from top to bottom in any group of the periodic table. As the principal quantum number (n) increases, the valence orbitals become larger. This reduces the net attraction between valence electrons and the nucleus.

FIGURE 11.27

Polarisability decreases across a period and increases down a group.

The hard–soft concept

Lewis acids and bases can be organised according to their polarisability. If polarisability is low, the species is categorised as ‘hard’. If polarisability is high, the species is ‘soft’.

A **hard Lewis base** has electron pairs of low polarisability. This characteristic correlates with high electronegativity. Fluoride, the anion of the most electronegative element, is the hardest Lewis base because it contains a small, dense sphere of negative charge. Molecules and ions that contain oxygen or nitrogen atoms are usually also hard bases, although not as hard as fluoride. Examples include H_2O , CH_3OH , OH^- , NH_3 and H_2NCH_3 .

A **soft Lewis base** has a large donor atom of high polarisability and low electronegativity. The iodide ion has its valence electrons in large $n = 5$ orbitals, making this anion highly polarisable and a very soft base. Other molecules and polyatomic anions with donor atoms from periods 3 to 6 are usually also soft bases. To summarise, the donor atom becomes softer from top to bottom of a group of the periodic table (figure 11.28).

A **hard Lewis acid** has an acceptor atom with low polarisability. Most metal atoms and ions are hard acids. In general, the smaller the ionic radius and the larger the charge, the harder the acid. The Al^{3+} ion, with an ionic radius of only 67 pm, is a prime example of a hard Lewis acid. The nucleus exerts a strong pull on the compact electron cloud, giving the ion very low polarisability.

FIGURE 11.28

The donor atom becomes softer down a group.

group 17	
F	hardest
Cl	
Br	
I	
At	softest

The designation of hard acids is not restricted to metal cations. For example, in BF_3 the small boron atom in its +3 oxidation state is bonded to three highly electronegative fluorine atoms. All the B—F bonds are polarised away from a boron centre that is already electron deficient. Boron trifluoride is therefore a hard Lewis acid.

A **soft Lewis acid** has a relatively high polarisability. Large atoms and low oxidation states often convey softness. Contrast the hard acid Al^{3+} with Hg^{2+} , a typical soft acid (figure 11.29). The ionic radius of Hg^{2+} is 116 pm, almost twice that of Al^{3+} , because the valence orbitals of Hg^{2+} have a high principal quantum number, $n = 6$. Consequently, Hg^{2+} is a highly polarisable, very soft Lewis acid. The relatively few soft Lewis acid transition metal ions are located around gold in the periodic table.

FIGURE 11.29

The Al^{3+} ion is a harder Lewis acid than Hg^{2+} because of its smaller ionic radius and higher charge.

The terms 'hard' and 'soft' are relative, so there is no sharp dividing line between the two, and many Lewis acids and bases are intermediate between hard and soft. Worked example 11.23 shows how to categorise Lewis acids and bases according to their hard–soft properties.

WORKED EXAMPLE 11.23

Ranking hardness and softness

Rank the following groups of Lewis acids and bases from softest to hardest.

- H_2S , H_2O and H_2Se
- Fe^0 , Fe^{3+} and Fe^{2+}
- BCl_3 , GaCl_3 and AlCl_3

Analysis

The first task is to decide whether the members of a given group are Lewis acids or bases. Then evaluate the relative softness and hardness based on polarisability, taking into account correlations with electronegativity, size and charge. Refer to the periodic table to assess the trends.

SUMMARY

11.1 Define acids and bases.

A Brønsted–Lowry acid is a proton donor; a Brønsted–Lowry base is a proton acceptor. According to the Brønsted–Lowry approach, an acid–base reaction is a proton transfer event. In an equilibrium involving a Brønsted–Lowry acid and base, there are two conjugate acid–base pairs. The members of any given pair differ from each other by only one proton. A solvent that can be either an acid or a base, depending on the nature of the other reactant, is amphoteric.

11.2 Identify acid–base reactions in water.

Water reacts with itself to produce small amounts of H_3O^+ and OH^- ions. The concentrations of these ions in both pure water and in dilute aqueous solutions are related by the expression:

$$[\text{H}_3\text{O}^+][\text{OH}^-] = K_w = 1.0 \times 10^{-14} \quad (\text{at } 25^\circ\text{C})$$

K_w is the autoprotolysis constant of water. In pure water:

$$[\text{H}_3\text{O}^+] = [\text{OH}^-] = 1.0 \times 10^{-7} \text{ mol L}^{-1} \quad (\text{at } 25^\circ\text{C})$$

The pH of a solution is a measure of acidity and is normally measured with a pH meter. As the pH decreases, the acidity increases. The defining equation for pH is $\text{pH} = -\log[\text{H}_3\text{O}^+]$. In exponential form, this relationship between $[\text{H}_3\text{O}^+]$ and pH is given by $[\text{H}_3\text{O}^+] = 10^{-\text{pH}}$.

Comparable expressions can be used to describe low OH^- ion concentrations in terms of pOH values: $\text{pOH} = -\log[\text{OH}^-]$ and $[\text{OH}^-] = 10^{-\text{pOH}}$. At 25°C , $\text{pH} + \text{pOH} = 14.00$. A solution is acidic if its pH is less than 7.00 and basic if its pH is greater than 7.00. A neutral solution has a pH of 7.00.

11.3 Perform calculations involving strong acids and bases.

In calculating the pH of solutions of strong acids and bases, we assume that they react completely with water. The autoprotolysis of water contributes negligibly to $[\text{H}_3\text{O}^+]$ in a solution of an acid. It also contributes negligibly to the $[\text{OH}^-]$ in a solution of a base.

11.4 Perform calculations involving weak acids and bases.

An acid HA reacts with water according to the general equation below.

The equilibrium constant is called the acidity constant, K_a .

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]}$$

A base B reacts by the general equation below.

The equilibrium constant is called the basicity constant, K_b .

$$K_b = \frac{[\text{OH}^-][\text{BH}^+]}{[\text{B}]}$$

The smaller the value of K_a or K_b , the weaker the substances are as Brønsted–Lowry acids or bases.

Another way to compare the relative strengths of acids or bases is to use the negative logarithms of K_a and K_b , called $\text{p}K_a$ and $\text{p}K_b$, respectively.

$$\begin{aligned}\text{p}K_a &= -\log K_a \\ \text{p}K_b &= -\log K_b\end{aligned}$$

The *smaller* the $\text{p}K_a$ or $\text{p}K_b$, the *stronger* the acid or base. For a conjugate acid–base pair:

$$K_a K_b = K_w$$

and:

$$\text{p}K_a + \text{p}K_b = 14.00 \quad (\text{at } 25^\circ\text{C})$$

The values of K_a and K_b can be obtained from initial concentrations of the acid or base and the pH of the solution. The measured pH gives the equilibrium value for $[\text{H}_3\text{O}^+]$.

When the initial concentration of the acid (or base) is larger than 400 times the value of K_a (or K_b), it is safe to use initial concentrations of acid or base as though they were equilibrium values when calculating pH or pOH. When this approximation cannot be used, we use the quadratic formula.

The weaker an acid, the stronger its conjugate base, and vice versa. Anions of strong acids, such as Cl^- and NO_3^- , are such weak Brønsted–Lowry bases that they cannot affect the pH of a solution.

If a salt is derived from a weak acid *and* a weak base, its net effect on pH has to be established on a case-by-case basis by determining which of the two ions reacts with water to a greater extent.

11.5 Explain the relationship between structure and acidity.

Binary acids contain only hydrogen and another nonmetal. Their strengths increase from top to bottom within a group and left to right across a period. Oxoacids, which contain oxygen atoms in addition to hydrogen and another element, increase in strength as the number of oxygen atoms on the same central atom increases. Oxoacids with the same number of oxygen atoms generally increase in strength as the central atom moves from bottom to top within a group and from left to right across a period.

11.6 Perform calculations involving buffer solutions.

A solution that contains appreciable amounts of both a weak acid and a weak base (usually an acid–base conjugate pair) is called a buffer solution, because it is able to absorb H_3O^+ from a strong acid or OH^- from a strong base without suffering large changes in pH.

For the general acid–base pair, HA and A^- , the following reactions occur in a buffer solution.

The pH of a buffer is controlled by the ratio of weak acid to weak base, expressed either in terms of concentration or amount.

Because the $[\text{H}_3\text{O}^+]$ is determined by the mole ratio of HA to A^- , dilution does not change the pH of a buffer. The equation below can be used to calculate the pH directly from the $\text{p}K_a$ of the acid and the concentrations of the conjugate acid HA and base A^- .

$$\text{pH} = \text{p}K_a + \log \frac{[\text{A}^-]}{[\text{HA}]}$$

In performing buffer calculations, the usually valid simplifications are as follows.

$$\begin{aligned}[\text{HA}]_{\text{equilibrium}} &= [\text{HA}]_{\text{initial}} \\ [\text{A}^-]_{\text{equilibrium}} &= [\text{A}^-]_{\text{initial}}\end{aligned}$$

Buffers are most effective when the pK_a of the acid member of the buffer pair lies within ± 1 unit of the desired pH.

Although the mole ratio of A^- to HA determines the pH at which a buffer works, the amounts of the acid and its conjugate base give the buffer its capacity for taking on strong acid or base with little change in pH.

11.7 Analyse acid–base titrations.

The pH at the equivalence point depends on the ions of the salt formed during the titration. In the titration of a strong acid with a strong base, the pH at the equivalence point is 7 because neither of the ions produced in the reaction affects the pH of an aqueous solution.

For the titration of a weak acid with a strong base, the approach towards calculation of the pH varies depending on which stage of the titration is considered.

1. Before the titration begins, the only solute is the weak acid, and so K_a is used.
2. After starting, but before the equivalence point, the solution is a buffer. Either K_a or K_b can be used.
3. At the equivalence point, the active solute is the conjugate base of the weak acid. K_b for the conjugate base must be used.
4. After the equivalence point, excess strong base determines the pH of the mixture. No equilibrium calculations are required. At the equivalence point, the pH is above 7.

Similar calculations apply in the titration of a weak base by a strong acid. In such titrations, the pH at the equivalence point is below 7.

The indicator chosen for a titration should have the centre of its colour change range near the pH at the equivalence point. For the titration of a strong or weak acid with a strong base, phenolphthalein is the best indicator. When a weak base is titrated with a strong acid, several indicators, including methyl orange, work satisfactorily.

11.8 Identify Lewis acids and bases.

A Lewis acid is an electron-pair acceptor, while a Lewis base is an electron-pair donor. Electrophiles are Lewis acids and nucleophiles are Lewis bases.

A Lewis base must have one or more pairs of valence electrons available for bond formation. A Lewis acid must be able to accept an electron pair to form a new bond. Most Lewis acids are one of the following: a molecule with vacant valence orbitals, a molecule with delocalised π bonds involving oxygen, or a metal cation.

A hard Lewis base has electron pairs of low polarisability and high electronegativity. A soft Lewis base has a large donor atom of high polarisability and low electronegativity. A hard Lewis acid has an acceptor atom with low polarisability. A soft Lewis acid has a relatively high polarisability. The hard–soft acid–base (HSAB) principle states that hard Lewis acids tend to combine with hard Lewis bases, while soft Lewis acids tend to combine with soft Lewis bases. This is reflected in nature, where hard metal ions tend to be found bonded to hard bases, and vice versa.

KEY CONCEPTS AND EQUATIONS

Concept	Section	Description/equation
Autoprotolysis constant for water $[H_3O^+][OH^-] = K_w$	11.2	This equation is used to calculate $[H_3O^+]$ if $[OH^-]$ is known, and vice versa. $[H_3O^+][OH^-] = K_w$
pH and pOH	11.2	These provide a convenient method for representing $[H_3O^+]$ and $[OH^-]$ in aqueous solution.
Relationship between pH and pOH: $pH + pOH = 14.00$ at 25 °C	11.2	This relationship can be used to calculate pH if pOH is known, and vice versa. $pH + pOH = 14.00$ (at 25 °C)
$K_a K_b = K_w$	11.4	This equation is used to calculate K_a given K_b , or vice versa.
Periodic trends in strengths of acids	11.5	Periodic trends can be used to predict the relative acidities of acids. The principles involved also let you compare the acidities of compounds containing different electronegative elements.
$pH = pK_a + \log \frac{[A^-]}{[HA]}$	11.6	This equation can be used to calculate the pH of a buffer solution.
Hard–soft acid–base principle	11.8	Hard Lewis acids tend to combine with hard Lewis bases. Soft Lewis acids tend to combine with soft Lewis bases.

KEY TERMS

acid Arrhenius theory – a substance that produces H^+ ions in water; Brønsted–Lowry theory – a proton donor; Lewis theory – an electron-pair acceptor.

acid–base indicator A dye having one colour in acid and another colour in base.

acid–base reaction A reaction that involves the transfer of a single proton from one species to another. (Note that this is the Brønsted–Lowry definition.)

acid–base titration An analytical procedure involving the gradual addition of a solution of an acid or base of known concentration

to a specified volume of a solution of a base or acid of unknown concentration.

acidic Describes an aqueous solution in which $[\text{H}_3\text{O}^+] > [\text{OH}^-]$.

acidity constant (K_a) The equilibrium constant for the dissociation of an acid in aqueous solution. For the general equilibrium:

$$K_a \text{ has the form } K_a = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]}$$

adduct The product of a reaction between a Lewis acid and a Lewis base.

alkaline An alternative word for basic.

amphiprotic A solvent that can act either as a proton donor or a proton acceptor.

autoprotolysis A process involving the transfer of a proton between two identical molecules.

autoprotolysis constant of water (K_w) The equilibrium constant for the reaction:

K_w has the form $K_w = [\text{H}_3\text{O}^+][\text{OH}^-]$, where

$$K_w = 1.0 \times 10^{-14} \text{ at } 25.0^\circ\text{C}.$$

base Arrhenius theory — a substance that releases OH^- ions in water; Brønsted—Lowry theory — a proton acceptor; Lewis theory — an electron-pair donor.

basic Describes an aqueous solution in which $[\text{H}_3\text{O}^+] < [\text{OH}^-]$.

basicity constant (K_b) The equilibrium constant for the reaction of a base with water. For the general equilibrium:

$$K_b \text{ has the form } K_b = \frac{[\text{BH}^+][\text{OH}^-]}{[\text{B}]}$$

Brønsted—Lowry A definition of acids and bases in which an acid is a proton donor and a base is a proton acceptor.

buffer capacity A measure of the amount of H_3O^+ or OH^- that can be added to a buffer solution without significant change in its pH.

buffer solution A solution containing appreciable amounts of either a weak acid and its conjugate base, or a weak base and its conjugate acid.

burette A device used for the addition of accurately measured volumes of solution in a titration.

conjugate acid–base pair Two species that differ only by a proton.

conjugate base The species in a conjugate acid–base pair that has the smaller number of protons.

diprotic acid An acid that can potentially donate two equivalents of protons to water.

diprotic base A base which is able to accept two protons.

electrophile Any molecule or ion that can accept a pair of electrons to form a new covalent bond; a Lewis acid.

endpoint The point in a titration when the indicator changes colour.

equivalence point The point in a titration when the stoichiometry of the reaction is satisfied.

hard Lewis acid A Lewis acid containing an acceptor atom of low polarisability.

hard Lewis base A Lewis base containing one or more electron pairs of low polarisability.

Henderson–Hasselbalch equation An equation that relates the pH of a buffer solution to the $\text{p}K_a$ of the weak acid and the ratio of the conjugate base to the acid:

$$\text{pH} = \text{p}K_a + \log \frac{[\text{A}^-]}{[\text{HA}]}$$

heterolytic cleavage Describes a bond-breaking process in which both electrons of a single bond end up on one of the atoms of the bond.

homolytic cleavage Describes a bond-breaking process in which each of the bonded atoms receives one electron.

hydronium ion (H_3O^+) The product of the reaction of a proton with water. It can also be thought of as a hydrated proton.

hydroxide ion (OH^-) The product of deprotonation of water.

Lewis acid An electron-pair acceptor.

Lewis base An electron-pair donor.

monoprotic acid An acid that can donate only a single proton to water.

monoprotic base A base that can accept only one proton.

neutral Describes a solution in which $[\text{H}_3\text{O}^+] = [\text{OH}^-]$.

nucleophile Any reagent with an unshared pair of electrons that can be donated to another atom or ion to form a new covalent bond; a Lewis base.

pH $-\log[\text{H}_3\text{O}^+]$

$\text{p}K_a$ $-\log K_a$

$\text{p}K_b$ $-\log K_b$

$\text{p}K_w$ $-\log K_w$

pOH $-\log[\text{OH}^-]$

polyprotic acid An acid which can donate more than one proton.

polyprotic base A base which can accept more than one proton.

resonance stabilisation The energetic stabilisation that occurs on delocalisation of negative charge over two or more atoms.

soft Lewis acid A Lewis acid having an acceptor atom of high polarisability.

soft Lewis base A Lewis base having a large donor atom of high polarisability and low electronegativity.

strong acid An acid that reacts completely with water to give quantitative formation of H_3O^+ .

strong base A base that reacts completely with water to give quantitative formation of OH^- .

titrant An acid or base of known concentration used in an acid–base titration.

titration curve For an acid–base titration, a graph of pH versus the volume of titrant added.

triprotic acid An acid that can donate three protons.

weak acid An acid that reacts incompletely with water to form less than stoichiometric amounts of H_3O^+ .

weak base A base that reacts incompletely with water to form less than stoichiometric amounts of OH^- .

zwitterion An ionic salt in which both cation and anion are part of the same molecule.

REVIEW QUESTIONS

Note: Unless otherwise stated, all questions refer to a temperature of 25.0°C .

The Brønsted–Lowry definition of acids and bases **LO1**

11.1 Give the definition of both a Brønsted–Lowry acid and a Brønsted–Lowry base.

11.2 What is the definition of a conjugate acid–base pair?

11.3 When asked to identify the conjugate acid of the HPO_4^{2-} ion, a student wrote H_3PO_4 . Was the student correct? Explain your answer.

11.4 Define the term ‘amphiprotic’.

11.5 Write the structural formulae of the conjugate acids of the following bases.

11.6 Write the structural formulae of the conjugate bases of the following species.

Acid–base reactions in water

LO2

11.7 Explain why the concentration of H_3O^+ in pure water at 25°C cannot be greater than $1 \times 10^{-7} \text{ mol L}^{-1}$.

11.8 At 40.0°C , $K_w = 3.0 \times 10^{-14}$. Calculate the pH of pure water at this temperature. Comment on the statement ‘pure water always has a pH of 7’ with reference to your answer.

Strong acids and bases

LO3

11.9 We have defined a strong acid as one that donates its proton completely to water. Given this definition, to what value should the K_a of a strong acid tend towards?

11.10 Will the conjugate acid of a strong base be very strong, strong, weak or very weak? Give your reasoning.

11.11 The $\text{CH}_3\text{CH}_2\text{O}^-$ (ethoxide) ion is a stronger base than the OH^- ion. Why can the ethoxide ion not exist in aqueous solution? Use a chemical equation that shows the reaction that occurs when the ethoxide ion is placed in water to illustrate your answer.

Weak acids and bases

LO4

11.12 Write the general equation for the reaction of a weak acid with water. Give the expression for K_a .

11.13 The following compounds are all weak acids. Write the balanced equilibrium equation for the reaction of each of these with water, and use the equations to derive the K_a expression for each acid.

11.14 Write the general equation for the reaction of a weak base with water. Give the expression for K_b .

11.15 The following compounds are all weak bases. Write the balanced equilibrium equation for the reaction of each of these with water, and use the equations to derive the K_b expression for each base.

11.16 Use the $\text{p}K_a$ values of the following acids to rank them in order from strongest to weakest.

Acid	$\text{p}K_a$
HOCl	7.52
HOCN	3.46
HOI	10.64

11.17 Acetylsalicylic acid is more commonly known as aspirin. It is a monoprotic acid with a K_a value of 3.24×10^{-4} . Is a solution of the sodium salt of aspirin in water acidic, basic or neutral? Explain.

11.18 Consider 0.1 mol L^{-1} aqueous solutions of each of the following salts: NaI , KF , $(\text{NH}_4)_2\text{SO}_4$, KCN , KOOCCCH_3 , CsNO_3 and KBr . Which solutions are: (a) acidic, (b) basic, and (c) neutral?

11.19 Gardeners often apply ammonium nitrate, NH_4NO_3 , to soil as a source of nitrogen for plant growth. Will this compound have any effect on the acidity of the moisture in the ground? Explain.

11.20 A solution of hydrazinium acetate is slightly acidic. Without looking at the tables of equilibrium constants, is K_a for acetic acid larger or smaller than K_b for hydrazine? Justify your answer.

11.21 Under what circumstances can we assume that the equilibrium concentration of a weak acid or base is equal to its initial concentration when we calculate the pH of a solution?

11.22 For which of the following solutions will the assumption outlined in problem 11.21 be valid?

The molecular basis of acid strength

LO5

11.23 How do the strengths of the binary acids vary from left to right across a period of the periodic table? How do they vary from top to bottom within a group?

11.24 Astatine, At, atomic number 85, is radioactive and does not occur in appreciable amounts in nature.

(a) Would you expect HAt to be a stronger or weaker acid than HI ?

(b) Would you expect HAtO_3 to be a stronger or weaker acid than HBrO_3 ?

(c) Would you expect the At^- anion to be a stronger or weaker base than the Cl^- ion?

11.25 Explain why perchloric acid (HClO_4) is a stronger acid than chloric acid (HClO_3).

11.26 Explain why HClO_4 is a stronger acid than H_2SeO_4 .

11.27 Explain why the OBr^- ion is a stronger base than the NO_2^- ion.

11.28 The position of equilibrium in the equation below lies far to the left. Identify the conjugate acid–base pairs. Which of the two acids is stronger?

11.29 The phosphate ion PO_4^{3-} is a weaker base than hydroxide ion, and HPO_4^{2-} is a stronger acid than water. Use these data to determine if the position of the equilibrium below lies to the left or the right. Justify your answer.

11.30 The $\text{p}K_a$ of formic acid is 3.74, while the $\text{p}K_a$ of hydrazoic acid is 4.74. Which of the formate and azide (the azide ion, N_3^- , is the conjugate base of hydrazoic acid) ions is the stronger base? Outline your reasoning.

11.31 The nitrate ion, NO_3^- is the conjugate base of nitric acid, a strong acid, and is a very weak base. The hypochlorite ion, ClO^- is a weak base; does this mean that its conjugate acid is strong? Explain your answer.

11.32 Formic acid, HCOOH , and acetic acid, CH_3COOH , are classified as weak acids, but in water HCOOH is more dissociated than CH_3COOH . However, if we use liquid ammonia as a solvent for these acids instead of water, they both appear to be of equal strengths and 100% dissociated. Explain why.

Buffer solutions

LO6

11.33 Write ionic equations that show how the components of the following buffer solutions react on addition of either H_3O^+ or OH^- .

- (a) NH_4Cl and NH_3
- (b) H_2CO_3 and NaHCO_3 (the ‘carbonate’ buffer in blood)
- (c) NaH_2PO_4 and Na_2HPO_4 (the ‘phosphate’ buffer inside body cells)

11.34 Buffer 1 is a solution containing 0.10 mol L^{-1} NH_4Cl and 1.0 mol L^{-1} NH_3 . Buffer 2 is a solution containing 1.0 mol L^{-1} NH_4Cl and 0.10 mol L^{-1} NH_3 . Which buffer is better able to maintain a steady pH on the addition of a small amount of strong acid? Explain.

11.35 An experiment investigating the aqueous stability of a new drug required a solution of the drug to be buffered at pH 5.50. Could a formic acid/sodium formate buffer be used for this experiment? Explain your answer.

Acid–base titrations

LO7

11.36 When an aqueous solution containing 0.0100 mol of propanoic acid is titrated with sodium hydroxide, will the solution be acidic, neutral or basic when exactly 0.0100 mol of sodium hydroxide has been added?

11.37 When an aqueous solution of trimethylamine ($K_b = 7.4 \times 10^{-5}$) is titrated with hydrobromic acid, will the solution be acidic, neutral, or basic at the equivalence point?

11.38 Two terms that are often used in titrations are ‘endpoint’ and ‘equivalence point’. What is the difference between them?

11.39 Qualitatively, describe how an acid–base indicator works. Why is it important that only the smallest possible amount of indicator is used in a titration?

11.40 Which indicator, phenolphthalein or methyl purple, should be used in the titration of dilute ammonia by dilute hydrochloric acid? Give your reasons.

11.41 While methyl orange would be an acceptable indicator for the titration of 1.0 mol L^{-1} HCl with 1.0 mol L^{-1} NaOH , it would not be a good choice for the titration of 1.0 mol L^{-1} CH_3COOH with 1.0 mol L^{-1} NaOH . Why is this?

11.42 A student chose to use thymol blue in a titration of CH_3COOH with NaOH . Was this the correct decision? Justify your answer.
